TEST ENVIRONMENT - The J 2334 test cycle is shown schematically in Figure 1. Based on the results of the statistically designed experiment, the key factors which make this test correlate successfully with on-vehicle tests are the use of a dilute salt solution during the immersion stage, and a controlled 50% relative humidity during the dry stage. Test coupons were exposed to this environment for a target duration of 80 cycles. Total test time to complete 80 cycles including weekends is 110 days, plus any holidays. Based on the 10.4 acceleration factor found for this test [1], the 80 cycles corresponds to roughly 3.4 years in an severe environment equivalent to an average of those at St. John's and Montreal.

The test cycle shown in Figure 1 is shown as it would run manually, that is, by manually moving the test specimens from a dry-stage chamber to a humid-stage chamber, then to an immersion tank, and finally back to the dry-stage chamber on a daily basis. The manual cycle can also be run by use of a single chamber which is switched back and forth between dry and humid conditions. Three of the participating laboratories ran the manual test.

An alternate method is to run the cycle as a fully automated, continuous operation by use of a chamber which can be programmed to create all three stages. When this is the case, the dry-stage hold on weekends and holidays is omitted. This reduces the test time for 80 cycles to 80 days. Four laboratories in the round-robin series operated the test in this fashion. Another two laboratories ran an automated test that included the weekend hold.

ROUND-ROBIN PARTICIPANTS - Nine laboratories have thus far participated in the round-robin study, see Table 3. Additional tests may be completed at a later date. All participants received identical sets of triplicate painted and scribed panels, as well as four pairs of bare, cold rolled steel mass-loss coupons from ACT. The tests were intended to be conducted as nearly as possible according to the the cycle shown in Figure 1. Conditions were monitored and recorded throughout the tests. Significant deviations from the procedure reported by participants are noted in Table 3.

EVALUATION - After 80 cycles, the coupons were removed from test and returned to ACT for final evaluation. Scribe creep, the delamination of paint next to the scribe, was evaluated by scraping and taping to remove any loose paint. Total width of paint delamination was measured at 10, 1-cm intervals along the scribe and averaged. This was done for each of the triplicate coupons.

RESULTS

SCRIBE CREEP - Results of the round-robin tests are shown on Figures 2 to 11 for each of the ten standard materials. All laboratories obtained results that generally give similar rankings for the performance of the ten standard materials, as follows (in order of decreasing performance):

thick coated > intermediate-thickness coated > thin coated > phosphated cold rolled > unphosphated cold rolled

This ranking is consistent with that of the on-vehicle tests.

MASS-LOSS COUPON RESULTS are shown in Figure 12. In general, mass-loss results fall in an order generally similar to that of the phosphated cold rolled steels, cf. Figures 9 and 11. An exception is noted in the case of Laboratory 9 which showed relatively low mass-loss values. This was found to be the result of improper mounting of the coupons -- spacers which should have been used to separate the coupons from the rack were omitted -- this caused one side of the coupon to be shielded from the environment by the rack.

PRECISION - The precision of a test method can be considered in terms of two components: (1) repeatability, the ability to replicate a result within a single laboratory; and (2) reproducibility, the ability to replicate a result from one laboratory to another.

Following 80 cycles of testing, and removal of loose paint, the ten measurements of scribe creep on each test panel were averaged to give a single panel value, x. Following the procedures and nomenclature outlined in References 12 and 13, the three values for each panel of a particular material tested in a given laboratory were used to calculate a cell average, x', and a cell standard deviation, s.

Repeatability - The repeatability standard deviation for the material, s_r, is defined as the the root-mean-square average of the cell standard deviations for all laboratories, that is,

$$s_r = \left(\sum s^2/p\right)^{1/2}$$

where p is this number of laboratories.

The repeatability interval, r, is defined as the 95% confidence interval for the difference between the scribe-creep values between individual panels of a particular material tested in the same laboratory, and is given by,

$$r = 2.8\ s_r$$

Values of r for each of the materials are plotted in Figure 13 as a function of the material's average scribe creep (that is, as a function of x" as defined below). Note that average scribe creep varies from roughly 2 mm for coated steels to 24 mm for unphosphated cold rolled steel.

A least squares line is drawn through the data on Figure 13. It shows that, on average, the repeatability interval is about 25% of the creep value.

Reproducibility - For the reproducibility of a

particular material, we calculated x" which is an average of the cell averages (x') from all laboratories, and a corresponding standard deviation, $s_{x''}$.

The reproducibility standard deviation, s_R, is defined as the larger of either $s_{x''}$, or the term,

$$\left((s_{x'})^2 + (s_r)^2(n-1)/n\right)^{1/2}$$

Finally, the reproducibility interval, R, is defined as the 95% confidence interval for the difference between the scribe-creep values for individual panels of a particular material as measured in different laboratories It is calculated as follows.

$$R = 2.8\ s_R$$

Values of R for the ten materials are plotted in Figure 14, along with a least-squares line. These data indicate that, on average, the reproducibility interval is about 144% of the measured value.

We note that the lab-to-lab reproducibility intervals, R, are significantly greater than the within-lab repeatability intervals, r. The relatively large reproducibility intervals probably result from deviations to the standard test procedures by the participating laboratories. To examine this hypothesis, we normalized the results in terms of the ratios of scribe creep of cold rolled steel to that of electrogalvanized sheet, as shown in Figure 15. This ratio is of particular significance because one of the salient strengths of the J 2334 test is that it yields a large value comparable to that of on-vehicle tests. Similar conclusions are also reached from looking at the absolute values. Also shown on Figure 15 are the deviations from the normal test procedures as given in Table 3.

Effect of specimen orientation - Laboratory 3, the only laboratory with a vertical specimen orientation gave the highest ratio plotted on Figure 15. Conversely, Laboratory 4, the only laboratory with a 30-degree orientation produced a low ratio relative to the laboratories without deviation (Laboratories 2 and 5). This result concurs with the those of on-vehicle tests conducted in Montreal and St. John's where it was found that this ratio was higher for vertical panels than for horizontal panels[9]. Both results indicate that the specimen orientation is an important factor to control for improving the reproducibility of this test.

Effect of dry-stage relative humidity - Laboratories 6 and 8 gave the lowest value of the ratio plotted in Figure 15. Previous work in the development of this test demonstrated conclusively that 50% relative humidity in the dry stage is one of the two most critical factors in achieving adequately high creep rates for cold rolled steel, thus giving a good correlation with the results of on-vehicle tests[1,2]. Moreover, the Lehigh University mechanism study showed that the 50% dry-stage humidity gives the best match of corrosion products and morphology[11]. The relatively low creep rates for cold rolled steel found by Laboratories 6 and 8 in this study provide further confirmation of the need to control dry-stage humidity at 50%.

Effect of salt application method - J 2334 was initially developed as a manual test. As shown in Figure 1, application of the salt solution in the manual test is easily and reproducibly accomplished by a simple 15-minute immersion. For all but one of the automated tests, other methods of salt application were employed. As shown in Figure 15, the alternate methods generally are associated with a lower ratio. The results suggest that the effect of application method is to decrease ratio as follows:

immersion > heavy spray > fog > light spray.

If so, use of immersion by all laboratories should improve the reproducibility of the test. Alternatively, it would be necessary to define and control the conditions of spray or fog in a way that can be easily replicated, and can be shown to be equivalent to immersion. Given the number of variables needed to define spray and fog conditions, such as spray volume, nozzle configuration, spray velocity, angle of impingement, droplet size, and collection rate, specification of reproducible spray and fog parameters may be difficult.

It is also noted that the spacing of test panels becomes more important when salt is applied by spray or fog because of the need to avoid sheltering. As an example, we note that Laboratory 9 provided a 1.2-cm spacing between panels. Since the panels were inclined at a 15-degree angle from the vertical, there could easily have been sheltering from the fog by adjacent, overhanging panels.

Other considerations - Other, yet unidentified, factors may be contributing to the reproducibility interval. Although there were no apparent effects of 80 vs. 110 days of testing to reach 80 cycles, any possible effect of this variable could be simply avoided by defining the total test time in an automated test.

CONCLUSIONS

As a final step in the development of SAE J 2334, the new laboratory test for determining the relative corrosion resistance of coated automotive steel sheet products, a round-robin study was conducted to

determine the precision of the test. Nine laboratories tested ten material combinations. Results of these tests lead to the following conclusions:

o Participants obtained a similar ranking of materials that is generally in agreement with those of on-vehicle tests.

o In terms of a percentage of the creep measured for a particular material, the within-lab repeatability interval was about 25%, and the between-lab reproducibility interval was 144%.

o It should be possible to improve the reproducibility by specifying and adhering to precisely defined conditions, particularly for conditions of specimen orientation, dry-stage humidity, and method of salt application.

ACKNOWLEDGEMENTS

The authors are grateful for the many contributions by members of the SAE/ACAP Cosmetic Corrosion Subcommittee, and the Auto/Steel Partnership Corrosion Task Force during the development of J 2334. Financial support for this work was provided by the Automotive Applications Committee of the American Iron and Steel Institute, and by the Auto/Steel Partnership. Most of all, we are pleased to acknowledge the participants in the round-robin study: Frank Lutze, ACT Laboratories, Inc.; Paul Ziman, Alcoa; George Donchez, Bethlehem Steel Corporation; Pankaj Shah, Ford Motor Company; Mike Ostermiller and Larry Thompson, General Motors; Steve Grossman, Q-Panel Lab Products; Mike Simko, USS Corporation; Kevin Smith, Atotech, USA, Inc.; and Cindy Meade, Singleton Corporation.

Methods for Analyzing the Value of Automobiles

ABSTRACT

Engineers, marketing specialists, and planners responsible for making the numerous cost/benefit trade-offs that arise in the development of a new product need to understand how the attributes of the product generate value to the customer. A recently proposed methodology for benchmarking product value is tested here using five family automobiles competing in the middle product segment. Reasonable agreement is found between value differences estimated from an analysis of demands and prices and those estimated from attribute differences. This finding supports the use of the methodology in forecasting the demands and profits of future products based upon the improvements expected in their attributes.

INTRODUCTION

Persons developing the design and manufacturing processes for a new product need to understand how the attributes of the product affect its value to the customer. For example, marketing specialists and product planners, working at the system level, make important value assessments for new features at the start of new product programs. As the details of the product design and its manufacturing processes unfold, engineers at the subsystem and component levels make numerous cost versus perceived value trade-off decisions. Because the customer is the ultimate judge of the wisdom of these decisions, the challenge shared by all stakeholders in the development process is to reliably project what the customer's reaction will be to an attribute change and how that reaction will affect the profitability of the product.

For example, suppose an engineer has discovered a design modification requiring a variable cost increase of $100 but no added investment which, if implemented, would improve the fuel economy for a new vehicle under development from its currently planned level of 21 mpg to 23 mpg. With the price of fuel at $1.20 per gallon, the economic value to the customer discounted over seven years is $396 using a 6% discount rate. Based upon value versus cost, it may appear that the decision at this point should be to proceed. However, customers may view the value of fuel economy in a subjective manner rather than in strict economic terms making it advisable to survey how customers would respond to the fuel economy improvement before authorizing the design change and increase in variable cost. Another engineer may have discovered that a reduction of interior noise at 70 mph from 70 to 67 dB could be achieved for a cost increase of $100. The decision of whether or not to proceed rests on understanding how the value to the customer is improved by reducing noise at cruising speeds.

Because the frequency of such decisions during the development of a new product is high, manufacturing enterprises can benefit by having a methodology for systematically forecasting how the value of its products will change as a function of their attributes. To be effective in making trade-off decisions against costs, the methodology must have wide support throughout the organization including marketing, finance, engineering, purchasing, manufacturing, and assembly. Also the methodology should quantify value in a cardinal as opposed to an ordinal sense, should offer insight, and should be straightforward to apply if it is to be widely used throughout the product development process from concept to completion.

The use today of any one of the several available product decision support tools is generally limited to one organizational unit or another. For example, multidimensional scaling [1] and conjoint analysis [2] are important customer survey tools currently used by market research specialists to gain an understanding of the utility of product attributes. However, these tools have received little application by engineers who use tools such as Taguchi's robust design methodology [3], value engineering methods [4], and Quality Function Deployment (QFD) [5] in making product trade-off decisions.

The restricted use of these tools is not surprising as multidimensional scaling and conjoint analysis were developed to examine major product questions at the more deliberate system design stage when the conceptual plans for the product are being established; whereas, the value assessment issues faced by engineers often appear at the subsystem and component design levels with the program launched and the program timing clock running. Taguchi, for example, in developing his theory of quality [3] has focused primarily on parameter and tolerance design issues at the component level.

The field of value engineering has developed as a successful operational discipline for component design, particularly in Japan, by defining value as the ratio of product function divided by cost [4]. However, this approach is sorely limited when needing to make trade-offs between different attributes at the system level because their values are defined in different units.

Because the applications of QFD, Taguchi methods, and value engineering require that value assessments be made, it should be possible to integrate these tools and couple them to the tools of marketing research if a common method for value assessment can be found. The purpose of this paper is to examine an approach to value benchmarking which we believe can be used by all stakeholders in the product realization process. It should be of interest to system level planners because it allows all trade-off decisions at the subsystem and component levels to be made in a manner fully consistent with the guidelines set at the system level. The lack of a common basis for value assessment within and between disciplines, in our view, has been a major impediment in having a product management tool that is broadly used.

Two other criteria must also be satisfied. One is that the tool be sufficiently transparent so that it can be easily understood and used by a wide range of specialists. The other is that it have sufficient rigor so that the results can be embraced with a reasonable level of confidence. In keeping with these criteria, the model used here for product demand [6] was developed following the guidelines of Little's decision calculus which is that a model should be easy to understand, not easily give bad answers, and treat the major areas of interest [7]. In what follows, four complementary techniques:

- Demand and Price Analysis,
- Customer Surveys,
- Value Curves, and
- Economic Assessment,

are integrated to form a value benchmarking methodology for products as summarized in Figure 1.

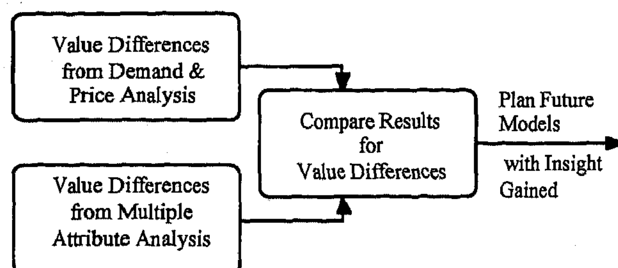

Figure 1: The value benchmarking process.

Vehicles in the mid-sized family automobile segments are evaluated here to provide a partial test of the methodology. The process begins by determining the values and value differences of the products currently competing in the market segment of interest by an analysis of market demand and prices (DP method). The results are then compared to value differences computed from the multiple attribute differences between the products. Three complementary techniques are used to assess how value is influenced by changes in product attributes: a direct value survey (DV method) for highly subjective attributes, value curves (VC method) for performance attributes which are not highly subjective, and economic value calculations (EV method) for attributes which lend themselves to straightforward economic analysis. The survey method can also be used as well for determining the value of selected performance and economic attributes.

There are important advantages to using several methods to evaluate how value is generated by changes in product attributes. Value assessment by one method, for example, can be crossed checked by one of the other methods. Also one method may be easier to use for one attribute versus another in terms of time and resources required. Although variants of each of the three methods for value assessment have been used by others, the effort here of bringing several value assessment methods to bear on the same problem and of comparing differences in product values computed from attributes with those computed from the analysis of demand and price is unique.

If the comparison between the two approaches for computing the value differences are in reasonable agreement, then insight and confidence has been gained for forecasting the value of future products based upon the changes planned in their attributes. Although the products studied here are automobiles, the methodology is general and should be applicable to other products including software and services.

TOTAL PRODUCT VALUE

LINEAR DEMAND MODEL -- The values or utilities of products currently competing within a market segment can be estimated by using a model for their annual demands or market share in terms of their prices and values. Simon [8] has evaluated several models for the demand D_i of product i as a function of its price and the prices of competing products. The simplest model studied by him:

$$D_i = a - bP_i + c\overline{P}_{j\neq i} \quad (1)$$

seemed as good as the more complex models where a, b, and c are constants and $\overline{P}_{j\neq i}$ is the average price of the products competing against i. The above expression can obtained be from a Taylor's expansion of demand as a function of price and keeping only the linear terms. When considering the variables of price <u>and</u> value, Cook and Kolli [6] have shown that demand is given by:

$$D_i = K\left\{V_i - P_i - \frac{1}{N}\sum_{j\neq i}(V_j - P_j)\right\} \quad (2)$$

based upon a Taylor's expansion in the vicinity of a so-called "cartel" reference point, Figure 2, where each competitor has the same reference demand D_R, price, P_R, and value, V_R.

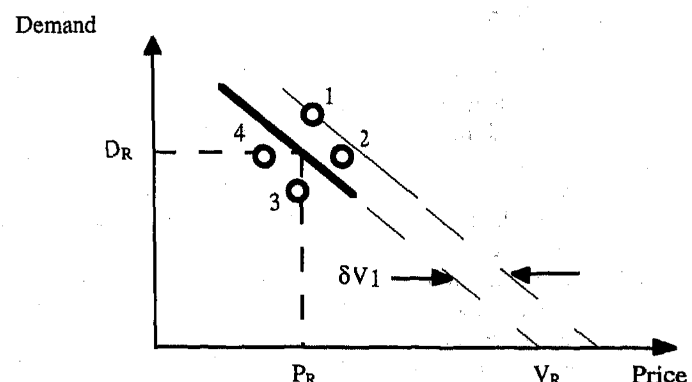

Figure 2: Movement from the cartel reference state when each product is differentiated in value and not offered at the same price.

The interpretation of the intercept shown in Figure 2 as the value of the reference state is fitting as the difference between it and the reference price, P_R, is a measure related to consumer surplus. The demand curve need not be linear over its entire range for this definition of value to be appropriate as linearity is assumed only in a region about the reference point in writing Eq. 2. All of the prices and values in Eq. 2 are treated here as variables.

The value increase from the cartel reference point of product 1 is noted as δV_1 in Figure 2. The slopes drawn are for the case when the prices of the four products are increased or decreased by the same amount and are equal to K/N The parameter $-K$ is the partial derivative of demand, D_i, with price, P_i, of a single competitor at the reference point, N is the number of competitors, and V_i is the value of product i. If one of the producers chooses to change price alone, however, then its slope of demand versus price is steeper and equal to K.

The cartel point is chosen to be the point defined by $\overline{P}$ and $\overline{D}$, the average price and demand, respectively, for the N competitors as this minimizes the error in using the linear approximation. When value is taken as a constant, the coefficient c, on comparing Eq. 1 with Eq. 2, is seen to be equal to $b[N-1]/N$. When prices and all other attributes but one, defined as g, remain unchanged, Eq. 2 leads to an unambiguous, operational definition for the change in value of product i associated with a small change δg:

$$V_i(g+\delta g)-V_i(g)=\frac{D_i(g+\delta g)-D_i(g)}{K}$$

A partial check of the consistency of the demand model given by Eq. 2 can be made by noting that the ratio of the price elasticity E_1, determined from the change in demand of a product when only its price is changed, to the price elasticity, E_2, determined from the demand slope with price shown in Figure 2 when all of the competitors change price by the same amount but hold value constant, should be equal to the number of competitors N [6]. For the automobile market, $E_1 \approx 6$ and $E_2 \approx 1$ [9] which yields, according to the above model, approximately six for the number of vehicles in the market segment that a buyer on average considers with some degree of interest when making a purchase decision which is not unreasonable. It is useful to note that although demand in Eq. 2 is written in terms of two variables and Eq. 1 is written in terms of only one variable, there is only one expansion coefficient that needs to be evaluated in Eq. 2 versus three in Eq. 1. This is a direct result of the high symmetry in the coefficients for an expansion about the cartel point and the fact that the total demand for the N members of the cartel should equal the demand for a monopolist selling the same product.

The quantity E_2 is equal, in theory, to the price elasticity for a monopoly at the reference state and can thus also be defined in terms of the value and price of the product in the reference state:

$$E_2=\frac{P_R}{V_R-P_R}\approx\frac{\overline{P}}{\overline{V}-\overline{P}} \quad (3)$$

where $\overline{V}$ is the average value of the N products being considered. Because E_2 is independent of N and $E_1 = NE_2$ is not, E_2 is the more fundamental elasticity.

For products currently in production, the N simultaneous equations represented by Eq. 2 can be solved for the values for each of the competing products in terms of their demands and prices yielding:

$$V_i=\frac{N[D_i+D_T]}{K[N+1]}+P_i \quad (4)$$

where D_T is the total demand for the N products. Value determined in this fashion is independent of how the producer sets price and represents *perceived value* [10] because the customers have purchased but not yet used the product. The coefficient, K, can be estimated from the ratio of demand and price in the reference state and the price elasticity E_1:

$$K=\frac{D_R}{P_R}E_1\approx\frac{\overline{D}}{\overline{P}}E_1 \quad (5)$$

The difference in value of product i relative to product k in the segment is given by:

$$V_i-V_k=\frac{\overline{P}}{[N+1]E_2}\left[\frac{D_i-D_k}{\overline{D}}\right]+P_i-P_k \quad (6)$$

The above expression can be used to determine value differences between two products from their differences in demand and price (DP analysis) when the demand and price differences are not large. This expression can also be used to determine the value difference between an alternative, i=2, and a baseline, k=1, from paired comparisons in a survey by rewriting it in the form for N=2:

$$4f-2=\left[\frac{3E_2}{P_1}\right]\{V_2-V_1-[P_2-P_1]\} \quad (7)$$

where $f=D_2/[D_1+D_2]$ is the fraction of persons in the survey that choose the alternative over the baseline when the alternative was priced at P_2 versus the baseline priced at a constant reference amount P_1 which is used instead of an average price $\overline{P}$. A linear plot of $4f-2$ versus P_2 goes to zero at the point f=0 ($D_1 = D_2$) and the value of $P_2 = P_N$ (the neutral price) at this point allows the value difference between the alternative and baseline to be computed from the relation $V_2-V_1=P_N-P_1$. The price elasticity E_2 can be solved for from the slope of the line.

LOGIT MODEL -- The logit model [11, 12] for the ratio of any two competing demands is given by:

$$\frac{D_i}{D_k} = \exp^{(U_i - U_k)} \tag{8}$$

where U_i and U_k in Eq. 8 are the respective utilities of competitors i and k. We will use the logit model to provide an assessment of the limits of applicability of the linear model and to explore the relative strengths and limitations of the two models for DP analysis as well as for the analysis of results from DV surveys. To compare the models, the parameters in linear model given by Eqs. 6 and 7 need to be related to the utilities in Eq. 8. On expanding the natural logarithm of Eq. 8 about the same D_T / N cartel demand point described above and noting that $Ln(D_i / D_k)$ is approximately equal to $[D_i - D_k] / \overline{D}$, we find that:

$$\begin{aligned} Ln(D_i / D_k) &= U_i - U_k \\ &= \frac{[N+1]E_2}{\overline{P}} \{V_i - V_k - [P_i - P_k]\} \end{aligned} \tag{9}$$

On rearranging Eq. 9, we obtain the logit model expression for the value difference between products i and k determined from the differences in demand and price (DP analysis):

$$V_i - V_k = \frac{N\overline{P}}{[N+1]E_1} Ln\left(\frac{D_i}{D_k}\right) + P_i - P_k \tag{10}$$

which should be compared to Eq. 6 for the linear model. When paired comparisons are analyzed in a DV survey to determine their value differences, the expression for the logit model equivalent to Eq. 7 is given by:

$$Ln\left(\frac{f}{1-f}\right) = \left[\frac{3E_2}{P_1}\right]\{V_2 - V_1 - [P_2 - P_1]\} \tag{11}$$

DETERMINING VALUE DIFFERENCES FROM ATTRIBUTE DIFFERENCES

Customer needs for automobiles are generally stated in terms of performance, appearance, comfort, reliability, durability, safety and operating costs. Several transformations may be required in going from a statement of needs by a customer to the quantifiable product attributes, which we term *system attributes*, that best connect the product to those needs. A customer may state, for example, that a quiet car is important. However, the physical scale for this attribute, sound pressure intensity, does not correlate as well to what persons perceive as noise as the dB psychometric scale which is based on the logarithm of the physical scale.

A customer may also give importance to quickness which has several system level measures including the acceleration time t_a from 0 to 60 mph and from 40 to 70 mph when passing on a two lane road. For this situation, it is necessary to weight the importance of each subset of the attribute when making an overall assessment of the value of acceleration. Moreover, a transformation to a psychometric scale given by $Log(1/t_a)$ may also be in order for this attribute as the driver's experience is likely dominated by the acceleration force and not time itself [13].

The value change associated with the change in a subsystem attribute should be evaluated from its impact on the system level attributes. For example, the value change due to an increase in horsepower (an attribute of the engine subsystem) should be determined through the sum of the changes in value it generates in system level attributes such as acceleration, top speed, and fuel economy. The weight of a car is a good example of a system level property that influences many system level attributes but is not in itself a system level attribute (by the definition used here) because customers do not experience the vehicle's weight directly. By contrast, the weight of a laptop computer is a system level attribute because customers carry them in their hand.

CUSTOMER SURVEYS -- The first extensive use simulated market conditions for assessing real market demand was made by Pessemier [14]. The DV method [15] used here blends elements of contingent valuation (see for example, [16] and [17]), conjoint analysis [2], and prospect theory [18] to estimate the value difference between a baseline product and an alternative.

There are two major differences between the conventional conjoint approach and the DV method. In conjoint analysis, price is a product attribute like any other whose utility must be determined. In the DV method, however, price is used to arrive at a direct estimate of the difference in value between a baseline product and an alternative based upon stated willingness to pay (WTP) or accept (WTA), Eqs. 7 and 11, respectively, for the linear and logit models. In this fashion, an absolute or cardinal estimate of the changes in the value of a product resulting from changes in its attributes can be obtained from customer surveys in a direct and straightforward manner. The procedure also incorporates a constant baseline in assessing value, the importance of which has been established from prospect theory.

In their development of consumer choice allocation experiments, Louviere and Woodworth [11] have described weaknesses in the theoretical underpinnings of classical approaches to conjoint analysis in forecasting consumer choices. The DV method is more nearly connected to their formalism than conjoint experiments. The major differences are not fundamental but expedient. One-at-a-time experimental designs (paired choice sets) are generally used for DV customer surveys because they are simpler cognitively for the respondent to work through than the statistically more efficient orthogonal arrays. Also a range of prices is used for the alternative versus the fixed price baseline product. From this, a neutral price is determined where the respondents in aggregate are indifferent between the baseline and the alternative, Eqs. 7 and 11. The value difference between the two is then computed directly as the neutral price less the baseline price.

The overall sampling error for the one-at-a-time design can be made equivalent to a more efficient design by increasing sample size. This is a small price to pay for the ease provided to the respondent in working through the survey. The effect of possible interactions between specific main effects can also be evaluated using the one-at-a-time design by simply bundling the factors of interest together as one might plan to market them (not as the combinatorial explosion of all possibilities). Although the DV method can

be used to obtain the value of most any product attribute, it should prove to be particularly useful in assessing the value of highly subjective product attributes such as the value of a product's appearance or the value of a brand name.

VALUE CURVES (VC) -- The VC method for attribute value assessment is based upon the premise that the value of performance attributes can be represented by continuous value curves if the performance measure is itself continuous. A similar concept is, of course, found in classical utility theory, except that the value curves here are not determined from a lottery but from the use of simple extrapolation functions that go through special attribute/value points.

Each performance attribute g is assumed to have three well-defined specification points, the first being the so-called ideal point g_I where value for the attribute is at its highest level (or a point beyond which further attribute improvements should give no noticeable benefit), the second being the baseline point g_0, and the third being the critical point g_C where the product becomes valueless independent of the level of other attributes [19].

For example, if an automobile were satisfactory in all other respects but the turning radius was so large it could not negotiate a right angle turn at a normal intersection, it would have no value. Or if its interior noise level was 120 dB, the threshold of pain, and could not be changed, it would be valueless even though otherwise perfect. The value curve for an individual will depend, in general, upon lifestyle (spirited versus conservative), income, education level, age, sex, etc. of the individual. The value curve used for a particular consumer segment such as buyers of mid-sized family sedans represents an average of their value relationships.

A representative value curve having these properties is shown schematically in Figure 3. Importantly, value curves defined in this manner have been directly linked [19] to Taguchi's loss of inferior quality, the curve in Figure 3 being known as a smaller is better (SIB) condition. The ideal location points used in the unfolding methods of multidimensional scaling described by DeSarbo and Rao [20] and DeSarbo and Manrai [21] are similar, at least conceptually, to the ideal specification point used in constructing value curves of the type shown in Figure 3.

Another feature of the VC method is that it offers a relatively rapid method for estimating value because the curves can often can be generated without a market survey and thereby used to quickly identify where the major opportunities for value improvement lie. If the baseline truly represents the expectations of the persons in the market segment for the attribute, results from prospect theory [18] suggest that value curves should have a discontinuous change in slope at the baseline point with the loss curve, as represented by the dotted curve in Figure 3 beyond g_0, falling off twice as fast as the gain. The baseline should truly represents the expectations of the customer if the value curve is assumed to have a break in slope. Of considerable importance is the fact that the curves can be expressed in absolute units of value by setting the value at the baseline point equal to the value determined for the current product in the marketplace from Eq. 4.

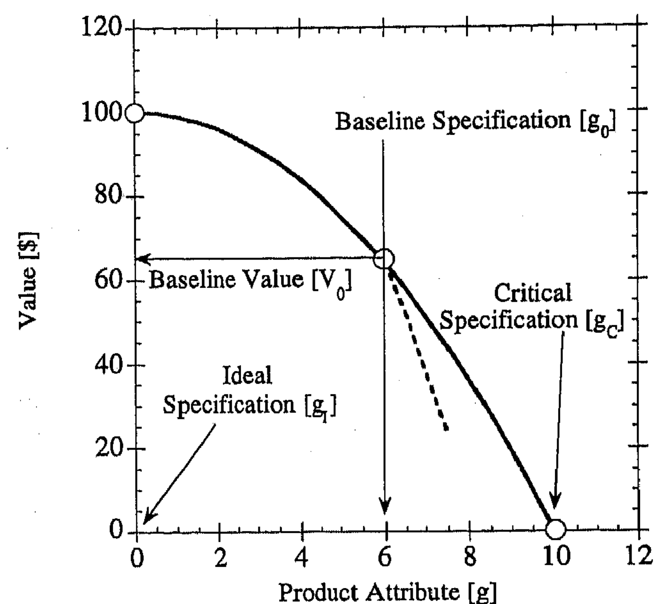

Figure 3: A three point value curve for a smaller is better condition showing a prospect loss break.

The procedure for estimating how a continuous performance attribute is expected to affect product value is to first make estimates of the critical and ideal specifications for the attribute and then substitute them along with the baseline specification into the expression given by [6]:

$$v(g) \equiv \frac{V(g)}{V_0} = \left\{ \frac{[g_C - g_I]^2 - [g - g_I]^2}{[g_C - g_I]^2 - [g_0 - g_I]^2} \right\}^{\gamma} \tag{12}$$

The exponent γ weights the attribute and for making a quick, back of the envelope calculation, it can be taken as equal to the time fraction that the attribute is influential during the use of the product.

For example, interior noise is affected by several environments such as city traffic, idle, full throttle acceleration, and cruising at 70 mph. Noise can be different for each condition with the exponent for each being approximately equal to the time fraction for the condition. The family of curves shown in Figure 4 are based upon one-half of a parabola between 40 and 110 dB having four different weighting exponents. The choice of 40 as ideal (meaning here a point at which no additional benefit accrues by reducing noise) and 110 dB is based upon a comparison by McConville [22] of the value curve with results of Leatherwood, Dempsey, and Clevenson [23]. The choice of 0.05, 0.2, 0.5 for the weighting exponents in Figure 4 are based upon our estimates of the weighting for noise during maximum acceleration in first gear, during idle, and during cruising at 70 mph, respectively.

The relationship of value versus interior noise in Figure 4 for $\gamma = 0.5$ can be used to analyze the hypothetical trade-off discussed a the outset between the reduction of noise at cruising from 70 to 67 dB for a cost increase of $100. From

Figure 4, we find that value is forecasted to improve by 2% for this 3 dB noise reduction. As we will show subsequently, the baseline value for a mid-sized family sedan computed from Eq. 3 is approximately twice its price or $33,000. This results in a forecasted increase in value of approximately $600 for the 3 dB reduction which is $500 more than the hypothetical variable cost increase of $100 stated earlier as needed to make the noise reduction.

The best estimate of the weighting coefficient is obtained by having customers evaluate the difference in value $V(g)-V_0$ between the baseline product and one or more products with the attribute levels different from baseline using the DV method just described. For the noise problem, the different attribute levels could be noise reductions of 5 and 10 dB, for example. This generates additional points on the value curve shown in Figure 4 and allows an estimate of the weighting exponent to be made using a least squares fit to all the points. This approach has been used to determine the weighting exponent of 0.16 for acceleration time from 0 to 60 mph [13]. This process also limits the impact of errors made in the determination of the baseline value V_0 as the DV results calibrate the overall value curve model when the exponent is determined in this manner.

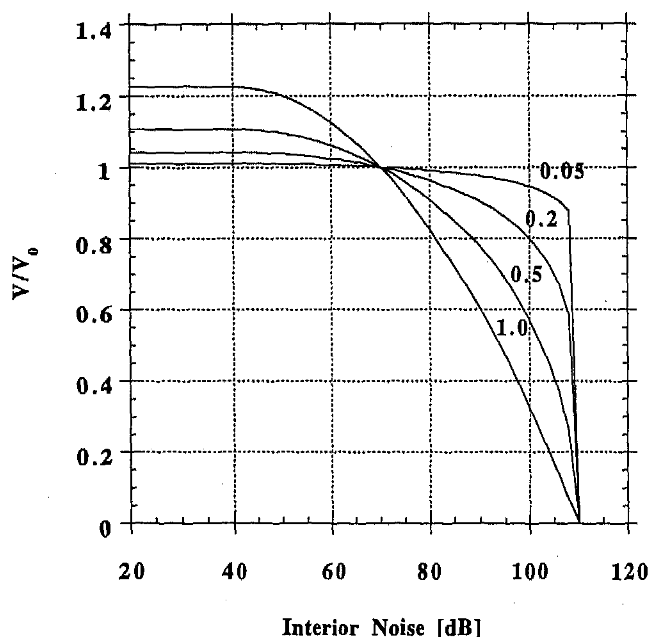

Figure 4: A family of value curves interior noise for four different exponential weighting coefficients.

When multiple product system level attributes g_1, g_2, g_2, ...are considered, the total value of the product is assumed to be determined by the heuristic expression [15]:

$$V_i = V_0 v(g_1)v(g_2)v(g_3)...v(g_j)+\Delta V_{Opt} \quad (13)$$

The term ΔV_{Opt} includes the value of salvageable options as well as the value of other attributes which are assumed to simply add to the overall value of product i in that they do not have a well-defined critical specification. The form of the above equation was chosen as the multiattribute value expression because it has the properties 1) that the value of the product goes to zero, apart form salvageable options, when any of the attributes reaches its critical specification and 2) that a linear relationship for value results with the attribute changes weighted by γ when the attribute changes from baseline are small.

ECONOMIC VALUE (EV) -- The EV method for assessing the value of product attributes directly is based economic considerations. For example, the cost savings resulting from an increase in fuel economy or reduction in maintenance costs of a vehicle should increase product value equal to the savings computed, suitably discounted over time. However, if fuel economy or maintenance costs fall below the expectations of the customer, prospect theory indicates that the value losses could be roughly two to three times their computed economic losses [18].

PERCEIVED VALUE DIFFERENCES OF 1993 MODEL YEAR CARS IN THE MIDDLE SEGMENT

PRIOR INVESTIGATIONS -- Automotive markets offer a rich data base for testing the influence of product attributes on demand. Of direct interest to the problem being considered here is the analysis by Agarwal and Ratchford [24] based upon the pioneering theoretical developments of Lancaster [25] and Rosen [26]. They investigated five vehicle attributes: engine displacement, handling, ride, time to pass, luggage volume, and rear leg room and determined the price elasticities for each attribute using linear regression. A 1% increase in displacement was found, for example, to yield a 0.035% increase in price. More recently, Kwoka [27] has used Katz's [28] price-quality model for market segmentation to analyze certain Chrysler models in terms of vehicle length which was used as a proxy for overall quality.

McCarthy and Tay [29] performed a regression analysis to consider how the utility of attributes as determined from a logit model differed between U.S. buyers who purchased European, Japanese, and domestic vehicles. Horsky and Nelson [30] considered the problem of positioning a new automotive brand at an optimal point in terms of performance, dependability, comfort, prestige, style, and price. Each of the attributes, except for price, were expressed on a perceptual rating scale that ranged from 4.0 to 7.0 for these attributes. Utility differences were determined using the logit model. The results were expressed in terms of a model linear in the attributes and the coefficients were determined using regression methods.

The regression analyses spanned a range of segments to gain a sufficient number of competing vehicles to obtain the coefficients for the attributes considered. There is strong correlation, however, between certain vehicle attributes when viewed across market segments [27] and this should influence the integrity of the regression coefficients if they are to be used to evaluate specific, individual product trade-off decisions within a given segment that do not involve those correlations. Moreover, vehicle features or option content may not be available in smaller, economy vehicles but offered as standard equipment in larger more luxurious vehicles thereby making increased vehicle roominess alone appear more valuable when evaluated across segments than when evaluated within a segment. Because of these limitations, it is necessary to utilize more direct methods such as conjoint analysis, contingent valuation, multidimensional scaling, etc. for estimating how the myriad array of individual attributes affect value.

The DV, VC, and EV methods, are utilized here separately and in combination as already discussed, to estimate how vehicle value is directly influenced by attributes. Also included in the calculations will be the differences in value resulting from different option content which can be sizable even within a segment. The results for the combined attributes are then checked against the overall value differences determined from DP analysis, Figure 1. Alhough a comparison of this kind between the values of competing products as determined from their attribute differences and from their differences in price and demand has not been made before, this type of comparison is important in arriving at a reliable, quantitative insight into the origins of the value differences between complex products and in understanding how those attributes can be best changed to improve customer satisfaction in a cost effective manner.

MIDDLE PRODUCT SEGMENT --- Five vehicles from the 1993 middle product segment of family vehicles which includes Accord, Camry, Century, Ciera, Cutlass, Dynasty, Grand Prix, Lumina, Regal, Passat, Premier, Sable, and Taurus were selected for study. The five had been available for several years without a total redesign thus buyers should have been reasonably informed about them. Total sales for the five selected comprised 70 pct of the total sales (retail plus fleet) for this segment. All vehicle models -- 2 door and 4 door sedans and station wagons -- were included in the value analysis but customers surveyed were restricted to buyers of the 4 door sedans which was the largest group in terms of sales.

Although the ratio of $E_1 / E_2 = 6$ for the two elasticities discussed earlier indicates that customers may roughly consider up to six vehicles when making a purchase decision, limiting the number to five for the analysis reduced the size required for the market survey. In this regard, the error introduced when using Eq. 9 to compute the difference in value between two vehicles for N equal to five versus seven, which is likely an upper limit, is less than 5 pct based upon differences in the ratio of $N/[N+1]$.

The names of the five vehicles are disguised using the letters A through E to avoid any presumption of being judgmental on the merits of one brand versus another because the value metric, although of importance, is insufficient in itself for making a purchase decision as the customer must weigh value against price. Vehicles having a computed perceived value less than the average value of the vehicles in a segment can be very popular in terms of demand and customer satisfaction if their prices are right. Also one individual may judge a given vehicle quite differently than another, but the values computed represent a quantity that must be considered as an average over the market segment. Moreover, the results are for the 1993 model year and they do not represent the values for current vehicles even though the brand names are the same.

DEMAND AND PRICE ANALYSIS RESULTS -- The resulting values determined from Eq. 4 are shown in column 4 of Table 1. The value differences in column 5 were computed by subtracting $33,556 (the average value for the five vehicles) from the values listed in column 4. The figure of $33,556 can be thought of as the value of a baseline vehicle whose dimensions and performance attributes are a composite average of the five. The retail annual sales and retail (median) transaction prices used in the computations are proprietary to one of the sponsors. With permission, we used the figures (but can not disclose them) in computing the value results shown in Table 1. The value differences computed from the logit model, Eq. 9, with D_k constant and equal to 0.2 are shown in the last column. Only for vehicle E, which had the lowest demand, is a significant difference seen between the DP analyses for the two models in Table 1.

Table 1: Values and value differences computed from demand and price analysis.

Model	Annual Number of Retail Sales	Transaction Price	Linear Model Value	Linear Model Diff.	Logit Model Diff.
A	*	*	$33,516	($40)	($63)
B	*	*	$36,458	$2,902	$2,844
C	*	*	$34,598	$1,043	$767
D	*	*	$30,187	($3,369)	($3,483)
E	*	*	$33,020	($536)	($1,516)
\verages=	200,440	$18,303	$33,556		

Because the annual sales figures used for demand were equal to the so-called "retail sales" computed as total sales less fleet sales, buyers in this segment have likely purchased the vehicles for their own personal or family use. Two of the five vehicles chosen (C and D) were available in both two door and four door models and four brands (A, B, C, and E) were also available as station wagons.

The negative demand slope of $K = 65.7$ annual units per dollar for the segment was computed using Eq. 5 for $E_1 = 6$. The reference demand and price were set equal to the average retail sales and transaction prices of the five vehicles. The reference quantities should be near the desired but fictitious cartel point about which the expansion in Eq. 2 is made. The differences in value shown in Table 1 are sizable in terms of how they can affect market share. A $2,000 value difference, on multiplication by K, equates to a change of roughly 120,000 units in annual sales *if no price adjustment were made*. For deviations in K of +/- 10%, the value differences in column 5 of Table 1 were found to deviate by -$181 to $153.

DIRECT ASSESSMENTS OF ATTRIBUTE VALUE -- A total of forty-one product attributes were evaluated for each vehicle, Table 2, to generate the attribute value differences for comparison to the DP results listed in Table 1. Of these, twenty-six represented different levels in available options. Two important attributes not considered were the differences in appearance of the vehicles and vehicle ride quality as they were too costly to properly investigate with the resources available. These differences are not likely of sufficient size in themselves to explain the large value differences shown in Table 1 but their uncertainty, of course, contributes to the error in the value differences determined from the comparison of attributes.

The baseline specifications for all the attributes considered, Table 2 column 1, except for major options and name value, were for a composite vehicle formed from the average of the five attributes for vehicles A, B, C, D, and E listed in Table 3. Total value in Table 3 is broken into six categories: Fuel Economy, Vehicle Range, Option value, Name Value, Value Curves, and Station Wagon Value. The value assessment for each category is described in the Appendix. The results shown in Table 3 were computed from the linear model results for name value and WTP for fuel

economy. The value differences were also computed using the logit model results for these two attributes and the differences were found to be small (see Table A.2). The value coefficients in lines 5 through 15 were multiplied together to arrive at the results in line 16a and then multiplied by $V_0 = \$33,556$ (the average value for the segment located at the bottom of column 4 of Table 1) to compute their combined effect on value, Eq. 13, shown in line 16c.

The total value for each vehicle computed from the attributes considered here was calculated using Eq. 12 as follows: The sum of the values in lines 1a through 4 were added to figures in line 16c computed from the value coefficients using Eqs. 10 and 11 to generate the subtotals in line 18. The station wagon values from Table A.5 were then added to arrive at the total attribute value differences relative to the composite vehicle reported on line 19. Because it seems unlikely that customers would be able to detect many of the small differences in the value coefficients in lines 5 through 15, we also considered what error was introduced by considering a threshold hurdle of 2% before using a coefficient. Only two coefficients (shown within borders) satisfied this constraint. The resulting product of the coefficients under this constraint shown in line 16b are seen to differ by no more than 1% ($336) from the product of coefficients without the threshold constraint.

The value differences in line 19 are compared in Figure 5 to the value differences obtained from the linear and logit DP analyses listed in Table 1. The straight line indicates where the points should fall if the attribute and DP approaches to determining the value differences were in exact agreement. The error bars shown on each side of the linear model points are for two standard deviations computed from the error between the linear model differences in Table 1 and the corresponding attribute differences in line 19 of Table 3. (Note, the degrees of freedom were four (not three) for this computation as the slope of the line is a fixed at unity and thus is not a statistical quantity computed from the experimental data.)

Except for vehicle E, the logit and linear models yield similar results. The minor shifts in the attribute value differences (y direction) in Figure 5 reflect the minor differences in the two model values shown in Table A.2. However, the fact that the linear model places the point for vehicle E closer to the line is not evidence that the linear model is better. We suspect that the larger deviation of E from the line for the logit model may result of the slope K in Eq. 5 being smaller for this vehicle. Although the advertising budgets are not available, there is anecdotal evidence that vehicle E was subordinate to its sister platform, vehicle A, in receiving sales promotion thereby likely reducing K for vehicle. (Less advertising is assumed to reduce demand but value is unchanged to a first approximation; thus, the slope K is reduced.) If a lower K were used in the calculations expressly for vehicle E, its computed DP value would be greater than the amount shown in Figure 5 for both the linear and logit models. Because the linear model is less sensitive than the logit model to changes in K on value, the DP results computed from it are closer to the theoretical line.

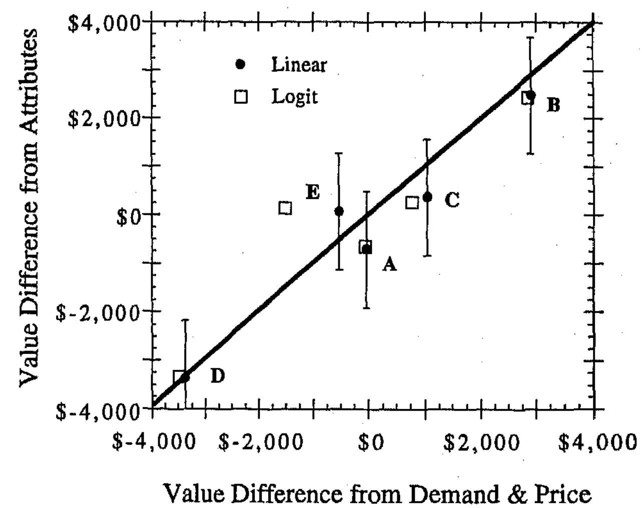

Figure 5: Comparison of vehicle value differences.

DISCUSSION

Apart from vehicle E as already discussed, reasonable agreement is seen in Figure 5 between the value differences computed from attributes and those computed from the analysis of demands and prices. Vehicle B has the highest value of the five. Based upon the results listed in Table 3, this arises from its relatively high name value, its 3 to 7 pct favorable noise level, and its high option content value. Vehicle D has the lowest value as a result of its low option content value, largely from not having an air bag, and its lower name value. The absence of a driver's air bag generated a loss, see Table A.3, of $1,000 for this vehicle relative to the other four which had it as standard equipment. The size of the loss is not unreasonable as it is likely that customers expected vehicles in this segment to offer a driver's air bag which results in vehicle D suffering a loss equal to 2 to 3 times the value of adding an air bag to the vehicle considering the findings of prospect theory [18].

Again, note that lower value does not necessarily imply lower demand and/or lower customer satisfaction as both should be a function of value received minus price paid and not value alone. Vehicle D had the lowest price of the five vehicles. Although vehicle C had the highest name value and highest value for fuel economy, its overall value was reduced below that of vehicle B because of its reduced interior room, higher interior noise level, and lower value of its option content.

Several of the attribute differences computed through the use of value curves, lines 5 through 15 in Tables 2 and 3 were likely too small to have generated a noticeable value difference between the vehicles studied here. These attributes, nevertheless, could be improved upon to differentiate the value of future vehicles.

Table 2: Attributes considered for their impact on value. SIB and LIB refer to smaller is better and larger is better, respectively.

Line	Attributes	Type	Attribute Units	Baseline	Critical	Ideal	Exponent

19	Total Attribute Value Difference		($705)		$2,480		$367		($3,371)		$71

Where possible, a comparison has been made between the attribute values found here and those reported elsewhere. A value of $250 for a 10% improvement in acceleration performance was used by Greene [31] and Greene and Liu [32] in their study of fuel economy policy. This figure was computed from Sperling, Hungerford, and Kurani's [33] preference survey results of motorists in New York and California in which 50% stated that they would pay $0.10 per gallon extra in fuel costs for a 10% improvement in power. For comparison, the marginal value for a reduction in the 0 to 60 mph acceleration time from 10 to 9 sec computed from the value curve parameters on line 14 of Table 2 is $270. The two are surprisingly close considering that the value curve parameters on line 14 of Table 2 were determined from the stated WTP from persons who actually drove vehicles, which were the same except for their acceleration performances, through a test route [13] and that the result used by Greene was obtained from responses to a written preference survey.

Train and Lohrer [34] reported marginal values for luggage space of 118 to 365 $\$/\mathrm{ft}^3$ (in 1978 \$). However, because this range was greater than the range of 26 to 156 $\$/\mathrm{ft}^3$ for interior volume found by Greene and Liu [31], Greene [32] assumed that Train and Lohrer's results were unreasonably high and chose to use a marginal value of 25 $\$/\mathrm{ft}^3$ instead. We can not support Greene's reason for discounting of Train and Lohrer's finding because the marginal values of interior room and luggage capacity should be the same when the competition between the two spaces is optimally balanced. Since it is in the interest of automobile manufacturers to make design trade-offs properly, the two marginal values should be similar rather than apart.

The calculation here for the marginal value of luggage space of 164 $\$/\mathrm{ft}^3$ (in 1993 \$) taken from its value curve determined from the parameters in Tables 2 and 3 is within Train and Lohrer's [34] range albeit at the low end when inflation is taken into account. Moreover, the assessment here of $404 for one inch of added front leg room to a nominal mid-sized vehicle, which is based upon Simek and Cook's [35] WTP evaluation, translates into approximately two cubic feet of interior room or 202 $\$/\mathrm{ft}^3$ and is comparable, as should be expected from the argument given above, to the marginal value of luggage space obtained here.

Value curves are more robust than marginal values for attributes because they provide a means for estimating diminishing returns as the attribute is improved as well as the size of the prospect loss if the attribute is reduced below what customers have become to expect, Fig 3. Human factor responses are used to estimate the critical and ideal specifications for the parabola and WTP results are used to determine the exponent γ which weights the parabola in Eq. 12.

CONCLUSIONS AND RECOMMENDATIONS

The combined use of the linear and logit aggregate choice models was found to be more beneficial to the overall analysis than the use of either model by itself. The linear model is more insightful because it is directly formulated in terms of demand rather than demand ratio and in terms of dollars for value and price rather than utiles. The model also shows the direct connection between the two elasticities E_1 and E_2 through the relationship $E_1 = NE_2$. It also makes fewer assumptions regarding buyer behavior and readily yields an estimate of total value, V_0, when the price elasticities are known. Knowledge of V_0 is necessary to compute value changes based upon the VC approach.

The logit model is useful for extending the limits of the linear model on demand and price when computing the value differences between existing products. When the two models are combined, Eqs. 10 and 11, the insight of the linear model is preserved and the added range of the logit model is gained. The added range of the logit model is also useful for the analysis of results from DV surveys, although the range of prices used here was not sufficient to detect a significant difference between the linear and logit model results.

The findings of prospect theory, in particular the treatment of gains versus losses and the importance of baselines, which have been developed in laboratory studies [18], should have major implications in real markets as shown by the results of the survey listed in Table A.2. The ownership experience of customers gives them different expectations or baselines.

For example, owners of vehicles having high reliability should view vehicles of lower reliability as having a prospect loss for this attribute. This loss, estimated from Table A.2 at roughly $700 per increased repair during five years of ownership (=$7,025/[2x5]), presents a significant hurdle to an automobile manufacturer desiring to win over customers currently driving a competing vehicle of higher reliability. In other words, adding $300 in value with additional features such as leather seats and an improved stereo system in attempting to win over customers to offset a $300 loss from expectations computed strictly from economic considerations will fail because it represents a true prospect loss of more than $600.

Because the term can be so large, understanding of the sources of the name value attributed to one manufacturer versus another is important to improving sales in competitive markets. If it is largely related to historical product reliability or the treatment of customers at a dealership, these can be corrected over time through well-designed and carefully implemented quality and customer service improvement programs. If it is image, for example, gained over years through superior craftsmanship or a racing heritage, it will be more difficult for other manufacturers to overcome.

ACKNOWLEDGMENTS

The authors are indebted to Greg McConville, John Runnion, and Mark Simek who developed the value curves for several of the product attributes considered here. We are also indebted to Shandon Alderson, Hussein Ali, Eric Monroe, Greg McConville, Becky Silver, and Tony Woods for a critical review of an earlier manuscript. Very helpful discussions with Devanathan Sudarshan are also gratefully acknowledged. Finally, we are deeply grateful to Caterpillar and Ford Motor Company for support of this research through unrestricted grants.

APPENDIX: ASSESSMENTS OF ATTRIBUTE VALUE

DIRECT VALUE (CONSUMER SURVEY) RESULTS --The value of the name of the manufacturer, repair frequency, and fuel economy were estimated using the DV method based upon a survey mailed to a random sample of 4000 persons who purchased one of the four vehicles (A, B, C, and D) during the first quarter of 1993. A total 858 quality responses were returned for an overall return rate of 21.5 pct. Although this response rate was low (no monetary inducements or follow-ups were used to encourage people to respond), it is adequate for the purpose of providing a first test of the proposed value benchmarking methodology. The baseline, brand A, was kept constant because findings from prospect theory have shown that it is important make comparisons to a single baseline. The number of respondents that had purchased a given brand was in proportion to the retail sales rate for that brand.

Four surveys were used, the differences being the order of the questions and the prices selected for the alternatives. The order of the questions were varied to minimize possible anchoring effects. For each attribute considered, a range of four prices were evaluated but only three of the four prices were considered in a given survey, the restricted price range allowing the length of the survey to be limited to four pages. This reduced the effective average sample size to 643 (=0.75x858). The results from the survey are summarized in Table A.1.

NAME VALUE OF MANUFACTURER -- The values of the names of the manufacturers of vehicles B, C, and D relative to the name of the manufacturer of vehicle A as determined form the survey are shown graphically in Figure A.1. The resulting values are averages over the WTP or WTA responses (greater or less than the baseline price of $16,000, respectively) given by buyers of vehicles A, B, C, and D. The plot is based upon the logit model, Eq. 11. The equivalent plot for the linear model, not shown, used the function $4f - 2$ for the y-axis, Eq. 7. The slope of the plots should equal $3E_2 / \$16,000$.

Vehicle E was not surveyed because it was manufactured by the same company as vehicle A and had the same platform but was marketed as a separate brand through a different division with certain appearance cue changes.

Table A.1: DV survey results.

Attribute Change	Alternate Price	Total Responses	Number Chosing Alternate	% Choosing Alternate
Vehicle A to B	14000	648	486	75.00
	15000	658	444	67.48
	16000	598	377	63.04
	17000	670	357	53.28
Vehicle A to C	14000	670	534	79.70
	15000	648	514	79.32
	16000	658	423	64.29
	17000	598	342	57.19
Vehicle A to D	14000	658	391	59.42
	15000	598	320	53.51
	16000	670	230	34.33
	17000	648	171	26.39
4 to 2 Repairs per Year	17000	598	501	83.78
	19000	670	341	50.90
	21000	648	122	18.83
	23000	658	110	16.72
4 to 6 Repairs per Year	11000	658	272	41.34
	12000	598	222	37.12
	13000	670	212	31.64
	14000	648	186	28.70
21 to 25 mpg	18000	648	308	47.53
	19000	658	234	35.56
	20000	598	152	25.42
	21000	670	159	23.73
21 to 17 mpg	11000	670	335	50.00
	12000	648	294	45.37
	13000	658	259	39.36
	14000	598	198	33.11

Thus, apart from options, vehicle E was not expected to differ significantly in value from the baseline vehicle and, by omitting it from the survey, the length and complexity of the survey was further reduced. The attribute price in Figure A.1 at the point where $Ln(f/[1-f])=0$ less the baseline price of \$16,000 is equal to the value, ΔV, added by the attribute under consideration.

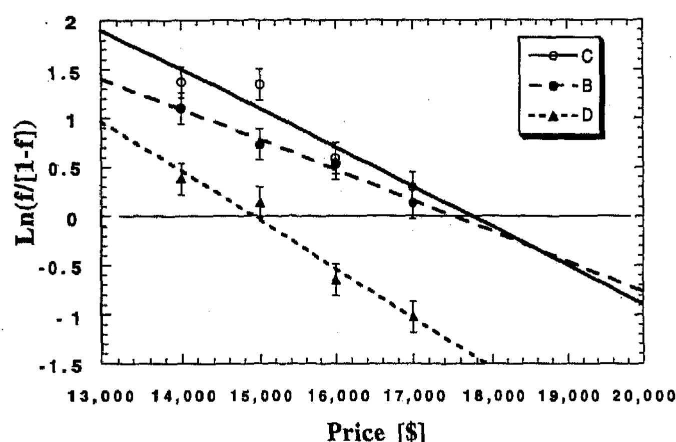

Figure A.1: Graphical determination of name value of manufacturers B, C, and D relative to manufacturer A as determined from the logit model, Eq. 11.

The error bars shown are ± two standard deviations or 0.16, the standard deviation of $Ln(f/[1-f])$ being approximately four times the standard deviation of 2% for f as determined from the binomial distribution for nominal sample size of 600 returned surveys. The agreement of this finding with actual standard deviation of 0.09 computed from the deviations of the points about the line in Figure A.1 is support that the model is representative of the behavior under study.

The DV results computed using both the linear and logit models are summarized in Table A.2 for name value, reliability, and fuel economy. Based upon the R^2 findings shown in column 6, the two models are seen to be statistically equivalent over the range of prices examined. The computed E_2 elasticities in column 7 for the three *simulated* vehicle purchase comparisons are roughly twice the value of unity for this quantity reported elsewhere [9] from the analysis of *actual* changes in vehicle demand with price.

The 90% confidence errors for E_2 shown in the last column of Table A.2 for the three vehicles were computed from the pooled slope errors using a t distribution with 6 df. The E_2 errors for repairs and fuel economy were computed from the respective pooled slope errors using a t distribution with 4 df. Persons may be more price sensitive in the simulated market versus the actual market but considering the error in the measurements of the price elasticity the confidence level is not high.

The difference between the simulated and market elasticities may be due to the choice set in the simulated market being much simpler (the only difference between the vehicles being the name of the manufacturer) than the more complex choice set between vehicles in the real market. Our chief interest in the survey, nevertheless, is the median price persons state that they are willing to pay and not so much as to how this price is distributed about the median.

VALUE OF RELIABILITY -- The difference between the values for reliability of roughly \$3,000 for two fewer repairs over five years or \$300 per repair in Table A.2 seems reasonable to us. The loss of roughly \$7,000 for two more repairs per year over five years (\$700 per repair) is also reasonable when viewed in the context of prospect theory [18] for gains versus losses of comparable sized attributes. This factor of two (roughly) between gains and losses is also seen in the fuel economy values reported in Table A.2.

Table A.2: Results of DVM Survey for Logit (bold) and Linear models.

Attribute Change	Model	Value	90% Conf. +/-	R^2	E_2	90% Conf. +/-
Vehicle A to B	**Logit**	**\$ 1,513**	**\$ 524**	**0.98**	**1.7**	**0.62**
	Linear	\$ 1,612	\$ 475	0.98	1.5	0.55
Vehicle A to C	**Logit**	**\$ 1,749**	**\$ 428**	**0.90**	**2.1**	**0.62**
	Linear	\$ 1,938	\$ 540	0.90	1.8	0.55
Vehicle A to D	**Logit**	**\$ (1,075)**	**\$ 177**	**0.96**	**2.7**	**0.62**
	Linear	\$ (1,057)	\$ 171	0.96	2.5	0.55
Vehicle A to E		Assumed Zero				
4 to 2 Repairs per Year	**Logit**	**\$ 3,382**	**\$ 124**	**0.91**	**3.0**	**0.8**
	Linear	\$ 3,278	\$ 139	0.95	2.7	0.7
4 to 6 Repairs per Year	**Logit**	**\$ (6,824)**	**\$ 708**	**0.99**	**1.0**	**0.8**
	Linear	\$ (7,025)	\$ 818	0.99	0.9	0.7
21 to 25 mpg	**Logit**	**\$ 1,509**	**\$ 292**	**0.93**	**2.0**	**0.57**
	Linear	\$ 1,422	\$ 303	0.92	1.7	0.43
21 to 17 mpg	**Logit**	**\$ (4,902)**	**\$ 457**	**0.99**	**1.3**	**0.57**
	Linear	\$ (4,918)	\$ 479	1.00	1.2	0.43

Although the value per repair results are of interest, they can not be used in the analysis because the repair frequencies of the vehicles are not available. However, the value of reliability is likely factored into the value determined for manufacturer's name. This hypothesis was partially checked by comparing the relationship between name value and the reliability index for these vehicles published by Consumer Reports [36]. A strong linear correlation was found. Vehicles B and C had the same high reliability index and the highest name values in Table A.2. Vehicle D had the lowest reliability index and is seen to have the lowest name value. Vehicle A was in the middle ground for both reliability index and name value.

FUEL ECONOMY -- The value of fuel economy was determined in two different ways: from the survey, Table A.2, and from a direct economic calculation based upon the fuel costs for driving an automobile for 100,000 miles. The EPA fuel economy ratings for the 1993 model year powertrain combinations were obtained from the *Automotive News 1993 Market Data Book* [37]. The average fuel economy, FE_i, for each vehicle was then determined by averaging over the 1993 model year installed powertrain percentages which are listed in the *Automotive News 1994 Market Data Book* [38]. The EPA metro and highway fuel economies were then multiplied by the factors of 0.6 and 0.4, respectively, and added together to arrive at the overall averages shown in line 1a of Table 3.

The economic analysis for the value of vehicle i having fuel economy FE_i relative to the value of the baseline vehicle having fuel economy, FE_0, was set equal to the difference in the amount of money spent for fuel at $1.20 per gallon over 100,000 miles:

$$\Delta V(fuel\ econ.) \equiv 1.20 \times 10^5 \left(\frac{1}{FE_i} - \frac{1}{FE_0} \right)$$

The results of economic analysis determined from this expression are compared with the results of the survey in Figure A.2. The economic calculations are shown for 0, 6, and 10% discount rates over a period of 7 years (14,286 miles/year). The stated willingness to pay for added fuel economy is seen to be about a factor of two greater than the economic value even without discounting. There are two possible explanations for this. Customers could be factoring into their assessment an imputed savings in environmental quality for improved fuel economy or they could be overestimating the economic value of fuel economy when taking the survey but would not do so if the true economic value had been made known to them. Because these questions remain unresolved at this juncture, the stated willingness to pay results for fuel economy in Table A.2 were averaged with the economic estimate (0% discount) to arrive at a final estimate for the value differences in fuel economy. Because the baseline of 21 mpg for the survey was below the fuel economies of all five vehicles, only the slope of the WTP line in Figure A.1 of 355(=1422/4) $/mpg (linear model) was used in arriving at the value of fuel economy based upon the survey results.

The term $\dot{V}_D$, taken as 15 [$/hr], is the estimated value in dollars that a person in the market segment of interest on average places on one hour of his or her time. As evaluated by Simek [40], the factor 6.8 is the time in seconds on average to add one gallon of fuel and 214 is the remaining time in seconds for needed to leave the road and arrive at the fuel pump plus pay the bill and return to the road. The factor of 0.8 represents the fractional amount of the total tank volume filled on average for each fuel stop, the assumption being that the tank is refilled when the fuel remaining is 20% of the total tank volume. Greene [31] calculated the value of range in a similar manner in considering alternate fueled and electric vehicles but used $10 per hour for the value of time versus our $15 here.

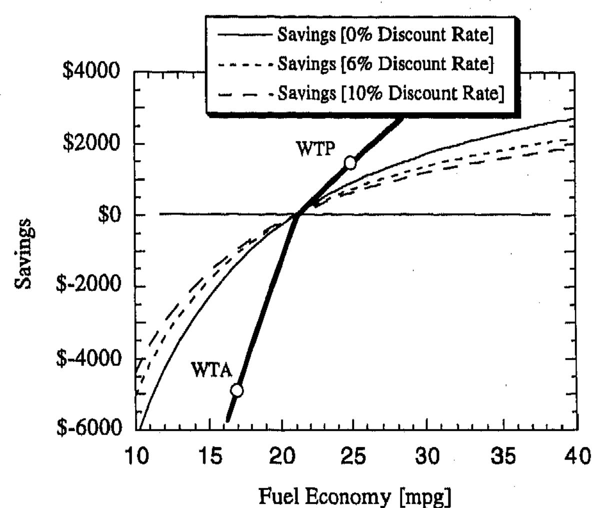

Figure A.2: A comparison of the added value of fuel economy obtained by the economic and survey methods for a 21 mpg baseline.

RANGE -- Increased vehicle range between refueling stops, which is governed by fuel economy and the size of the fuel tank, increases vehicle value as it eliminates lost time in reaching a destination. Fuel tank volumes were taken from the vehicle attribute summary for the 1993 model year given by *Consumer Reports* [39]. The value of a vehicle i having a fuel tank volume of T_i and fuel economy of FE_i was taken as equal to the monetary value of the time lost in refueling the vehicle over 100,000 miles estimated by Simek [40]:

$$V(range) \equiv \frac{10^5 * \dot{V}_D}{3600 FE_i} \left[6.8 + \frac{214}{0.8 T_i} \right]$$

OPTIONS -- When a person buys a car, he or she also generally considers the purchase of several optional features or "options." Here these purchases are considered separately from the larger decision to buy the vehicle in the first place which means that we will compute price elasticities on the basis of the option price instead of the price of the vehicle. Also model option purchases were considered as being independent of each other and the linear model was used for simplicity.

If D persons buy a product annually and half of these also purchase an option, then the purchase price is just equal to the neutral price described in the DV method, the differences between the two prices being equal to the added value of the option. When the percentage is off 50%, we can use the linear model value differences computed from Eq. 4 written in the form:

$$V_{Opt} = V_2 - V_1$$

$$= \frac{2(D_2 - D_1)}{3K_{Opt}} + P_{Opt} \quad (A.1)$$

where D_2 is the number of persons purchasing the option out of the total number of persons $D = D_1 + D_2$ and where V_{Opt} and P_{Opt} are the option value and price, respectively. On substituting for the slope of option demand K_{Opt} in Eq. A.1 taken at the reference point of $D_2 = D_1 = D/2$ the relation:

$$K_{Opt} = \frac{E_{Opt}D}{2V_{Opt}}, \quad (A.2)$$

we have after rearranging that

$$V_{Opt} = \frac{P_{Opt}}{1 - \frac{4[2f_{Opt} - 1]}{3E_{Opt}}} \quad (A.3)$$

where $f_{Opt} = D_2 / D$. If the price elasticity for the option is known then the value of the option can be estimated from its price and its fraction of total sales.

As the fraction of sales of the option increases, its value according to Eq. A.3 increases. This result can be used to arrive at self-consistent relationship for the price elasticity of demand for an option as follows: On summing Eq. 4 over all the products in the segment, we find that the average value of a product in a segment is related to the average price (reference price) by the relation:

$$\overline{V} = \overline{P}\left[\frac{1+E_2}{E_2}\right] \quad (A.4)$$

which is obtained from Eq. 3. As discussed earlier, the elasticity E_2 for automobiles is approximately unity which makes the average perceived in the segment equal to roughly twice the average price for the segment. Therefore, as the purchase rate of an option increases towards 100%, the value of the option should approach twice the option price if the value of the option is to be folded into the overall value of the product in a self-consistent manner. This relationship holds in Eq. A.3 when E_{Opt} is equal to 8/3 which is certainly not unreasonable. With E_{Opt} set equal to 8/3, it also follows that the purchase of an option approaches zero as the option price approaches 1.5 times its value.

The option values estimated using Eq. A.3 for the five vehicles under consideration are shown in Table A.3 and the overall impact of the options on vehicle value are given in Table A.4. The prices represent the option list prices, P_L, for these vehicles obtained from *Edmund's 1993 New Car Prices* [41] except for the 4 wheel disc brake and driver's airbag options which represent estimates as discussed below. The true option transaction price is given by $P_{Opt} = P_L d$ where d is a discounting fraction. In all likelihood, the transaction price lies between the dealer's price (approximately $0.86 P_L$) and option list price.

Blanks in the price listings represent instances where the options were either not available or were bundled together. The latter was typical for vehicle B and almost entirely the case for vehicle C. Because vehicles A and E were built off the same platform, the option values for E were set equal to those of A because the sales of vehicle A were much higher than those for vehicle E which means that results based upon vehicle A should be more reliable. The percentages of installed options were for the 1993 model year were taken from those listed in the *Automotive News 1994 Market Data Book* [38]. The results for import vehicles were determined by averaging the percentages across the vehicles built in North America and built off-shore.

The values of the options for which prices were available were computed from Eq. A.3 using the list prices (d=1) and are shown in bold face in Table A.3. The last column in Table A.3 shows the average of the bold face values for each option. This average value was entered as the value for those options for which we were unable to find a quoted option price.

The list price of $500 for a driver's air bag was taken from *Consumer Reports* for a 1992 mid-sized vehicle [42]. This was necessary because the driver's air bag was standard equipment for vehicles A, B, C, and E but was not available on vehicle D. It was also necessary to estimate the price of the 4 wheel disc brake option because its price was folded into the option price for anti-lock brakes in *Edmund's* [41] summary; whereas, these two options were not bundled for all vehicles.

The average *option content value per vehicle* in Table A.4 was computed by multiplying the value per option in Table A.3 by the percentage installed for each option divided by 100. The differences in option value with respect to vehicle A is shown at the bottom of Table A.4 for no discounting of the list price, d=1, and for discounting equal to the approximate dealer price, d=0.86 [41]. It is likely that the actual average price paid for an option is somewhere between the list price and the dealer price. In subsequent calculations, we have used the results for d=0.86.

INTERIOR ROOM -- The results of Simek and Cook [35] based upon combined considerations of the percentage of the adult population which would be satisfactorily accommodated by the major interior dimensions for these five vehicles and of the stated willingness to pay for added space using the DV method, were used to estimate the value coefficients for interior room in line 5 of Table 3. Polynomial expressions up to fifth order were generated for value as a function of front and rear head room, front leg room, rear knee room, and front and rear shoulder room. Stated willingness to pay results for additional space were determined using the DV survey method only for head room and front leg room.

This method for assessing value of interior room did not generate ideal and critical points which is why such points are absent for this attribute in Table 2. The interior room dimensions used in the computations by Simek and Cook [35] for the value of interior room of these five vehicles were taken from the listing published by the Motor Vehicle Manufacturer's Association [43] for the 1993 model year vehicles.

VC METHODS -- The value coefficients for the remaining performance attributes were determined from Eq. 10 after arriving at estimates for the ideal and critical specification

points and the exponent. A feature of the VC method is the ability to make quick, directional estimates of the value improvement on changing an attribute. If an attribute is found to have a significant effect, an improved estimate can be made using DV survey method in which respondents evaluate the attribute change versus a baseline. Both methods have been used here.

Runnion [44] estimated the value curve for turning radius based upon a critical attribute equal to the upper limit on turning radius for making a right angle turn while keeping within a 15 foot wide lane. The critical and ideal attributes determined by him are listed in line 6, Table 2.

The critical attributes and exponents for lines 6 through 10 are rough estimates suitable only for directional analyses. Overall length and overall width in lines 7 and 8 represent dimensions which we judge as making the vehicle too large and cumbersome to be driven and parked effectively by most drivers. The exponents for lines 7 and 8 represent a consensus reached by seven persons engaged in value benchmarking research. For line 9, the 95% male and 5% female bent torso heights were used, respectively, for ideal and critical door-top to ground clearances [45]. Although the exponent chosen of 0.03 is small, it reflects what is certainly an upper limit on the fractional amount of time needed to enter and exit a vehicle. The exponent for luggage capacity, line 10 of Table 2, was set equal to an assumed (4/52) time fraction of weeks out of the year that the full luggage capacity would be used on average. As none of these attributes in lines 7 through 10 are seen to have important impact on the value differences in Table 3, it is not likely that a more careful evaluation of their impact would significantly change the results of the attribute value computations in line 19 of Table 3.

The critical value and ideal values for interior noise in lines 11 through 13 in Table 2 are those obtained by McConville [22] referred to in the body of the text. The interior noise levels, acceleration times from 0 to 60 for vehicles A (=E), B, and C, and the skidpad lateral accelerations times in Table 3 were obtained from *Road and Track* [46]. The 0 to 60 acceleration time for vehicle D was obtained from an earlier model [47] and assumed unchanged for the 1993 model year. The exponent of 0.16 represents McConville and Cook's [13] determination, discussed earlier, based upon an analysis of the value of acceleration performance using a combination of VC and DV methods. The critical and ideal attributes listed for skidpad lateral acceleration are our estimates for these quantities and the exponent of 0.2 is our estimate of the time fraction during vehicle operation that handling is important.

STATION WAGON VALUE -- Station wagons were also treated as an option and their values were estimated using Eq. A.3. The results are shown in Table A.5. Although the price premiums for the station wagons are not shown in column 5 of Table A.5 because they are proprietary, the average premium is given at the bottom of the column. The values for vehicles B and C are seen to be somewhat lower because of their low sales versus vehicles A and E. However, the low sales for the wagons from manufacturers B and C may not be representative of low demand but of limited vehicle availability in which case the assumptions assumed in using the model do not apply.

Table A.5: Station wagon option value results.

Determining the Value of Vehicle Attributes Using a PC Based Tool

E. M. Monroe and H. E. Cook
University of Illinois at Urbana-Champaign

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Product engineers and product planners are routinely faced with trade-off decisions involving the cost of adding a product feature or modifying an existing feature versus its added value to the customer. The purpose of this paper is to assess the use of a personal computer (PC) for surveying respondents' willingness to pay (WTP) for four options – two-tone color, 4x4 drive, sporty trim package, and extended cab -- available on the base 1997 Ford F-150 truck. The results show that the respondents' stated WTP reflected the value of the options as determined from their prices and fraction of sales.

INTRODUCTION

Product value, cost, and the pace of product innovation are the fundamental metrics that generate profits to companies selling products in highly competitive markets [1]. In making trade-off decisions relative to cost, value engineers consider the performance divided by cost [2] of the various alternatives. Although this approach has been found to be very useful in making trade-offs at the component level of design, it is not effective at the system level of design where the trade-off is often between two attributes which have different measures of performance requiring a comparison to be made between quantities having different units. The trade-offs presented by added trunk space, versus reduced fuel tank volume, and/or rear leg room is a good example of this type of system level problem.

There are other approaches, however, which do not have this difficulty because they convert changes in full system level performance to changes in value to the customer in units of dollars. Once this has been achieved, a direct comparison can be made between the added value and the added costs. The process known as contingent valuation [3] has been widely used for assessing the societal benefits in dollars of potential infrastructural investments such as airports, parks, and recreation facilities by asking potential customers what they are willing to pay (WTP) or accept (WTA) for a proposed change. Although the use of WTP for product features has seen only limited use, the approach, in our view, has considerable merit based upon determinations of the value of vehicle acceleration [4], vehicle interior room [5], the name value of a vehicle manufacturer [6], and the value of vehicle options [7] using what we term the Direct Value (DV) survey method to distinguish it from classical conjoint analysis survey [8].

The purpose here is to report on the use of a PC based tool for assessing the value of product features using the DV method. Although commercial software [9] is available for conjoint analysis surveys, we constructed the software used here so that it would provide the added support needed for the DV method for soliciting questions and analyzing the responses. The survey was used to evaluate four options – two-tone color, 4x4 drive, sporty trim package, and extended cab -- available on the base 1997 Ford F-150 truck. The respondents were adults attending the University of Illinois at Urbana-Champaign Engineering Open House in March 1996. This F-150 truck was chosen because it was a new model with representative photographs readily available from information brochures at dealerships showing the third door open and closed and several exterior options.

THE DV METHOD FOR ASSESSING VALUE

The DV survey method combines elements of conjoint analysis [8], contingent valuation [3], prospect theory [10], and choice theory [11]. Paired comparisons are made between a fixed baseline and one or more alternatives and respondents are asked to make a simulated purchase decision (choice) between them. Usually the alternative differs from the baseline in only one attribute and never more than a few. With the features of the alternative and the baseline fixed, the respondent is asked to choose between the baseline at a fixed price and the alternative over a range of prices. By aggregating the results and plotting the fraction f of all of the respondents surveyed choosing the alternative as a function of price, a neutral (median) price can be found where 50% of the respondents in aggregate prefer the alternative and 50% prefer the baseline. The difference between the neutral price and the baseline price equals the added value generated by the product feature or the change in the feature. The added value could, of course, be negative. If we write the baseline price as P_0 and the neutral price as P_N the added value of the feature or option is given by:

$$V_{Opt} = P_N - P_0$$

This is does not imply that the value determined is the price that should be charged for the option or feature. The price of an option or feature should reflect both its cost and value.

PC TOOL

There are several important advantages of a PC based tool over a written survey in assessing the value of certain attributes of a product including the ability to readily generate color images, animation, sound, and noise. Logic can also be included in the software to help the respondent when questions arise and to detect and thus avoid logically incorrect answers. If the demographic information about the respondent is obtained up-front before the survey is presented, the survey given can be selected from a library that targets the specific demographic profile of the respondent. Moreover, the data acquisition and analysis can be automated. Although a PC tool is not today well suited to delivering a survey to a geographically wide respondent base, it can be used at special locations such as shopping areas and dealerships frequented by persons whose demographics are close to those of interest. However, as the computer internet grows in size and speed, PC based market surveys may well become more important for quantitatively assessing customer needs than mail surveys.

The PC tool was divided into six modules as shown in Figure 1. The four central modules -- Instruction Interface, DVM Product Comparisons, Demographic Interface, and Thank You Interface -- controlled the real time interaction with the respondent. The Design Interface at the start and the Data Analysis Interface at the end were used to set up the survey and to analyze the results obtained for value, respectively.

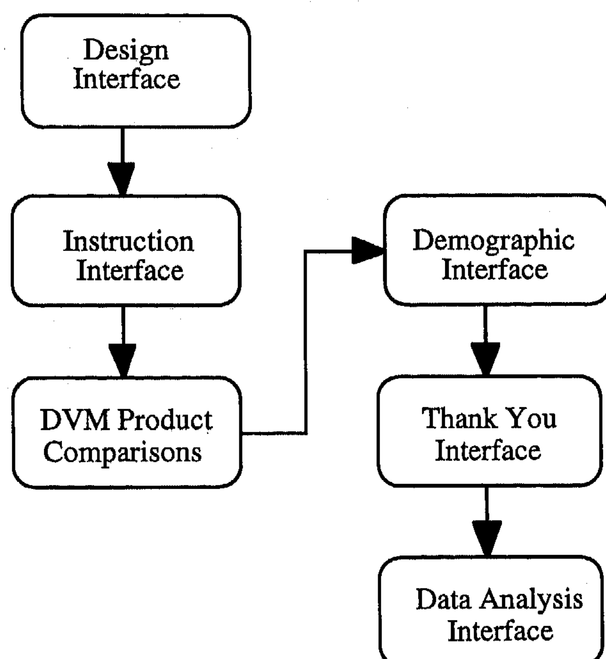

Figure 1: Visual Basic DVM Procedure

INSTRUCTION INTERFACE - The Instruction Interface, the first screen seen by the respondent, is shown in Figure 2. It described what the survey was about and gave general directions to the respondent. The respondent clicked the start survey button to begin.

SURVEY INTERFACE - The PC tool took the respondent through a sequence of screens in which alternatives to the baseline were presented to the respondent and he or she indicated a simulated purchase of the baseline or the alternative at the prices shown by clicking on the appropriate button. One of the survey screens used is shown as Figure 3 in which a baseline 4x4 XLT package at $19,200 is compared against the 4x4 XLT with the extended cab at $24,000. The passenger side access door on the extended cab image could be opened and closed by the respondent using the two buttons just below the picture.

If the respondent clicked the "Buy Alternative" button, the alternative's price was increased and the respondent was again asked to reconsider the choice at the new price level. The baseline price remained fixed throughout. When the baseline was selected, the price of the alternative was reduced. These steps were repeated until the respondent switched from "Buy Alternative" to "Buy Baseline" or vice versa. The highest price the respondent was willing to pay for the alternative was recorded as part of the database and a new feature relative to the baseline was presented to the respondent. This process was repeated until all of the alternatives were considered. Six alternatives formed by combinations of the four features under consideration, Table 1, were presented to each respondent.

Table 1: DV Experimental Design

Vehicle	Base	Two-Tone	4x4 Drive	Sport Trim	Extd. Cab
Base	1	0	0	0	0
Alt 1	1	0	0	1	0
Alt 2	1	0	1	0	0
Alt 3	1	1	0	0	0
Alt 4	1	0	1	1	0
Alt 5	1	1	0	1	0
Alt 6	1	0	1	1	1

The median WTP by the respondents in total and by selected demographics is shown in Table 2. The neutral price was also computed using three other methods: 1) a best fit plot of the WTP prices on normal probability paper, 2) a logit model plot [12] of $Ln(f/[1-f])$ versus price and 3) a linear model plot of $4f-2$ versus price. (The logit and linear model plots yield neutral prices at the point where $Ln(f/[1-f])$ and $4f-2$ are zero.) The results for the normal probability plot were very close to those shown above computed from the MEDIAN function in the spreadsheet and also with those determined from the logit and linear model plots.

Table 2: Summary of Median WTP

Option	All (57)	Own truck (22)	Not Own Truck (35)	Male (35)	Female (22)
Baseline	$19,133	$19,117	$19,150	$19,150	$19,175
Color	$200	$200	$350	$100	$500
4x4 Drive	$2,000	$1.900	$2,300	$1,950	$1,825
Sporty Trim	4433	$467	$400	$500	$250
Extended Cab	$2,433	$2,267	$2,550	$2,400	$3,150

DEMOGRAPHICS INTERFACE -- Upon completing the survey, respondents were asked to complete the demographics interface shown in Figure 4. This information was coded with the WTP response of each respondent. As noted above, if the survey administrator desired to have different surveys for persons in different demographic segments, the demographic information could be asked for initially and logic commands would then present the appropriate survey to the respondent.

THANK YOU INTERFACE - The final interface, shown in Figure 5, thanked the respondent for his or her time. The "Restart Survey" button shown was used by the administrator to restart the survey for the next respondent.

VALUE OF ATTRIBUTES

The WTP results for each of the six alternatives considered were assumed to be represented by a linear model of the form:

$$[X][\lambda]=[Y] \tag{1}$$

where $[X]$ for this problem is the 7 rows of alternate vehicles plus baseline by 5 columns of attributes array of 0's and 1's shown in Table 1. The matrix $[\lambda]$ is the column array of unknown coefficients representing the values that each off-baseline attribute added to the baseline value when present on the vehicle. The array $[Y]$ is one of the WTP column arrays in Table 2 determined for each alternative. The five unknown coefficients $[\lambda]$ were solved for using the regular least squares solution given by:

$$[\lambda]=\left[X^TX\right]^{-1}\left[X^T\right][Y] \tag{2}$$

where $[X^T]$ is the transpose of $[X]$. This solution was readily obtained using spreadsheet matrix operation commands. The baseline coefficient λ_0 is not a value but the price of the baseline product. If desired, the baseline value of a product can be determined from an analysis of the price and demand of the vehicles competing in the market segment and is roughly two times price.

The values calculated for the options are shown in Figure 6 for all participants, for truck versus non-truck owners, and for men versus women. The ± 95% confidence limits computed for each side of the median (assumed to be the same as for the average) are shown in Table 3. A significant difference exists between the value assessed by women for the two-tone paint and the extended cab options.

Table 3: Confidence Range (95%) on One Side of Mean

	All (57)	Own Truck (22)	Not Own truck (35)	Men (35)	Women (22)
Color	120	193	153	153	193
4x4 Drive	315	507	402	402	507
SportyTrim	120	193	153	153	193
Extended Cab	120	193	153	153	193

OPTION PRICING

The addition of an option to a product line can increase profits by the incremental profit generated per unit sold and by increasing the number of products sold. The price for the option which optimizes profits can be estimated from the value and variable cost of the option. To a first approximation, the price of the option is independent of the fixed costs for the option.

The total demand for the product (those with and those without the option) can be written as [13]:

$$D=K\left\{V-P-\frac{N-1}{N}\overline{[V-P]}_{Comp}\right\} \tag{3}$$

where K is the negative slope of the demand with price, V is the average value of the product, P is its average price, N is the total number of products competing, and $\overline{[V-P]}_{Comp}$ is the average value less demand for the N-1 competing products. The average value and price of the product are given respectively by:

$$V=V_0+fV_{Opt} \tag{4}$$

$$P=P_0+fP_{Opt} \tag{5}$$

The fraction of persons taking the option relative to the baseline product according to the linear model is given by:

$$f=0.5+\frac{3E_{Opt}}{8}\left[1-\frac{P_{Opt}}{V_{Opt}}\right] \tag{6}$$

which should be valid over the range of f from 0.25 to 0.75. The expression for the logit model is given by [6]:

Finish

Figure 4. Demographic Interface.

Thank you for taking the time to complete the previous survey.

The information from this survey will be used to develop vehicles that better serve your needs.

Figure 5. Thank You Interface.

$$Ln\left(\frac{f}{1-f}\right)=\frac{3E_{Opt}}{2}\left[1-\frac{P_{Optt}}{V_{Opt}}\right] \quad (7)$$

The two models closely agree for f in the range 0.25 to 0.75. The term E_{Opt} is price elasticity for the option.

Gross total profit (GTP) equal to cash flow excluding charges for fixed cost and investments is given by:

$$A=D\{[1-f][P_0-C_0]+f[P_0+P_{Opt}-C_0-C_{Opt}]\} \quad (8)$$

The behavior of the GTP/GTP$_0$ versus the option price is shown in Figure 7 where GTP$_0$ is the gross total profit if the option were not offered. The ratio for the 4x4 Drive option has been computed for illustrative purposes. A family of curves are shown for variable costs over the range of 0.2 to 0.8 times the value of this option. For simplicity, it was assumed that competitors did not change the value or price of their products and the price elasticity of 1.9 for the 4x4 option in Table 4 was rounded off to 2.0.

The price elasticities shown in Table 4 were computed in two steps. First, the elasticities for each of the six alternatives were computed from the slopes of $Ln(f/(1-f))$ and f versus price for the logit and linear models, respectively, with E_{Alt} set equal to E_{Opt} in Eqs 6 and 7. The R^2 statistic ranged between 0.93 to 0.98 for these plots. The linear model slopes were computed from points lying within the range of f from 0.25 to 0.75. The elasticities for the individual options were then computed from the E_{Alt} using a linear elasticity model for the experimental design given by Table 1 , the elasticity for the baseline being set equal to the average of the six E_{Alt}. Except for the extended cab, the elasticities for each of the options are seen to be independent of the range used for the logit model and in agreement with those computed from the linear model over its range of applicability.

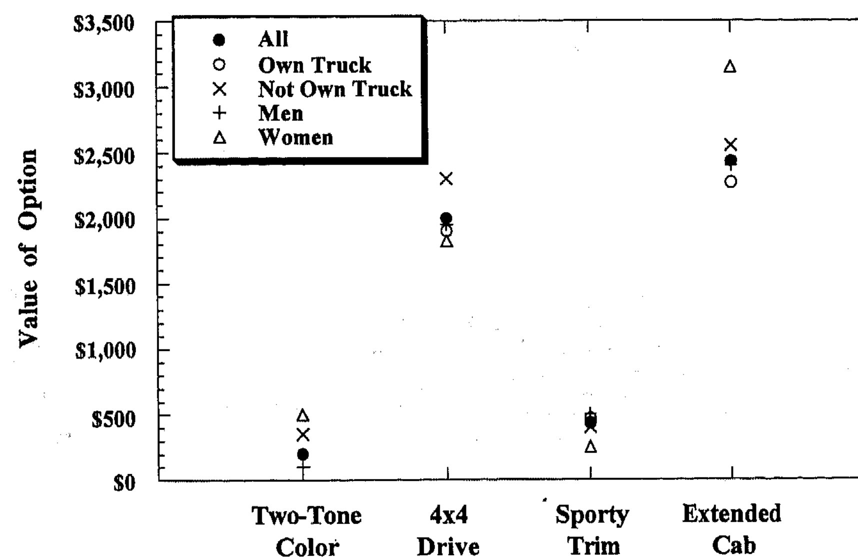

Figure 6: Values of Options

DISCUSSION

Our purpose here was to evaluate the use of a PC tool to assess the values of product options using the DV method. The tool was shown to be very useful for estimating the value of options such as the two-tone color and sporty trim whose appeal is primarily visual as well as options such as the 4x4 drive whose appeal is primarily functional. Although the extended cab option is also primarily functional, it also has significant impact on the overall appearance of the vehicle and thus has an important subjective component. We believe the PC tool, because of its ability to show color images, allowed both of these options to be properly considered by the respondents and in a manner better than could be achieved with a written survey. Of course, having respondents view and drive full scale prototypes would be superior but this approach is not feasible in the early design stages where only conceptual renderings of the product are available. The results obtained here confirm that the PC tool is capable of delivering a DV survey,

Of some surprise to us was the finding that persons in the local survey valued the options the same, within the statistical error of the experiment, independently of whether they did or did not own trucks. This suggests that deep product knowledge was not a factor in influencing the values of the options considered. This finding plus the fact that the different segments of respondents agreed that two-tone paint and sporty trim were of considerable less value than either the 4x4 drive or the extended cab supports the belief that stated WTP results are not capricious but reflect reasoned responses

which can be used for assessing the intrinsic value of product attributes.

If desired, the value of an option already in production can be determined from the average price of the option and the percentage of persons choosing the option provided that the price elasticity of the option is known. Using the prices and the number of options sold on the F150 truck for the 1995 model year (the latest results available to us), we also computed the market values for the same options, the results being shown in column 4 of Table 5. The last column, for comparison, shows the option values computed from the neutral prices determined from the logit plots of the WTP prices of all respondents. (These values differ slightly from the values computed from the median prices in Table 2. If the option elasticities are not known, we suggest using 2 as an estimate of the elasticity.) The results of the comparison give further support to the use of WTP to determine the value of an option. Nevertheless, the results here do not necessarily reflect an assessment of the average value of these options for the national market because of the local nature of the survey.

The forecasted profitability calculations shown in Figure 7 for the 4x4 Drive option were made, as already stated, by assuming for simplicity that competitors did not make any price or value changes. Because of this, the gross added profits shown for placing this option in production are a considerable overestimate.

If the 4x4 Drive were truly a new option which was introduced by one manufacturer ahead of its competitors, the latter would likely react over the near term by lowering their prices once they saw its impact on the demand for their products and develop their own 4x4 Drive over the longer term because, as can be seen from Eq. 3, the advantage gained by a net increase in value minus price resulting from the introduction of a new product feature can be offset by a reduction in price of the competing products. However, competitors will generally not lower prices to totally offset the feature advantage because of the fear of starting a price war. Likewise, the manufacturer with the feature or option advantage should offer it at a fair price rather than at a low price because such action could start a price war [13], the fair price being roughly the sum of the option's variable cost plus value divided by two.

SUMMARY

- The PC tool worked well in estimating the value of visual as well as functional options.
- Respondents seemed comfortable with the PC as a medium for the survey.
- For the options surveyed, truck owners and non-owners valued the options approximately the same.
- Values of the options obtained from option price and option fraction of total sales agreed very well with the option values determined from survey.

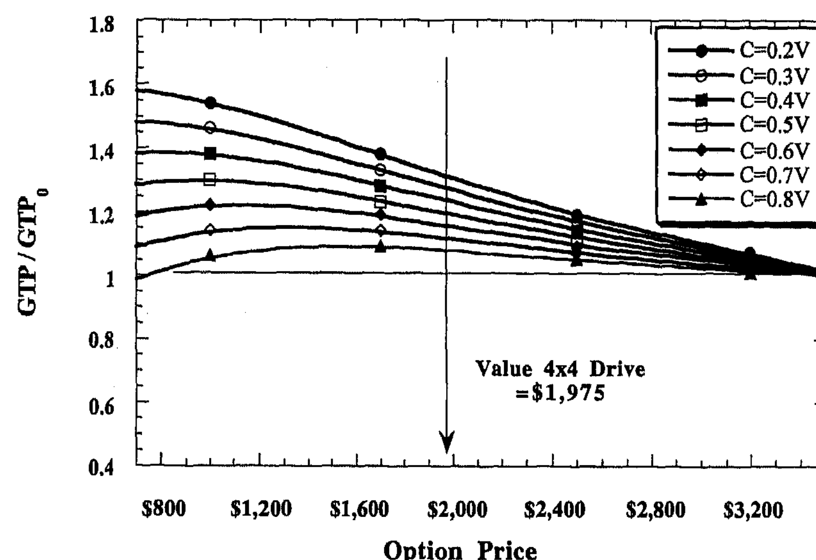

Figure 7 Idealized ratio of profits with and without 4x4 Drive option as a function of option price.

Evaluating Mail Survey Techniques for Determining the Value of Vehicle Options

ABSTRACT

In developing new products and improving existing products, engineers make numerous trade-offs between the cost of a new or modified feature and its value to the customer. One method for estimating value is to ask potential customers their willingness to pay (WTP) for the product change. Their stated WTP may, however, depend upon how the question is framed. Mail survey techniques based upon simulated choice experiments were used for estimating value to the customer. The main objective was to explore how the framing of the survey questions affected the WTP response and if one or more of the methods provided simulated responses in reasonable agreement with actual buyer behavior. It was found that the best way to frame the questions was to give respondents multiple choices for price of the alternative versus the baseline product as opposed to having a choice of only one price or having to write in a price representing their WTP.

INTRODUCTION

Automotive engineers working in diverse areas of the product realization process -- manufacturing, vehicle system design, component design, assembly, and service – are routinely faced with trade-off decisions between value to the customer and cost. Value trade-off issues can also occur when cost is not a factor. A typical problem of this nature might involve the desire to lower the roof-line of a future vehicle to improve aerodynamics and visual appeal but it compromises head room. How much value is added by the better visual appeal and improved aerodynamics and how much value is lost by the reduction of head room?

In all cost/value and value/value trade-offs, the alternative chosen should be the one that is forecasted to give the highest profit or internal rate of return over the life of the vehicle. To use forecasted profitability as a basis for decision making requires that estimates be made of value to the customer and costs to the company for each alternative. Most companies have procedures in place to arrive at cost estimates and marketing research tools can be used to arrive at an estimate of value.

The purpose of this paper is to consider the use of mail survey techniques based upon simulated choice experiments for estimating value to the customer. Respondents were asked to state their willingness to pay (WTP) for an alternative vehicle (pay more or pay less) with the option installed versus a baseline vehicle without the option. Our main objective was to explore how the framing of the survey questions affected the WTP response and if one or more of the methods provided simulated responses in reasonable agreement with actual buyer behavior.

The market survey method which we used combined elements of conjoint analysis [1], contingent valuation [2], prospect theory [3], and choice theory [4]. The approach has been termed the Direct Value (DV) method [5] because it asks respondents, as in contingent valuation, their WTP in contrast to classical conjoint analysis where price is simply as another product attribute whose utility is to be determined. A constant baseline is used in the DV method because prospect theory [3] has shown that a fixed baseline is important in quantifying value differences between alternatives. A neutral price is determined from the responses to the survey where one-half of the respondents choose the baseline product and one-half choose the alternative. The value of the alternative relative to the baseline is equal to the neutral price less the baseline price. This value difference can, of course, be positive or negative. The method has been used, for example, to estimate the value of vehicle acceleration [6], the interior room of automobiles [7], and the value of certain attributes for mid-sized vehicles [8].

We are focusing on the value of options here because it allows us to test DV survey results against actual buyer behavior. The ideal vehicle of choice for this experiment would have the options available as separate choices, the buyer being unencumbered by having to take a package of options to obtain a desired single option. Unfortunately, none of the vehicles we reviewed were ideal. The Ford Mustang was chosen because it was simply the vehicle which more nearly approximated the ideal for this study. Buyers of the V6 Mustang could choose the anti-lock brakes (ABS) as an option without having to choose it as part of a package and , by comparing the make-up of different option packages, we were able to arrive at estimates of the price, if they had been offered separately, of the V8 engine (versus V6), ABS (across all models), convertible, automatic transmission, air-conditioning, and leather interior.

VALUE

The word value is used across many disciplines but it is seldom defined in the same way. As shown by Cook and DeVor [9], for example, value, or the lack thereof, is related in Taguchi's cost of inferior quality which when added to manufacturing costs yields his quality loss function. Value engineers on the other hand define value as function divided by cost [10]. This approach has been very helpful at making trade-offs at the component level of design. However, when trying to make cost/value trade-offs across subsystems, this definition gives different units for value depending on what performance variable is being measured. It also does not account for the distinct likelihood of diminishing returns on performance as it improves.

To overcome these limitations and link value in the engineering contexts to value and utility defined in other disciplines, we will use value as it appears in the linear demand expression by Cook and Kolli [11] because this gives an operational definition which is ideally suited to handling the problem of interest, namely forecasting demand and profits for product alternatives. In the absence of a price change, the change in value, δV, associated with the change in the product attribute g is equal to the change it produces in demand δD divided by the negative slope of the demand curve with price, K:

$$\delta V = \frac{\delta D}{K}. \tag{1}$$

This results in value having the units of price (dollars) independent of the system, subsystem, or component being considered. Moreover, based upon the definition of K Eq. 1, it follows that a change in value of δV will have the same effect on demand as a change in price of $-\delta P$.

There are two important ways in which this definition of value can provide information to support decision making in developing new products. Both are obtained through the application of the equation for demand written in terms of the value and price of the product i and the values and prices of competing products $j \neq i$ given by [11]:

$$D_i = K\left\{V_i - P_i - \frac{1}{N}\sum_{j \neq i}\left[V_j - P_j\right]\right\} \tag{2}$$

where N is the number of products competing in the market segment. This expression describes how demand for a product is influenced by its value and price and by the values and prices of the products competing against it. Because Eq. 2 is based upon a Taylor's expansion, the values and prices of the products should not be too different which limits the application of the expression generally to the top four to six competitors in the market segment of interest. When the demand and prices of the competing products are known, the values for the products can be solved for from Eq. 2.

When an option for a product is being considered in a simulated paired choice experiment, N=2 and Eq. 2 can be rewritten in the form:

$$f = 0.5 + \frac{3E_{Opt}}{8}\left[1 - \frac{P_{Opt}}{V_{Opt}}\right] \tag{3}$$

where f is the fraction of persons selecting the option and $1-f$ is the fraction selecting the baseline. The term V_{Opt} is the value of the option, P_{Opt} is the price of the option, and E_{Opt} is the price elasticity of demand for the option evaluated at f=0.5 and $P_{Opt} = V_{Opt}$. We see from Eq. 2 that a plot of f should be linear (in the vicinity of f=1/2) and that the option price at the point where f =0.5 is equal to the value of the option. The linear model given by Eq. 3 is expected to be accurate within the region $f = 0.5 \pm 0.25$ but become increasingly inaccurate outside this region. As a result, plots of f versus the option price can be used to determine the value of the option by setting it equal to the option price at which f=0.5.

The non-linear, logit model [12] for the logarithm of the ratio of the two fractions extends the range of applicability of the demand model at the expense of additional assumptions regarding buyer behavior and, for this problem, is given by [8]:

$$Ln\left(\frac{f}{1-f}\right) = \frac{3E_{Opt}}{2}\left[1 - \frac{P_{Opt}}{V_{Opt}}\right]. \tag{4}$$

The equivalent form for the linear expression for direct comparison to the logit model is given by:

$$4f - 2 = \frac{3E_{Opt}}{2}\left[1 - \frac{P_{Opt}}{V_{Opt}}\right]. \tag{5}$$

The two models are in close agreement in region $4f - 2 = 0 \pm 1$ When using Eq. 4 for determining the value of the option, plots of $Ln(f/[1-f])$ should be made as a function of the option price, the option value being the price at which $Ln(f/[1-f])$=0.

SURVEYS

Shown in Figure 1 are portions taken for entry number 9 from the three types of surveys used in determining the value of Mustang options. In the first survey, Figure 1a, respondents wrote-in a price; in the second, Figure 1b, they responded to a single price; and in the third, Figure 1c, they responded to a sequence of three of prices, a paired choice being made in each of the three lines. The write-in and one price formats, respectively, asked for and showed the full price for the vehicle alternative. The three prices format, however, showed the increase in price for the option versus the baseline.

A total of 5000 surveys were sent out in July 1995 to people who purchased 1995 Mustangs in various body styles and trim levels during March and April of 1995. The response rate for the one and three price versions was 27% versus 22% for the write-in version. The actual fractions of options purchased by respondents to the survey are shown in Table 1. The sample error in the points is within ± 0.07 (± two standard deviations).

Figure 1.c: Three Price Example

Figures 1a-c: Examples of three types of surveys used.

Table 1: Fraction of Options Actually Purchased by Respondents to the Surveys. (COBRA % also included in V-8.)

Option	One Price Set 1	Set 2	Set 3	Fill-In	Three Prices	Average
V-8	0.56	0.57	0.50	0.55	0.56	0.548
(COBRA)	0.06	0.06	0.06	0.05	0.04	0.053
Convertible	0.23	0.27	0.20	0.20	0.22	0.225
ABS	0.79	0.79	0.76	0.77	0.78	0.779
Auto. Trans.	0.47	0.46	0.51	0.51	0.42	0.475
Air	1.00	0.99	1.00	1.00	1.00	0.997
Leather	0.35	0.33	0.28	0.35	0.29	0.318

Graphs of f versus option price are shown as individual plots in Figure 2 for each of the six options considered. For a direct comparison, the cumulative results for the write-in respondents were tallied at the same three price points used in the three price version which were the same as the three prices used in the combined sets of the one price versions. For the V-8 and the convertible, the two highest priced options considered, the write-in and three price methods are seen to give close agreement but both are in poor agreement with the one price result because of its much lower price sensitivity. The intercepts of the lines with the horizontal line drawn at f=1/2 is the value of the option according to the linear model.

The largest discrepancies between the write-in and three prices version occurred for the automatic transmission and the air conditioner. Based upon the results from the three prices version, the automatic transmission was not viewed as a good in the economic sense as only 49% of its respondents said that they would take the automatic at no price increase over the manual. This is in close agreement with the 51.5 % respondents in the single price version who said they would take the automatic transmission at no price increase. But both are in marked disagreement with the write-in result of 89%. Part of this discrepancy (roughly one-half) results from a bias due to a statistical fluctuation in which 54% of the fill-in respondents selected the automatic transmission for their actual purchase; whereas, only 42% of the respondents in the three prices survey actually purchased the automatic, Table 1.

For options that are not considered as a good by a large fraction of the segment, there is little benefit in making plots of the type shown in Figure 2. The reason is that such plots return only one estimate of value for an option when there is clearly a bimodal distribution of those who will pay for it and those who will need to be paid to take it. With such options, the fraction of persons that view the option as a good should be determined and the WTP distribution should then be developed for them only. For options suspected as being goods for only a portion of respondents, one of the alternate prices for the option in the survey should be the same as the baseline. The fraction of persons, f_0, choosing the alternative at no price difference can then be used to generate a "corrected" fraction equal to f/f_0 representing the distribution of the population that views the option as a good. For the automatic transmission, dividing each of the three data points shown by 0.49 shifts the value intercept from 0 to $1,800, which represents its value to the segment that sees it as a good.

The air conditioner was not a true option here as people who might not otherwise want it would get it if they chose any option package because it was included in every package. If the write-in price intercept of $916 is used for the value of this option, we see that it is about as valuable as leather interior or ABS which we feel, by comparison, results in an underestimate of air conditioner value.

Although the above comparisons are helpful in judging the merits of the different surveys, comparisons with actual purchases of these options should be more enlightening. For this, we have plotted the point for the percentage of each type of option actually purchased in each of the graphs Figure 2. The actual percentages could also be determined from the survey as respondents were asked whether they had purchased each of the six options. The actual option price was determined from published pricing of the options. Of the three types of surveys, the three price version is seen to give the best agreement with the actual options purchased. However, the most rigorous test, as already stated above, is to compare the survey findings for ABS against the percentage of persons that actually chose the ABS option among those who purchased the V-6, Figure 3. The three prices method is seen to give the best agreement with actual purchase behavior.

OPTION VALUE COMPUTATIONS

In Table 2, we show the values of the six options computed from the intercepts of the best fit lines using the linear and logit models, Eqs. 2 and 3. The logit model values are shown first because they are preferred as several of the data points were outside the range of applicability of the linear model. This is most dramatic for the air conditioning where f for the lowest price is so near 100% that it is also very likely out of the range of applicability for the logit model. So only two data points were used for each model in making the extrapolations which means that the error in the result is large.

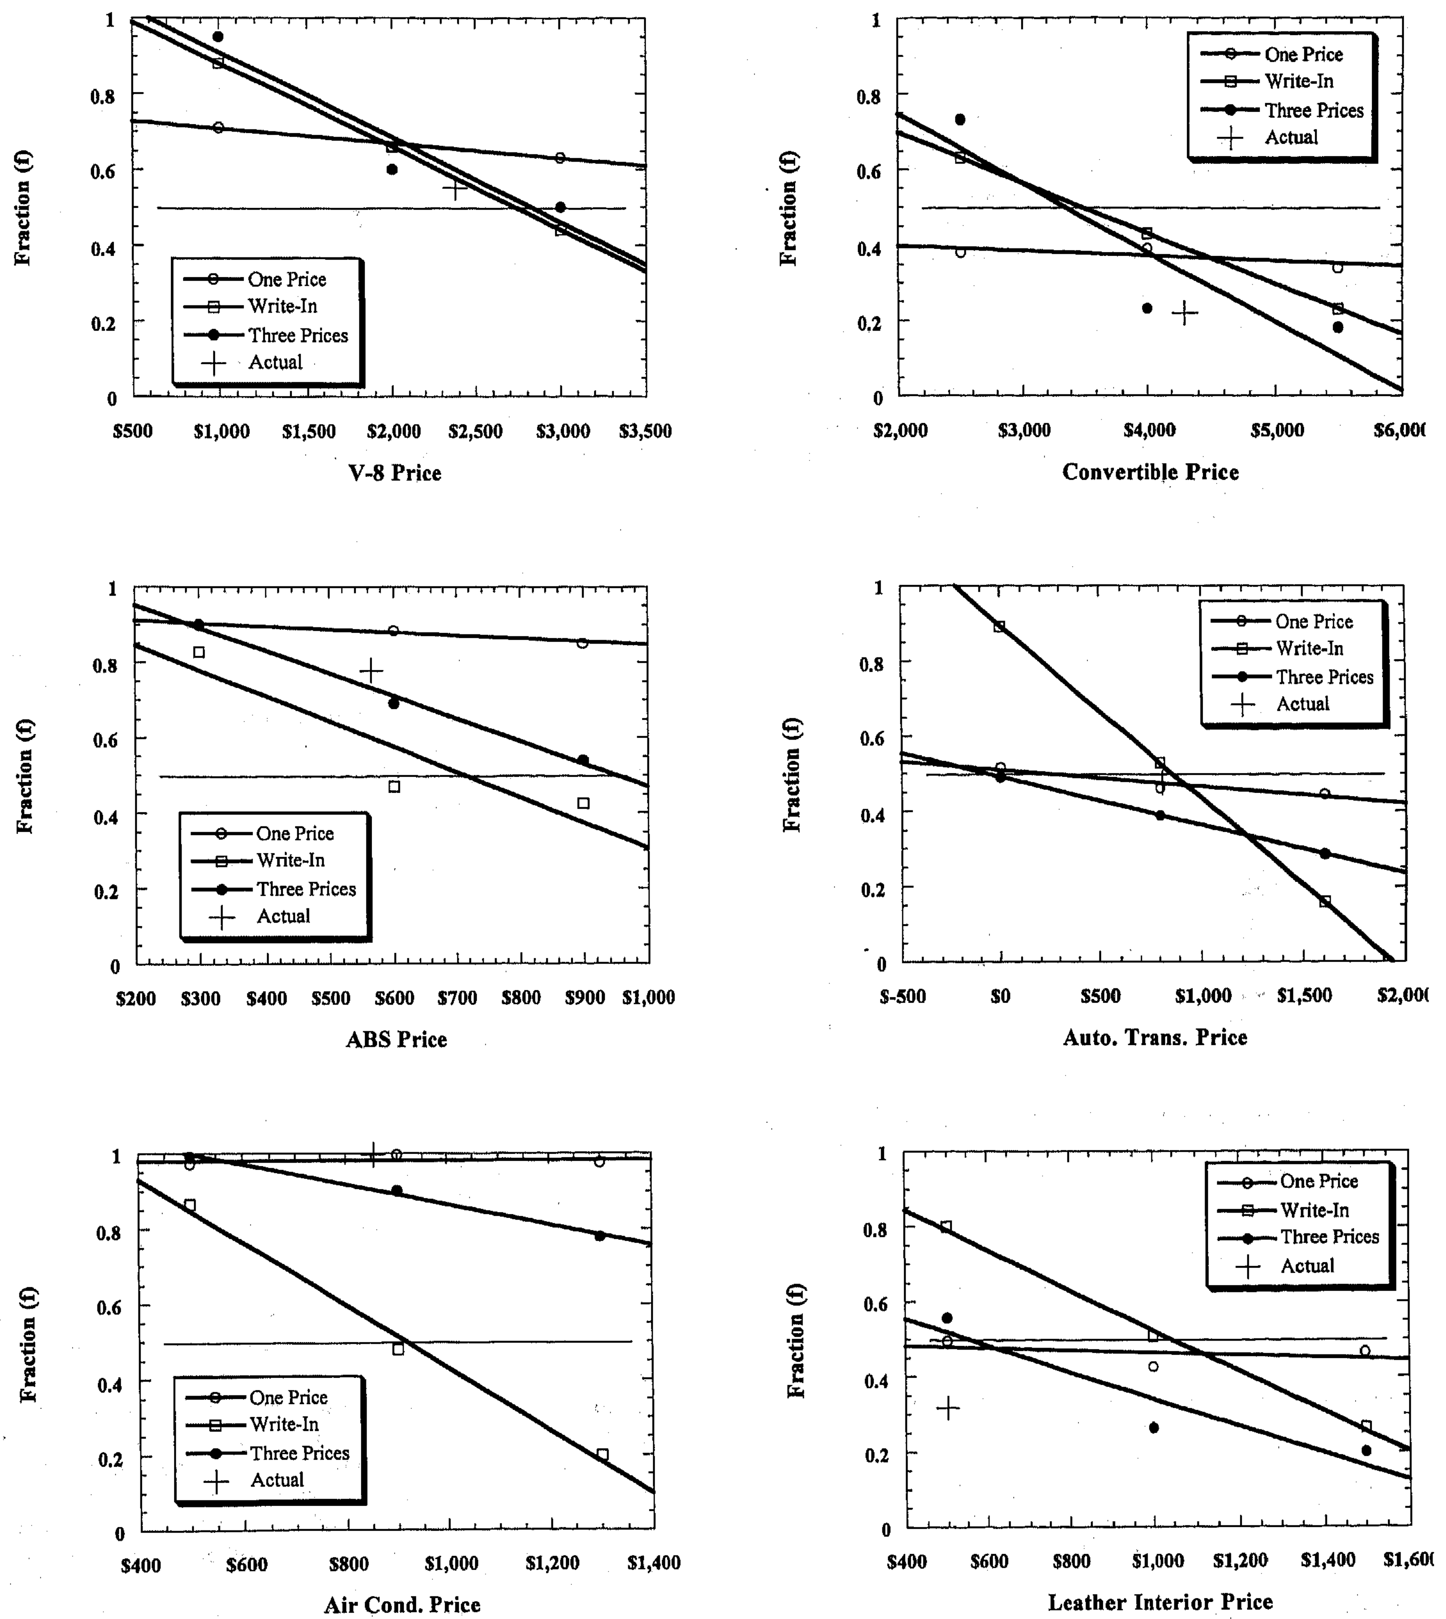

Figure 2: Linear Plots of the fraction of respondents selecting the alternative versus WTP price for the six options evaluated.

PRICE SENSITIVITY -- A plot of $Ln(f/[1-f])$ versus P_{Opt}/V_{Opt} according to the logit model, Eq. 4, is shown in Figure 4 for all of the three prices data. A line with a slope of 4 is seen to fit the scatter reasonably well in the positive region except for the highest point for the air conditioning option which was noted earlier as likely lying outside the range of both the linear and logit models. For a slope of 4, the option elasticity is seen from Eq. 4 to be equal to 2/3 of the slope or 2.7. It is not necessary that all of the options should have the same price elasticity. It is only roughly true for the options considered here. We note for comparison that on average the price elasticity E_1 of cars when only one manufacturer changes price is approximately 6 and the price elasticity E_2 when all change price is approximately 1 [13]. Because the alternative to buying the options in question is not to buy (a true substitute was not offered) we expect the elasticity to be around 2 (two times E_2 in theory). Thus the finding of 2.7 is not unreasonable. We will consider this point further in the discussion section.

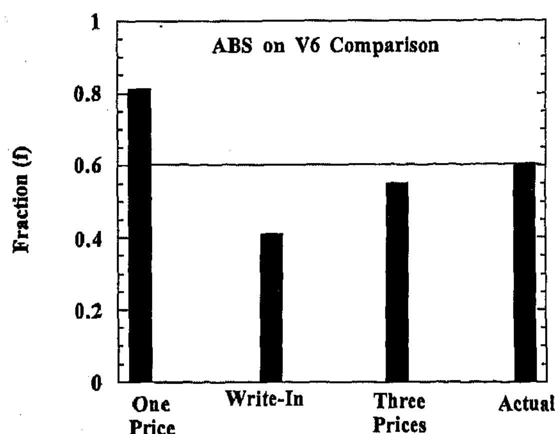

Figure 3: The fractions f at the purchase price for the ABS option as computed from the three WTP surveys are compared with the actual fraction of respondents who purchased the V6 and the ABS option.

Table 2: Option Values Determined from the Three Prices Survey for the Logit and Linear Models.

	Model	
Option	**Logit**	**Linear**
V-8	$2,751	$2,800
Convertible	$3,290	$3,360
ABS	$908	$948
Auto. Trans.	N/A	N/A
Air*	$1,826	$2,200
Leather Interior	$549	$552

* Two Data Points

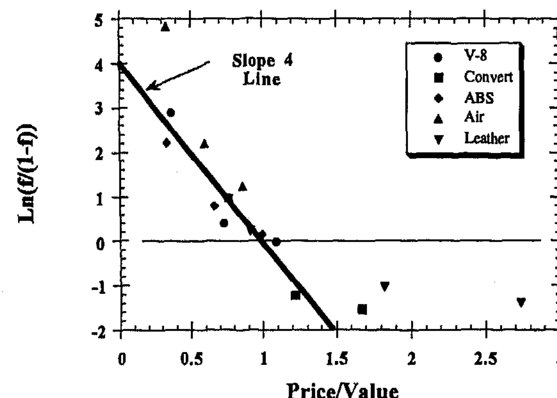

Figure 4: $Ln(f/[1-f])$ versus P_{Opt}/V_{Opt} according to the logit model, Eq. 4, as determined from the three prices survey results.

OTHER SURVEY QUESTIONS

OTHER VEHICLE ATTRIBUTES -- The respondents were also asked to force rank the ten vehicle attributes shown in Table 3 where the results are compared between V-8 and V-6 buyers. The results enclosed within borders are for attribute rankings which differed by more than two points between V-6 and V-8 buyers. The V-6 buyers ranked fuel economy and good price higher than V-8 buyers and acceleration performance lower which is not surprising.

Table 3: Attribute Rankings by V-8 and V-6 Buyers

Attribute	V-8	V-6
Styling	1	3
Reliability	3	2
Good Price	4	1
Fun to Drive	2	4
Ergonomics	6	5
Acceleration	5	9
Resale Value	7	8
Operating Costs	8	6
Fuel Economy	10	7
Interior room	9	10

OTHER VEHICLES CONSIDERED -- Use of the demand expression, Eq. 2, to solve for the values of competing products, requires that, N, the effective number of products competing against each other be known as well as their demands and prices. The names of other vehicles considered by Mustang buyers in making their purchase decision, as obtained from responses to the survey, are shown in Figure 5. The number of other vehicles considered is shown in Figure 6 and the number of other vehicles test driven is shown in Figure 7. The average number of vehicles considered computed from Figure 6 is 4.36 including the Mustang vehicle purchased.

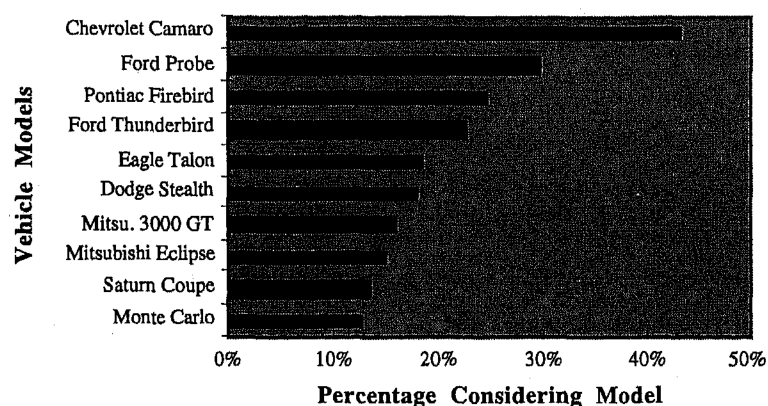

Figure 5: Other vehicles considered by respondents in making their purchase decision.

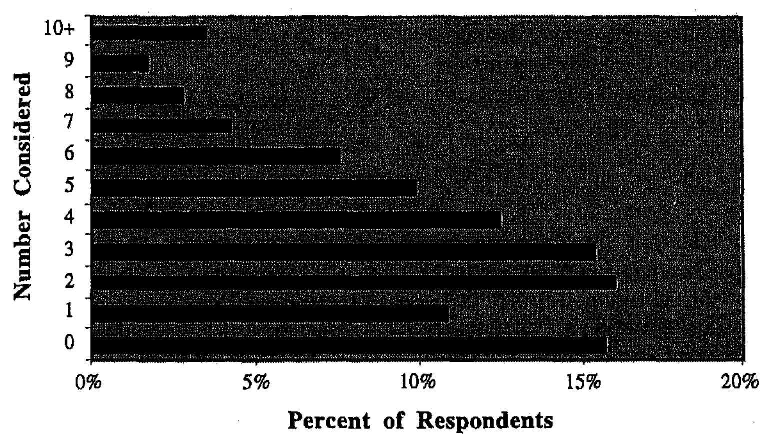

Figure 6: The number of other vehicles considered by respondents in making their purchase decision.

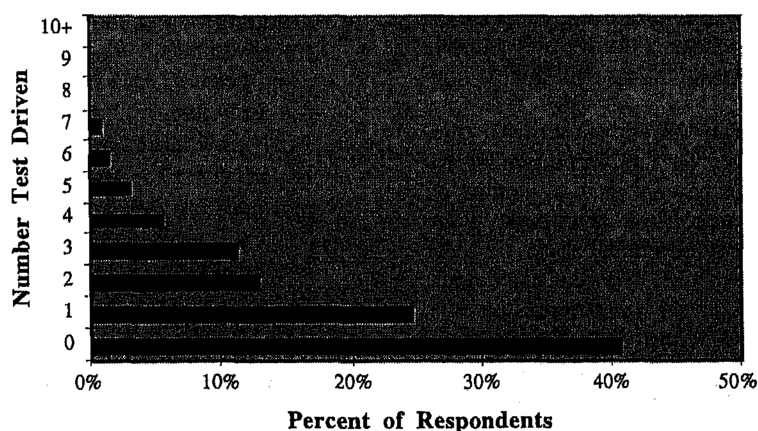

Figure 7: The number of other vehicles test driven by respondents in making their purchase decision.

PROFIT FORECASTING

The basis for making a decision regarding improving an attribute or an adding an installed option can be made, as stated earlier, on forecasted annual profitability given by:

$$A = D\left\{[1-f][P_0 - C_0] + f\left[P_0 + P_{Opt} - C_0 - C_{Opt}\right]\right\} \quad (6)$$

where C_0 and P_0 are the baseline cost and price of the vehicle in the absence of the option. The value and price expressions for substitution into Eq. 2 for demand D are given by:

$$V = V_0 + fV_{Opt} \quad (7)$$

and

$$P = P_0 + fP_{Opt} \quad (8)$$

where V_0 is the value of the vehicle without the option. The option fraction f according to the logit model is given by:

$$f = \frac{\exp\left\{\frac{3E_{Opt}}{2}\left[1-\frac{P_{Opt}}{V_{Opt}}\right]\right\}}{1+\exp\left\{\frac{3E_{Opt}}{2}\left[1-\frac{P_{Opt}}{V_{Opt}}\right]\right\}}. \qquad (9)$$

Substitution of Eqs. 7, 8, and 9 into Eq. 6, allows the forecasted profitability of the option to be computed as a function of its price and cost. The same expression can be used for an alternative such as a higher horsepower engine which would likely increase value due to improved acceleration with an offset for the loss of fuel economy. This combined value problem has been considered elsewhere [6]. A computation of the profitability of an option as a function of price has been given by Monroe and Cook [14] using the 4x4 drive option on a truck as an example for a range of costs.

DISCUSSION

The major finding here is that the mail survey having the sequence of three prices gave better agreement with actual buyer purchases for the Mustang options than either the write-in or single price surveys. The major concern with the single price survey results was that the fraction of persons selecting the alternative was approximately constant with price. A possible explanation for this behavior is that the choice between the baseline and any alternative considered as a good (i.e. excluding automatic transmission) was made by respondents to the one price surveys according to whether or not they had actually chosen the option when they purchased the vehicle. To fully account for the one price results using this line of reasoning, 10 to 40% of those persons who did not actually buy the option also had to select the alternative at the lowest price offered.

When respondents were asked to write-in the maximum price they would pay for the alternative or to judge the alternative versus the baseline across a range of three prices for the alternative, they exhibited price sensitivity of approximately the same amount as can be seen in Figure 2. We have already argued that the elasticities determined from the three prices and the write-in surveys were reasonable. The greater price sensitivity for the three prices surveys yields less statistical uncertainty in estimating the value of the option from the neutral price intercept. This is one more reason to prefer this approach. Unfortunately, we do not know the price elasticities of the options studied here from actual market behavior to make a direct comparison to the elasticities determined from our simulated buyer behavior.

Although we have concentrated on options in this study, the DV procedure as already noted can be used, in principle, to determine the value of any vehicle attribute. In For example, in our study of the value of vehicle acceleration each of the 86 respondents drove three vehicles having different acceleration performance through a city/suburban test route [6]. At the end of testing, they were asked their willingness to pay for the two higher performing vehicle versus the baseline vehicle.

CONCLUSIONS AND RECOMMENDATIONS

When respondents were asked to choose sequentially between a baseline Mustang at a fixed price and an alternative Mustang having an option added and offered at three different prices, their simulated purchase behavior was in much better agreement with the actual behavior of Mustang buyers than when a single price was given for the alternative or when the respondents were asked to write in their WTP for the option. Thus we recommend that the respondents in DV surveys be asked to make a series of choices between a baseline at a fixed price on the left and the alternative under consideration on the right as shown in Figure 1.c. Although Figure 1.c used three alternative prices, the desire to have the price range chosen for the alternative to bracket the neutral price for good statistics supports using a sequence of four or five prices for the alternative. To counter possible anchoring effects, the price sequence for one-half of the surveys should be decreasing and the other half should be increasing.

Advanced Finite Element Analysis in the Structural Design of Airbag Modules

Simon Xunnan He
AlliedSignal Safety Restraint Systems

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper demonstrates how to use advanced finite element modeling techniques such as airbag modeling, material plasticity with consideration of failure and effects of temperature and strain rates, surface to surface sliding contact treatment, nonlinear transient dynamics, and so on, to perform structural analysis of airbag modules. A technique to calculate the transient dynamic loads on the structure of an airbag module is first demonstrated. The dynamic transient loads on the structure are calculated by an integrated airbag modeling and sliding contact treatment with the structural model of the airbag module.

Other techniques for modeling special design features of the airbag module, such as tear seam, tear tie, and hinge on a cover, press fit of a gas diffuser, housing, connections of each component, and so on are also illustrated and discussed. All modeling techniques are illustrated by analysis examples in product development. Some tests have been done to verify the modeling techniques and good correlation has been achieved.

INTRODUCTION

The structure of an airbag module is subject to transient dynamic loads during airbag inflation and deployment. When finite element analysis is applied to assist the structural design, the unknown dynamic loads on the structure, the complex contacts among the components, the large deformation, material yielding and failure, and the effects of temperature and strain rates to the materials make the analysis very challenging.

A passenger or driver airbag module normally contains an inflator, a gas diffuser, a bag (cushion), a housing with mounting brackets, a cover, and mechanical connections. A side impact airbag module may not have the cover and the diffuser. The inflator and the bag designs are determined by the performance requirements of the safety restraint systems. All other components are designed in the airbag module development that ensures the required airbag performance and meets the interior trim and packaging requirements.

The cover must meet a structural requirement that it must open quickly when the airbag starts to inflate and must stay with the airbag module during the airbag deployment. For the reduction of cost, a cover is usually made by thermoplastic material molded into one piece. A tear seam or tear tie and a hinge are designed on the cover to fulfill the opening function. They are normally designed by reducing the material thickness and adding ribs in these areas. When the inflator is fired and the bag is pushing the cover, the tear seam or tear tie must break first, then the cover opens and rotates along the designed hinge by material yielding at the hinge. No fracture at the hinge area is allowed because a broken piece of cover could threaten the safety of the occupants. The finite element analysis can significantly reduce the time in the material selection and the structural design of the cover, especially the tear seam/tie and the hinge.

The gas diffuser is designed to even the gas flow from the inflator into the bag. The gas diffuser of a passenger airbag is usually a separate piece from the inflator. Due to a high gas pressure, some structural problems need consideration and analysis. For example, for a cylindrical type of diffuser design with a press fit onto the inflator, the finite element analysis can assist to find the thickness of the cylinder and the interference of the press fit that will ensure the integrity of the diffuser with the inflator during the assembly and inflator firing.

The housing not only provides a storage space for the inflator and the cushion, but also provides a structural support to the entire module and a mounting to the structure of an instrument panel. The complex connections with other components make the structural analysis very challenging, especially for the determination of the loads and restraints as well as the plastic deformation and failure.

The challenges in the finite element analyses of all those structures lie in the calculation of the transient dynamic loads, the prediction of material and structural

failure, and the modeling of complex contact between components.

METHODOLOGY

The first challenge in the finite element analysis of an airbag module is how to determine the loads on the structures. It is conceptually clear that all airbag components are subject to a transient dynamic loading during airbag inflation and deployment. However, it is difficult to determine these loads prior to some prototype tests. For example, an experimental study was done trying to catch the pressure loading on a passenger airbag cover during bag inflation [1]. This is usually costly in the early stage of product development and only applicable to the similar cover designs with the same inflator.

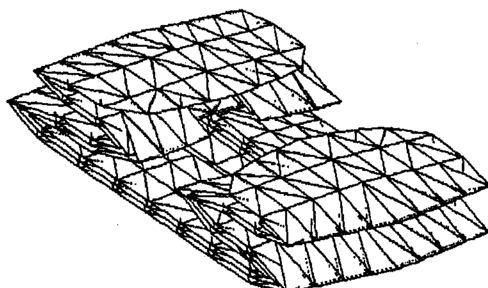
Analytical method to calculate the dynamic loads on airbag components during bag inflation is highly desirable and is possible with advanced modeling techniques of airbag inflation and contact interaction in some FEA codes. For example, the transient dynamic pressure on the cover and the housing during the airbag inflation and deployment can be obtained by integrating an airbag model into a structural finite element model of the airbag module. The load source comes from the airbag inflation in the airbag model, and the pressure loads on the components are calculated from the contact interfaces defined between the airbag cushion and the components. Other types of transient dynamic loads, such as the load on the brackets, the pressure on the gas diffuser, etc. can also be calculated in the advanced finite element modeling in the similar methods.

Another challenge in the finite element analysis of an airbag module is how to model material plasticity and failure of airbag components, especially the cover. The tear seam or tie on the cover is modeled with membrane elements with plasticity and plastic strain failure criteria. A modeling feature of failed element deletion is used to simulate the fracture of the tear seam or tie. The hinge, another highly interested area in the cover, is modeled by shell elements with the same features as the tear seam. The large plastic deformation and possible fracture in the hinge area during the cover opening can be studied in this model. The effects of the temperature and strain rate on the material properties of thermoplastics, such as elastic modulus, yield stress, as well as the failure plastic strain are modeled based on test data and the formulations in Reference [2].

Connections, such as spot welts, rivets, bolts, are all modeled by discrete elements with post yield properties and stress or plastic strain failure criteria because they are also the possible failure areas and absorb some energy before the failure. Contact interfaces are defined among the connections of the components themselves, such as the cover to the housing. A contact interface is also defined between the cover and the instrument panel because the moment that the cover hits the IP may be the worst scenario for the hinge. When the entire model is analyzed, the time history of reaction forces at mounting points of the brackets can also be used as the dynamic loading for the IP structure.

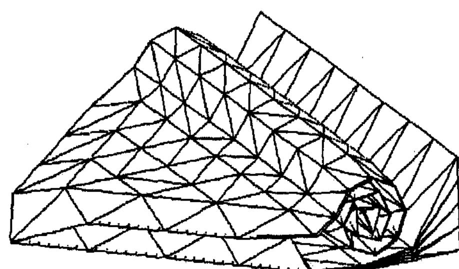
The analysis can be done in one FEA run or by multiple step runs to save run time. For example, in the study of the cover, after the cover is fully opened and no longer in contact with the bag cushion, the airbag model and contact interfaces related to the cushion can be deleted from the entire model in a restart run to save run time. All time history of dynamic loads on each component generated from the contact interfaces and connections can be used in separate component analyses for design optimization.

MODELING PROCEDURE, NUMERICAL STUDIES AND TEST CORRELATION



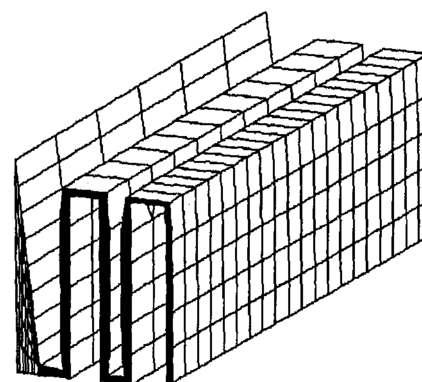
This section is to discuss in details about the finite element modeling of key structures of airbag modules. A modeling of transient dynamic loads induced by airbag inflation and deployment is described first.

MODELING OF THE TRANSIENT DYNAMIC LOAD INDUCED BY AIRBAG INFLATION AND DEPLOYMENT The most important modeling technique in the finite element analysis of the airbag module structures is the modeling of the transient dynamic load induced by the airbag inflation and deployment. The load source is the airbag inflation and deployment. The dynamic load is transmitted to each component through different path. Some are due to the direct gas pressure, such as the diffuser. Some are due to the momentum change of the cushion and the cover. The most are through the cushion impact under the gas pressure. For those subjected to direct gas pressure, analytical methods with a close form can probably be found to calculate the pressure history during the inflation. An example is a gas diffuser analysis that follows. For those subjected to the momentum change of the cushion and the cover as well as the impact of the cushion, such as the cover, the housing and brackets, a method that integrates an airbag finite element model and a structural finite element model of an airbag module can be used to calculate the dynamic load.



In the past years, many studies have been done in the airbag modeling [3] [4] [5]. All of them are for airbag performance analysis in the occupant protection. Sophisticate modeling features such as math models of inflation, cushion materials and elements, as well as the single contact interface are available to model airbags. With a modeling feature of automatic surface to surface contact interface that several FEA codes provide, it is possible to integrate an airbag finite element model into the structural finite element model of the airbag module and calculate the dynamic load on the structures induced by the airbag inflation and deployment.

During the airbag inflation, the gas puts the direct pressure on the components forming the gas flow path, such as the diffuser and cushion. Then the motion of these components transmits the load to other components through the impact contact, such as the contacts of cushion to the housing, to the cover, etc. Therefore, the contact interfaces play a very important role in the dynamic load calculation.



Airbag Modeling The airbag model used in the structural analysis of airbag module includes a mesh of the cushion, a math model of the inflation, and a rigid body of the inflator. The rigid body of the inflator is to provide the space, the mass and moment of inertia of the inflator. The cushion may be modeled as a directly folded mesh, a mapped and folded mesh, or a mapped and scaled mesh with a technique of initial matrix [6] or reference geometry [7] on the fully filled bag, as shown in Figure 1. The deference in the dynamic load calculation by the last two meshes is insignificant, while the mapped and scaled mesh is much easier to create. The gas jetting effect should be included in the inflation model because this jetting effect is significant on the dynamic load calculation. Figure 2 shows these differences on the resultant contact forces on the cover of a passenger airbag module in analysis.

Figure 1. Finite Element Meshes of Airbag Cushions

Another type of dynamic load on the structures of airbag modules is due to the momentum change in high speed motion of components, such as the cushion and the cover. The maximum loads on the brackets, cushion fasteners, as well as the hinge of the cover come from this motion. The integrated structural FEA model with the airbag model can also model this type of dynamic load. A few examples are included in the following sections.

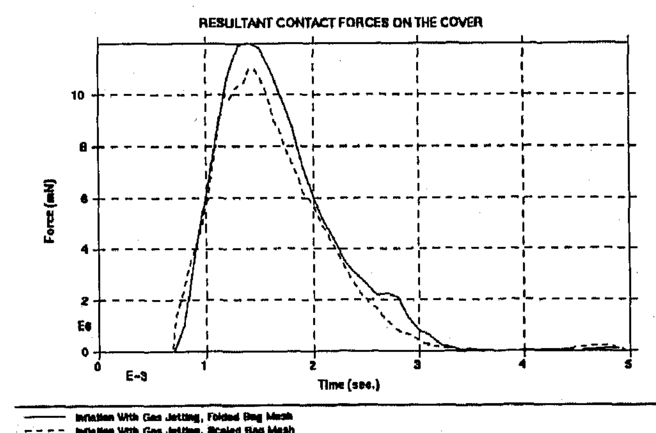

Figure 2. Effects of Defferent Airbag Models on the Dynamic Load on the Cover

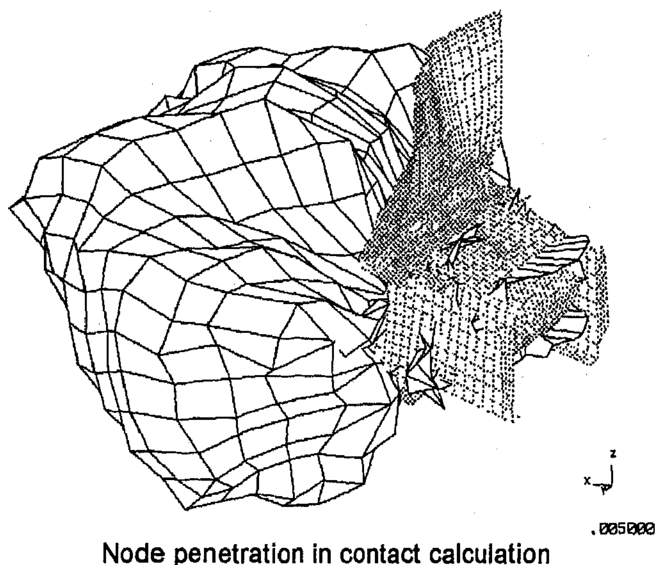
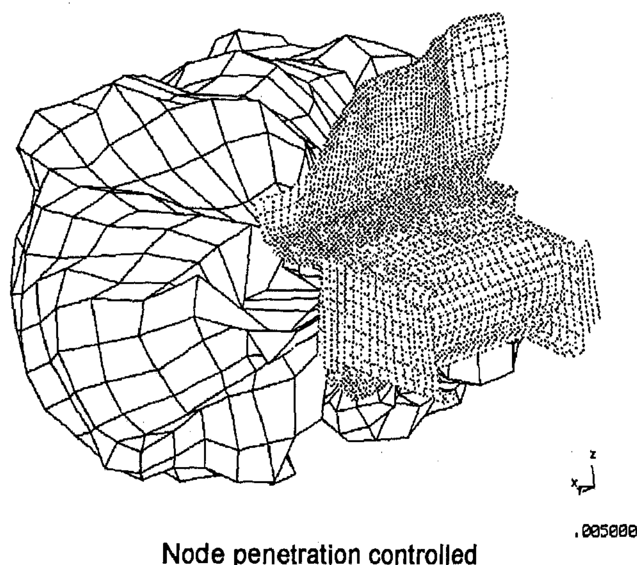


Contact Interface Definition During airbag inflation and deployment, multiple contacts between the cushion and other components as well as among other components themselves occur. These contacts play an important role in load transmission. Contact interfaces must be defined in the finite element model of an airbag module to handle these contacts. First of all, a contact interface between the airbag cushion and all surrounding components must be defined. If dynamic impact forces on particular portions of these components are of interest, several contact pairs that are exclusive can be defined and then the contact forces can be output for component analyses. For example, the impact forces on the front panel of the cover and on side panels of the housing can be used to do separate component analysis for design optimization. Then, for the meshes of airbag cushion, single surface contact should be defined to treat the cushion contact itself.

Contact interfaces among other components may need to be defined, such as the contact of the cover to instrument panel due to the large rotation of the cover that may be the worst scenario for the hinge of the cover, the contact of the housing to instrument panel due to the large plastic deformation of the side panels so called bell mouthing, as well as contact between the cover and the housing, and so on. It is impossible for a FEA code without a sophisticated contact treatment to perform accurate structural analysis for airbag modules.



Even for a FEA code with contact modeling, it sometimes runs into trouble in implemention. In practice, a common problem in interface definitions is the unrealistic node penetration that is caused by a penalty contact algorithm used in some FEA codes. For example, in an automatic surface to surface contact of LS-DYNA3D, the airbag nodes could largely penetrate other components defined in the contact interfaces by the default parameters. The experience shows that in this type of contact definition this problem could be solved by adjusting the stiffness penalty factor of the cushion side so that its contact time step is in the same magnitude as that of the other contact side. Figure 3 shows a finite element analysis of an entire passenger airbag module by LS-DYNA3D in which large node penetrations occur between the cushion and the housing in the automatic surface to surface contact definition with default parameters. The time steps in both surfaces are 0.3E-4 second and 0.5E-5 second that have a difference of one order of magnitude. By adjusting the contact stiffness penalty factors to 20 in the cushion side to achieve a time step of 0.6E-5, the node penetrations are totally avoided, as shown in Figure 3.

GAS DIFFUSER MODELING A challenge in the finite element modeling of a gas diffuser is to find the structural behavior under the dynamic load due to the inflation with pre-stresses due to the assembly. An example is a modeling of a cylindrical press-fit type of airbag gas diffuser, as shown in Figure 4. The purpose of the analysis is to find a feasible interference tolerance

and the thickness of the cylinder to ensure that during the inflation the press fit can hold the diffuser and there is no structural failure and no gas leak through the press fit surfaces.

Node penetration in contact calculation

Node penetration controlled

Figure 3. Node Penetration in Contact Calculation and Penetration Control

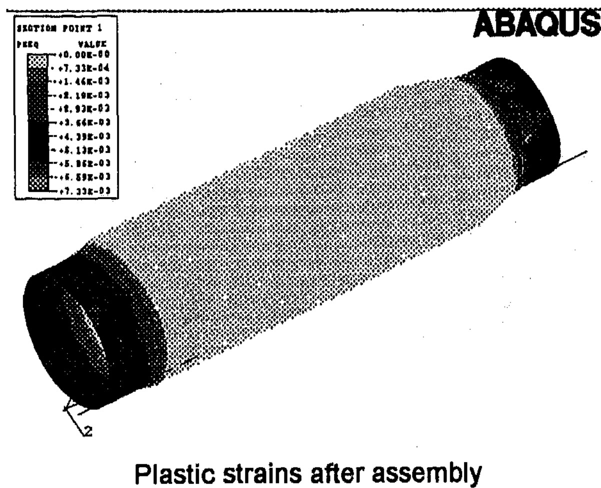
During the press fit assembly, the diffuser body is pressed onto the inflator. That means that the diffuser cylinder is already pre-stressed when it is subject to the inflation pressure. The inflation pressure will further stress the diffuser and reduce the pressure in the press fit surfaces. If the pressure on the press-fit surfaces drops to zero, gas leak may occur. If the friction forces in the press-fit surfaces become smaller than the axial throttle force caused by the inflation pressure, the diffuser may be pushed out of the inflator.

Considering the thin shell structure of and the loads on the diffuser, the diffuser can be meshed by shell elements with material plasticity. The inflator can be modeled as a rigid surface because of the large stiffness ratio between the inflator and the diffuser. The press-fit is modeled by contact interfaces with interference.

The analysis is done by two steps. The first step is to calculate the stresses and plastic strains in the diffuser after the press-fit. Depending on the FEA codes, this can be done by defining an initial interference in the contact interface, such as in ABAQUS [8]. The initial interference simulates the upper and lower tolerance limits of the press fit. This can also be done by pushing a rigid shaft with a diameter of nominal value plus upper and lower tolerances into the diffuser in LA-DYNA3D. Any other FEA codes with similar features should also be able to do so.

The second step is the analysis of the diffuser under the inflation pressure starting with pre-stresses calculated from step one. This can be done by a restart run from the end of the first step. The dynamic pressure on the diffuser, P_d, during the inflation can be calculated by an analysis of thermodynamics in a control volume for the diffuser if the exit gas properties, mass flow rate $\dot{M}_{in}$ and temperature T_{in}, of the inflator are known. The governing equations for the calculation of pressure in the diffuser are

$$\left.\begin{aligned} \dot{P}_d &= \frac{Rk}{V_d}(T_{in}\dot{M}_{in} - T_d\dot{M}_{out}) \\ \dot{T}_d &= \frac{1}{M_d}[k(T_{in}\dot{M}_{in} - T_d\dot{M}_{out}) - T_d(\dot{M}_{in} - \dot{M}_{out})] \\ \dot{M}_d &= \dot{M}_{in} - \dot{M}_{out} \end{aligned}\right\} \quad (1)$$



The details of the derivation of the equations and calculation of each term are in Appendix.

For the FEA codes with multiple chain airbag modeling features such as LS-DYNA3D, the dynamic pressure can also be calculated within the code by defining a chain of control volumes for the diffuser and the airbag with an appropriate inflation model. The additional pressure on the diffuser caused by the exit gas jetting from the inflator can also be estimated by considering gas momentum [5]. It should be pointed out that the gas flow will cause a pressure gradient inside the diffuser. The best method to get the dynamic pressure is to use computational fluid dynamics. For structural analysis, however, the method used in this paper with an estimation of gas jetting effect is appropriate.

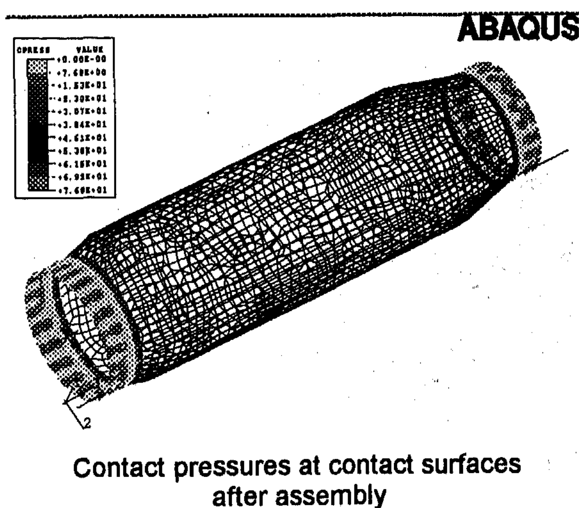


Figure 4 first shows the effective plastic strain and the press-fit pressure of the diffuser after the press fit assembly. The maximum press-fit pressures occur at the inboard circumferences of the press-fit area. The

analysis also found that for a feasible interference tolerance in manufacturing, the diffuser is already yielded at the press-fit area after the assembly. The result implies that the thickness of the diffuser is the only key factor to control the holding force and a loose tolerance can be used to reduce manufacturing cost.

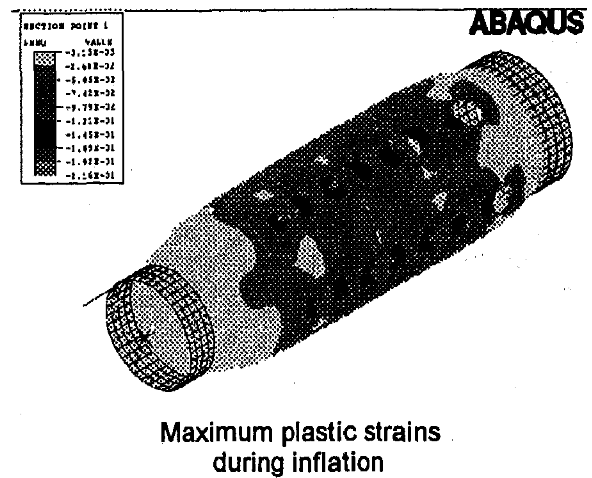

Figure 4 then shows the maximum effective plastic strain and the minimum press-fit pressure of the diffuser during the inflation for the same tolerance as above. It can be seen that the maximum plastic strains moved to the holes on the diffuser body and the remaining press-fit pressure shifted towards outboard circumferences and reduced by 65% for this case. The strength of the diffuser, the minimum holding force, and the leaking possibility can be judged from the results of this analysis. It should be noted that for the structural strength of the diffuser, the largest interference tolerance should be used to see the worst scenario in the structure, while for the minimum holding force and leaking concern, the least interference tolerance should be used.

HOUSING AND BRACKET MODELING An airbag housing plays a very important role in the airbag module. It not only provides a storage space for the inflator and cushion assembly, but also provides a structural support to all other components. For example, the cover can be mounted on the housing, the cushion and the diffuser can also be mounted on the housing in a passenger airbag module, and the entire airbag module is mounted on the IP frame through brackets on the housing. Permanent deformation is allowed in extreme deployment condition but fracture should be avoided. The complex dynamic loading and connections with other components and material plasticity form the characteristics of the housing modeling.

A housing and brackets are normally made by stamped sheet metal with spot welding or riveting, die cast non-ferrite metal, extruded non-ferrite metal, and even high temperature and high strength plastics. Shell elements with plasticity and failure are appropriate to model the housing structure. All mechanical connections such as spotwelds, rivets, bolts, and so on are modeled

with discrete elements or node constraints with post yield properties and failure criteria. Besides, contact interfaces are also needed to model the on-off boundaries between the connected components. The dynamic loads on the housing and brackets during the airbag deployment include the gas pressure, impact pressure from cushion, inertial forces due to the momentum change of the cushion and the cover, and so on. To calculate the dynamic loads, am integrated finite element model of the airbag and housing, brackets, as well as the cover is normally needed depending on the interests.

Figure 5 shows a finite element model of a passenger airbag housing and brackets with the cushion and the diffuser mounted on it (one side panel of the housing is not shown). The interest of this analysis is to find the strength of the structures and appropriate designs of the connections of the diffuser to the housing. Shell elements with material plasticity are used to model the housing. An airbag model is integrated in the model. The cushion is hooked on the diffuser that is connected to the housing. Contact interfaces are defined to model the hooking. The housing is restrained on the brackets that provides the mounting of the module to the IP frame.

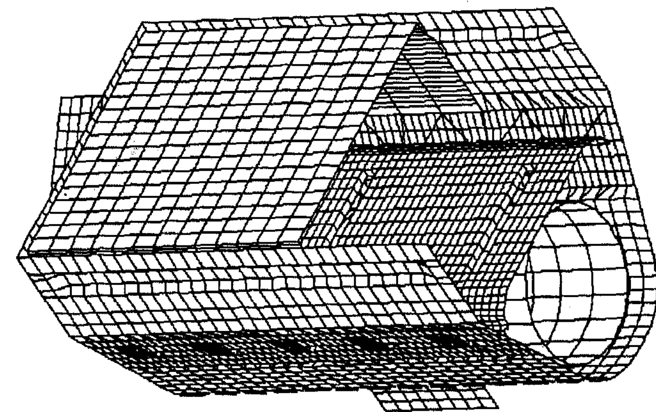

Figure 5 also shows the analysis results that the hooking failed and the diffuser and the cushion were separated from the housing during the airbag inflation. This was verified in tests and redesigns have been made.

Figure 6 is an analysis example of a driver airbag housing and bracket. Excessive plastic deformation of the housing and bracket may alter the facing direction of the bag during the deployment as shown in the figure. The dynamic load on the bracket is due to the change of momentum of the cushion during the deployment and can be calculated in the analysis. The reaction forces at the mounting points were measured in tests for the verification of the analysis model. The analysis results correlate with the test results quite well.

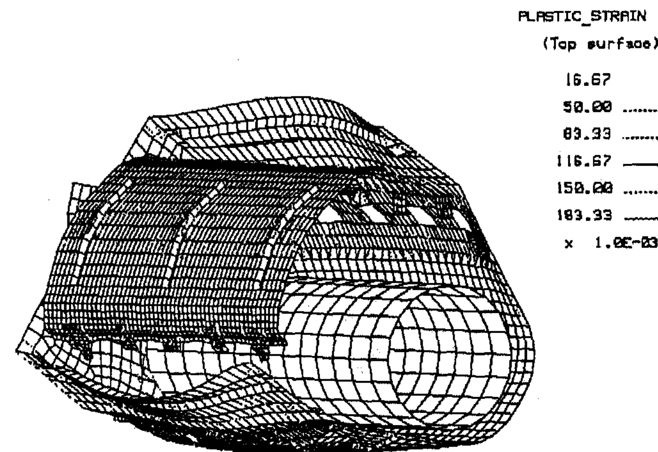

Figure 7 is another analysis example of a side impact airbag housing and bracket. The integrity of the housing, bracket, as well as connections are studied in the analysis. The load comes from the inflation and deployment of the airbag. To calculate the dynamic load, a finite element model of the side impact airbag is integrated in the structural model. Folded cushion is used to catch more accurate loading. The reaction forces at the mounting points were measured in tests for the verification of the analysis model. The analysis results are well correlated with the test results.

COVER MODELING Airbag covers are often made by thermoplastic material molded into one piece including two crucial features, a tear seam or tie and a hinge. The tear seam is designed to break during the airbag inflation. It must be the first place on the cover to break when the airbag starts inflation. It also needs to break at a designed pattern such that the cover opening will not partially block the deployment of the cushion. To prevent deployment delay, it should also absorb as less energy as possible during the breaking. The hinge is designed such that the material will yield along a line but not break during the airbag deployment. This will let the cover to open along the hinge axle and keep the cover staying together with the module. Any fracture in the hinge could be of significant danger to the safety of the occupants.

The effects of temperature and strain rates on the properties of the thermoplastic material are significant, as shown in Figure 8 for a typical material used in production and must be considered in the modeling. The cover structure can be well modeled by shell elements with plasticity and failure. Special attentions should be paid to the modeling of the tear seam, tear tie, and the hinge.

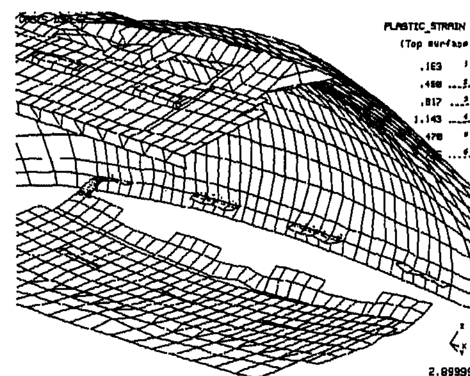

Figure 8. Effects of Temperature and Strain Rate on Properties of Thermoplastic Materials

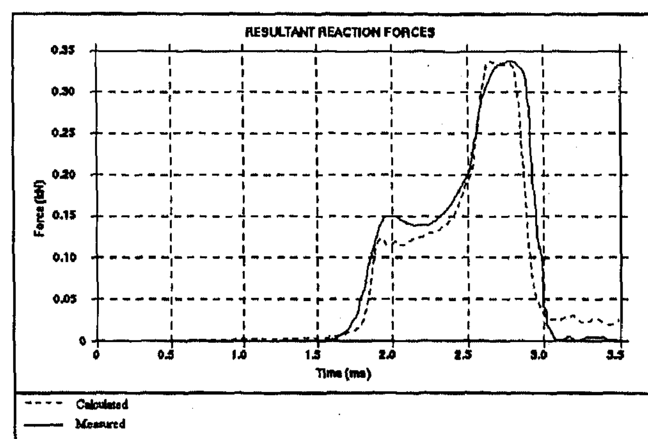

Tear Tie and Tear Seam Modeling From tests, the failure of the tear tie is found as stretching failure. It is also found that some permanent deformation exists after the fracture. This means that some energy has been consumed during the breaking. Since the thickness at the tear ties is several times thinner than that of the cover, it can be modeled with membrane elements with a plastic strain failure criterion. Figure 9 shows tear tie modeling in a cover design of a passenger airbag module and the element failure and deletion during the airbag inflation (cushion and housing are not shown). The dimensions follow the geometry and the thickness uses the minimum thickness. Note that the time unit is millisecond and the failure process lasts less than 1.0 millisecond. A test to verify the modeling was done by measuring the reaction forces at the two bottom plate restraints. Figure 9 also shows the calculated and measured reaction forces. They are well correlated. The reaction forces also indicate the sequences of the yielding and break of the tear ties and the total duration of the fracture.

FE mesh of a passenger airbag cover with tear ties

Elements of tear ties start to fail

Elements of tear ties totally fail

Comparison of reaction forces in analysis and test

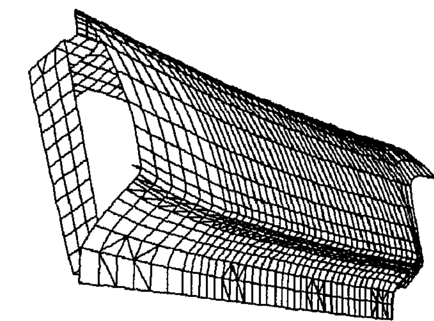

Figure 9 FEA Modeling of Tear Ties of A Passenger Airbag Cover

The failure of a tear seam is different from the tear ties. Before break, a tear seam is stretched as that of the tear ties. Once a fracture is initiated at a point (sometimes this point is particularly designed at a specific location), the failure propagates very rapidly along the entire tear seam. The best modeling method is the elements using fracture mechanics and adaptive meshing. The implementation of this technique in commercial FEA codes is still under development at present. To solve this problem, membrane elements with strain failure and a feature of failed element deletion are used to model tear seam failure. In this way, the first failed and deleted tear seam element transfers its load to the connected tear seam elements and these connected elements fail and are deleted again until all the tear seam elements fail and are deleted. This is similar to a crack propagation with an approximation.

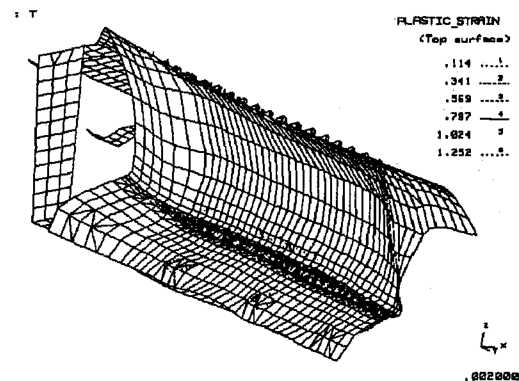

Figure 10 shows a horizontal bottom tear seam design. It is modeled by a series of membrane elements with a plastic strain failure criterion. The dimensions follow the geometry and the thickness uses the minimum thickness. Figure 10 also shows the initiation and propagation of the element failure and deletion along the tear seam during airbag inflation (airbag cushion not shown). The failure starts from the center of the tear seam and develops towards both ends. The effects of temperature and strain rates are found on the time of failure initiation and the duration of the failure propagation. The tear seam design modeled in Figure 10 has a non-symmetrical geometry and so the opening of the cover is also biased to one end. This was also observed in tests. A design modification has been done and a symmetrical opening is achieved.

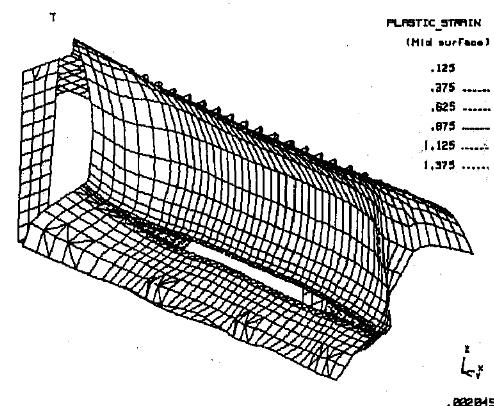
The advantage of using membrane elements to model tear seams and tear ties is that during the failure, tear seams and tear ties absorb energy that is a part of the reason for the delay of the airbag deployment. This has been proved in many tests.



Hinge Modeling Hinge is often designed with a thinned material with some rib stiffeners to force a slender yielding area on the cover when the cover is opening. The tests show that the failure at this area is due to bending. Shell elements with a plastic failure criterion are used to model the hinge area, as shown in Figure 11 for a typical production design. The effects of temperature and strain rates on the yield stress, elastic modulus, and failure strain must be considered in the hinge modeling, because the function of the hinge will cover a wide temperature range from -30 °C to 80 °C. Under low temperature and higher strain rate thermoplastic materials behave more brittle. The hinge design shown in Figure 11 that only yields under room temperature fractures under a temperature of -30 °C, as shown in Figure 11 for the FEA results and a test result.

SUMMARY AND CONCLUSIONS

The challenges and solutions in finite element analysis of the structures of airbag modules are presented in this paper. The finite element modeling of the structures of airbag modules requires advanced finite element modeling techniques, such as airbag modeling, highly non-linear material property with consideration of effects of temperature, strain rates, and failure, capability to treat surface to surface sliding contact, multi-step restart runs, and so on. The modeling techniques of key components are also presented with test correlation.

The finite element analysis in structural design of airbag modules can be implemented by integrating an airbag model into the structural finite element model. The transient dynamic load induced by airbag inflation and deployment can be calculated from the airbag model and the contact algorithm during the analysis. To achieve accurate dynamic loads, the most sophisticate inflation model with jetting effect and carefully defined contact interface should be used. Mapped and scaled cushion mesh does not have significant deference from the folded cushion mesh. Most key design features, such as tear ties, tear seam, hinge, and so on can be evaluated with non-linear material property with failed element deletion. The strengths of all components, i.e., housing, brackets, mechanical connections, as well as cushion enforcement can all be predicted in the integrated finite element model.

APPENDIX DERIVATION OF GOVERNING EQUATIONS OF DIFFUSER PRESSURE

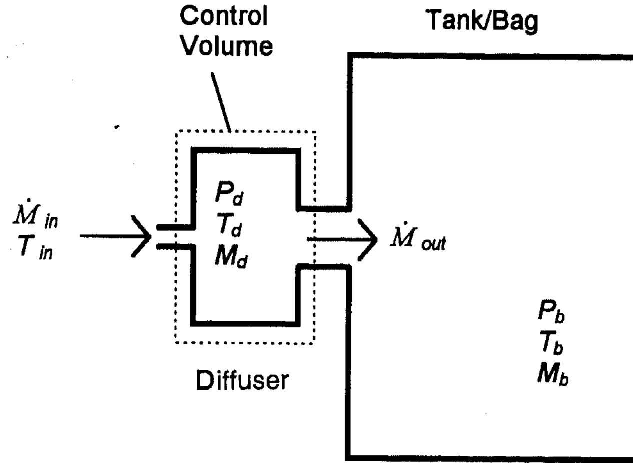

Figure A1. Thermodynamics Model to Calculate Diffuser Pressure

Assuming an isentropic process for the inflation, one has the following:

By the assumption of ideal gas property inside the diffuser

$$P_d V_d = R M_d T_d \quad \text{(A1)}$$

By the conservation of mass

$$\dot{M}_d = \dot{M}_{in} - \dot{M}_{out} \quad \text{(A2)}$$

By the conservation of energy

$$\frac{d}{dt}(M_d C_v T_d) = C_p T_{in} \dot{M}_{in} - C_p T_d \dot{M}_{out} \quad \text{(A3)}$$

Differentiating equation (A1) and rearranging equation (A3), we have

$$\begin{bmatrix} V_d & -RT_d & -RM_d \\ 0 & 1 & 0 \\ 0 & C_v T_d & C_v M_d \end{bmatrix} * \begin{Bmatrix} \dot{P}_d \\ \dot{M}_d \\ \dot{T}_d \end{Bmatrix} = \begin{Bmatrix} 0 \\ \dot{M}_{in} - \dot{M}_{out} \\ C_p T_{in} \dot{M}_{in} - C_p T_d \dot{M}_{out} \end{Bmatrix} \quad \text{(A4)}$$

This is the matrix form of simultaneous equations (1) in the text. By taking an inverse of the matrix at the left side, one has the simultaneous equations (1).

The mass flow rate out of the diffuser $\dot{M}_{out}$ can be calculated based on one dimensional orifice flow [9]

$$\dot{M}_{out} = CA \frac{P_d}{R\sqrt{T_d}} \left(\frac{P_b}{P_d}\right)^{\frac{1}{k}} \sqrt{2g_c\left(\frac{kR}{k-1}\right)\left(1-\left(\frac{P_b}{P_d}\right)^{\frac{k-1}{k}}\right)} \quad \text{(A5)}$$

where

$$\left(\frac{P_b}{P_d}\right) = \begin{cases} \dfrac{P_b}{P_d} & \text{if } \dfrac{P_b}{P_d} > \left(\dfrac{2}{k+1}\right)^{\frac{k}{k-1}} \\ \left(\dfrac{2}{k+1}\right)^{\frac{k}{k-1}} & \text{if } \dfrac{P_b}{P_d} < \left(\dfrac{2}{k+1}\right)^{\frac{k}{k-1}} \end{cases} \quad \text{(A6)}$$

ABSTRACT

New sensor approaches termed magnetostrictive sensor (MsS) and nonlinear harmonics (NLH) for vehicle safety applications such as crash detection and occupant seat weight sensing are described. Both sensor approaches utilize the changes in the magnetic properties of ferromagnetic materials that occur when a stress (or a strain) is applied to the material. The MsS is a passive device suitable for vehicle crash sensing. The NLH is an active device suitable for occupant seat weight sensing. Technical features of these sensors are also discussed together with preliminary results of ongoing testing.

1.0 INTRODUCTION

Vehicle safety sensing applications have increased dramatically with the increased use of airbag technology. Of the various vehicle safety sensing applications, there are three areas which have generally produced inadequate performance, they are: 1) single point crash detection for frame/body vehicles; 2) side impact detection and; 3) occupant seat weight sensing.

In this paper, we describe two sensor approaches termed "magnetostrictive sensor (MsS)" and "nonlinear harmonics" (NLH)" for the above mentioned application areas. Both sensor approaches utilize the changes in the magnetic properties of ferromagnetic materials that occur when a stress (or a strain) is applied to the material. The MsS [1,2] is a passive device suitable for vehicle crash sensing. The NLH [3] is an active device suitable for occupant seat weight sensing

In the following, an overview of the currently proposed sensor solutions and their limitations for the three application areas mentioned above is first given in Section 2. Then a description of the MsS and NLH is given in Section 3 including their physical principles, sensor design configurations, and their general properties and technical advantages. Specific applications of these sensor approaches to crash detection and occupant seat weight sensing are then given in Section 4 followed by conclusions in Section 5.

2.0 BACKGROUND ON VEHICLE SAFETY APPLICATIONS

The use of electronic accelerometer based single point sensing for vehicle airbag deployment has increased substantially in the last few years. Their use has been slower than anticipated but still climbing. An overview of this technology is given in [4] and [5]. A natural extension of their use is for other applications including side impact detection and frontal impact detection for frame/body vehicles.

2.1 FRAME/BODY VEHICLE CRASH SENSING - For many frame/body vehicles, acceleration values near zero can be encountered until the required Time-To-Fire (TTF) for a single point module located in the passenger compartment. This leaves even the best algorithm designers with no chance of achieving the desired requirements. A robust sensing concept capable of producing information at a faster rate from the passenger compartment is desired.

2.2 SIDE IMPACT DETECTION - Similarly, side impact sensing with accelerometer based approaches has produced at best marginal results. The inherent problem with an accelerometer based approach is the variation encountered for ON/OFF crashes across the side of the door. For example, a pole crash located at the B-pillar (assume an accelerometer is mounted at the B-pillar), will produce a substantially different sensor output than a similar crash at the A-pillar. Yet, the crashes to the occupant are similar in terms of potential injury. A detailed discussion of the disadvantages of crush zone sensing is given in [5].

There are other approaches to side airbag deployment as well (Autoliv [6] and Siemens [7]). In [6], a mechanical firing pin approach is described. This

sensor approach suffers from the same inherent weakness as an accelerometer based approach, namely, the large variation in sensor output based on location of the crash on the side of the vehicle. The idea behind both the accelerometer based approach and the mechanical based approach is to reduce this effect by creating an "array" sensor from a "point" sensor.

In both [5] and [8], the benefits of array sensors are described . In [8] a crush zone sensor is described. Unfortunately, this array sensor is truly an array causing other problems. In [5], frontal crash detection using a single point module approach is described as the best of both worlds (assuming an appropriate algorithm): array sensing from a point sensor. The front part of the vehicle acts as the array, the sensor simply produces similar waveforms for similar crashes (e.g. an offset pole crash on either side of the vehicle).

Therefore, it is beneficial to create an array sensor for side impact detection. By stiffening the vehicle or adding a crossbeam, the accelerometer/firing pin approaches begin to look more like a vehicle side array sensor. However, the inherent weaknesses still exists.

In [7], an air pressure approach is described that again expands on the notion of array sensing from a point. However, disadvantages of this approach include: variation over life, mounting in the door and the limited capability of the approach in sensing only those crashes impacting the door. Without dwelling on this concept, it does not provide the robustness that a magnetostrictive sensor approach can provide.

2.3 OCCUPANT WEIGHT SENSING - With the recent attention on fatalities due to airbag deployment, increased emphasis has been placed on passenger sensing. In particular, weight has been deemed the appropriate parameter for disabling the airbag. Several approaches have been proposed and are being proposed. Without getting too specific, several problems exist with current and proposed approaches including:

- Cost
- Implementation without disrupting the seat
- Temperature compensation
- Robustness to variability in seat occupancy scenarios
- Area coverage

These issues and potential solutions will be addressed further in section 4.

3.0 TECHNICAL BACKGROUND ON MsS AND NLH APPROACHES

3.1 MAGNETOSTRICTIVE SENSOR (MsS) - The MsS is a passive sensing approach which relies on a specific physical phenomenon, that exists in ferromagnetic materials, called "inverse magnetostrictive (or Villari)" effect [1,2]. The Villari effect refers to a change in magnetic induction (B) of material with application of stress, in comparison to the magnetostrictive (or Joule) effect which refers to changes in physical dimension of the material with magnetization. Being a passive device, the MsS is limited to detection of only time-varying or transient stresses (or strains) in the material such as those produced by mechanical impacts or those acoustic emission signals produced by cracking [1,2]. The MsS has a very broad frequency response, ranging from a few Hz to a few 100 kHz. The sensor can also be applied to nonferrous material such as plastics, if a thin layer of ferromagnetic material is plated or bonded to the material surface in a local area where the sensor is to be placed. In addition, the MsS requires neither a direct physical contact to the material nor a couplant for sensing.

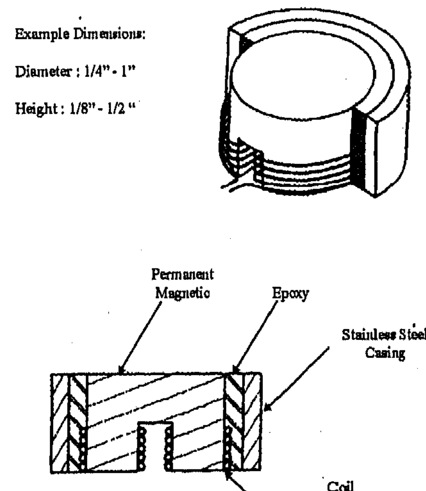

Figure 1 : Typical MsS Sensor

A typical MsS is depicted in Figure 1. It consists of an inductive coil and a permanent magnet. When stress in the material changes with time, the resulting changes in B due to the Villari effect induce an electrical voltage in the coil. The permanent magnet provides a static bias magnetic field to the material which will enhance the sensor sensitivity. The transient stresses produced by a crash or impact will propagate through the material. The attenuation of such impact stress waves in vehicles is negligibly small. Therefore, the MsS can sense the crash or impact event at a location far away from the exact impact site as long as the path

for the wave to propagate is good. The MsS can survey a large area and, thus, functions like an "array" sensor from a point and is ideally suited for vehicle crash detection.

3.2 NON-LINEAR HARMONIC SENSOR (NLH) - The NLH sensor operates in a similar fashion to the MsS, but it is an active device [3]. An example NLH sensor which consists of a U-shaped ferrite core with an excitation coil and a detection coil wound on each leg is depicted in figure 2. When a ferromagnetic material such as steel is excited by a sinusoidal magnetic field (H), the corresponding magnetic induction (B) of the material is no longer sinusoidal but shows a distorted waveform. This distortion is due to nonlinear magnetic permeability and the magnetic hysteresis of the material. The distorted B-waveform contains harmonic frequencies of the applied H. In addition, the magnetic hysteresis curves of a ferromagnetic material change significantly when the material is subjected to mechanical stress or strain. The NLH sensor transmits a sinusoidal H to a ferromagnetic material and then detects the resulting B waveform.

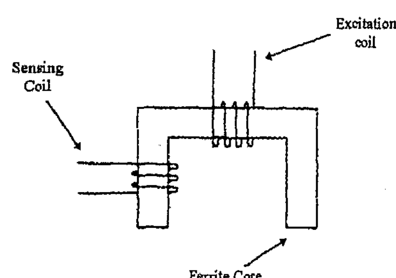

Figure 2 : Typical NLH Sensor

Typically, a coil is used for applying H and detecting B. The H is achieved by sending a sinusoidal current of a given frequency through an excitation coil (e.g. 1kHz). The resulting time-varying B induces an electrical voltage in the detection coil. The stress on the material of interest is determined by harmonic analysis of waveform. In general, the magnitude of the third harmonic of the resultant waveform is related to the stress on the material. In steel, up to about 50 percent of the yield strength, the relationship is linear (i.e. the greater the magnitude of the third harmonic the greater the stress).

The chief differences between the NLH sensor and the MsS are:

- The MsS is a passive device, whereas the NLH requires power
- The NLH sensor can sense constant stress

The NLH approach is similar to those approaches described as magnetostrictive sensors used for torque measurements [9] except that the NLH utilizes nonlinear harmonic components, whereas, the other utilizes the fundamental component.

3.3 TECHNICAL FEATURES - The two sensing approaches have the following features in common:

- Temperature insensitivity
- Non-contacting
- No moving parts
- Small and inexpensive

The MsS also has the following features:

- Passive (produces a signal without power)
- No DC offset (i.e. detects transient stresses)
- An "array" sensor from a point

The NLH also has the following features:

- Active
- Detects DC or constant stress

4.0 VEHICLE SAFETY APPLICATIONS

4.1 FRAME/BODY VEHICLE CRASH SENSING - The MsS can be used in the same fashion as an accelerometer for vehicle crash sensing [10]. Since the frontal crash sensing field is more mature, we will focus on the application of using a single point module for frame/body vehicles (e.g. trucks).

Because of the structure of frame/body vehicles, accelerometer signal values are near zero until the required TTF for passenger compartment mounting locations. This is due to the fact that the frame encounters the crash object well before the body has. By cutting a ferromagnetic hole (e.g. rubber or plastic) in the body above the frame and then facing the MsS at the frame, we are able to detect stress waveforms in the frame from the body. This will allow faster response from a single point sensor module located in the passenger compartment.

4.2 VEHICLE SIDE IMPACT DETECTION - The MsS is ideally suited for side impact detection. The device can be mounted on or near the door without necessarily being mounted on a surface. For example, one could mount the sensor on the crossbeam and face it at the door skin. Therefore, stress on the skin can be measured. Again, the "array" nature of the sensor will allow the sensor to produce waveforms even if the sensor is not contacted directly or is nearby the "hit" area. A good propagation path is all that is needed. There are other locations on or near the door that the

sensor can be placed to provide a good signal with ease of mounting. For example, placing the sensor on the sill facing the base of the door will allow the door to be sensed but the sensor to be mounted within the passenger compartment. Various isolated side impacts can be detected with this arrangement. If a pole hits the A or B pillar or is on-line with the sill mounting location, the signal strength should be similar for the same impact speed. This response should be differentiated from that of an accelerometer, where depending on the mounting location (e.g. A/B pillar location or the middle of the door) substantially different waveforms will be produced.

These two features (i.e., non-contacting and array sensing from a point) make the MsS ideally suited for this application.

4.3 OCCUPANT WEIGHT SEAT SENSING

The occupant seat weight sensing problem has become a very important issue in the automotive safety community. The key to the problem is to determine the occupant's or object's weight with a very high resolution. The goal is to change the airbag deployment characteristics (e.g. do not deploy) if the weight is less than a given threshold(s). There are many issues involving this approach but basically there are three main concerns: performance, cost, and ease of implementation.

The NLH sensor is suited to this application. By placing the sensor under the seat on either the pan, springs or mounting points; stress upon the seat can be measured. For example, for seat designs which feature an array of wires holding the seat cushion in place, stress on the wires can be measured as follows. As an object is placed in the seat the foam causes stress on the wires. The stress applied to the wire by the occupant is detected by using a NLH sensor placed on the wire. The NLH output can then be converted to weight. The sensor location, design and placement will be related to the given seat, but should not affect the seat's deign. This will allow a seat weight sensor that is inexpensive, robust, and easy to implement.

5.0 CONCLUSION

We have shown that the MsS and NLH sensor have good potential for automotive safety applications. There are several Tier One suppliers testing these devices with so far excellent results. In addition, the MsS has also shown good potential for condition monitoring of combustion engines such as knock and misfire.

Development Methodology of an Airbag Integrated Steering Wheel in Order to Optimize Occupant Protection Balanced Against Out-of-Position Risks

Oliver Spiess, Thomas Marotzke, and Matthias Zahn
PETRI, Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

With the increasing number of air bags being used in vehicles there has been a corresponding increase in the number of occupants injured or even killed due to air bag deployment, particularly under out-of-position conditions. Current publications addressing the dangers of air bag deployment has led to worldwide public uncertainty on the safe use of these passive restraint components.

A main goal of the air bag module development must be to balance the out-of-position risks with the overall occupant protection performance to reach the highest biomechanical quality.

Further considerations must be given to the development and production costs, quality and styling of the air bag module and steering wheel. Design, function, cost and styling have competing impact during the product development phase. Economic and efficiency factors require new production and manufacturing of systems that use pre-assembled components as assembly groups, such as the so called "high level assemblies."

Cooperation of system and module design, testing and numerical simulation experts is required to successfully address these concerns. An existing study of an air bag integrated steering wheel as a component of the entire restraint system shows that a strong integration of the CAD, CAE and testing disciplines is the most methodical and effective procedure for restraint system development. The goal of the study is to show and discuss modern, and above all, effective methods for increasing occupant protection. The emphasis lies on the out-of-position occupants.

This study shows the methodology of a development and assessment of a concept for an out-of-position optimized air bag integrated steering wheel. Furthermore, solutions are shown to reduce the out-of-position risks for an air bag integrated steering wheel. The developed solutions are built as functional prototypes. Static deployment tests with a 5th %ile HYBRID III Dummy are performed to analyze and evaluate the effects of the new technology.

INTRODUCTION

Today the driver air bag is standard equipment for a passenger vehicle in the US. In contrast to Europe, the air bag in the US was introduced as a passive restraint system which had and still has to protect the occupant according to the FMVSS 208 along with the kneebolster and the seat design. At this time, however, the study was conducted with an unbelted occupant. The reason for such a decision from NHTSA was a low belt rate of 20% for occupants.

Today the safety potential of an air bag is not in question, with studies showing that 1500 occupants have been saved by the air bag in the last years. Another study of frontal crashes showed an 18% reduction of fatalities due to the air bag and other NHTSA studies showed a reduction of severe injuries to the head, thorax and abdomen [12].

The optimal use of air bags for the ride down of the occupant is only guaranteed if they are fully inflated before contact with the occupant occurs. If the occupant is in contact with the air bag during the unfolding process injuries can occur. These injuries are abrasions, fractures, head injuries and injuries of the inner organs. The situation where the occupant is close to the air bag - or even the worse case - has direct contact with the

module is referred to as out-of-position condition. The possibility of negative side effects from the air bag system in some accident conditions has been known since its introduction to the market. With the rapidly rising number of air bag equipped vehicles, the incidence of accidents with air bag related injuries or fatalities is increasing. Due to the physics, especially small and incorrectly belted occupants have shown the highest risk of severe injuries caused by the interaction with the air bag during its deployment and unfolding process. Press-reports of such accidents, particularly low speed impacts, are the focus today for public discussion of the out-of-position topic.

As a consequence, the following demands for the air bag are in discussion:

- "depowered air bags"
  Reduction of the energy of driver - and passenger air bags

- "smart air bag technology"
  An air bag system which is adjusted to the crash severity and occupant position

The simple change toward "depowered bags" reduces the safety potential for the in-position occupant with no guarantee for an increased safety potential for out-of-position occupants [1]. The "smart air bag technology" necessitates the development of new sensor technology with reliable detection and decision algorithm. The implementation into the vehicle is time consuming and costly. This demands system knowledge and high innovative technology from the safety system supplier. The aim is to reduce the development time and costs and to be flexible for shifting demands.

The development of new solutions should not be a coincidence-product. To reach this goal means to effectively use the available technical and research tools and methods of the system development combined with the product development of the components. The ideal goal must be to develop optimal solutions for a component or the system with no increased cost. That means the supplier has to identify the areas of cost savings and effectiveness of the system in the vehicle. An essential requirement for this is that the supplier is already included as a development partner during the concept phase.

METHODOLOGY

Three fundamental departments of the supplier add up to an engineering team for system development:

- Concept design (CAD)
- Occupant crash simulation (CAE)
- Crash testing (crash facility, dummy-, measurement- and film technology, component facility)

The CAD department is the link to the product development, however, they have enough capacity to develop product innovations out of ongoing research and development activities. The CAD engineers provide vehicle interior geometry and component design for numerical models to be used by the occupant crash simulation. Furthermore, they provide concepts for test rigs and modifications of serial components of occupant protection systems.

The occupant crash simulation develops a parameter matrix of the restraint system components. This allows for a first adjustment of the restraint system to be tested using a sled test facility with high speed measurement, film and video technology.

The occupant crash simulation and the crash test department are connected by a close development loop as shown in Figure 1. Both development tools are well coordinated to efficiently develop the restraint system and to minimize the risks during the development.

SYSTEM DEVELOPMENT METHODS - CAD, CAE and crash testing are connected by a close development loop as shown in Figure 1.

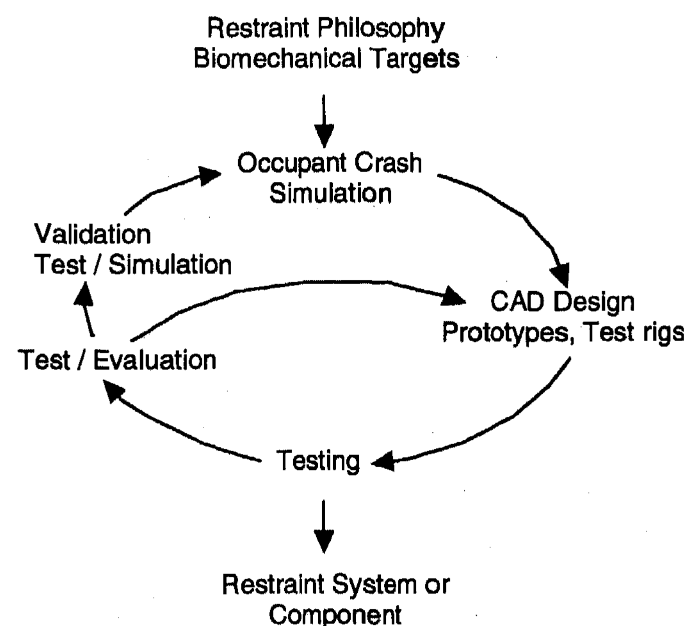

Figure 1: System development method [2]

The evaluation of crash and component tests allows for a step by step validation of the occupant crash simulation model of the vehicle and of the restraint system components. The goal of the occupant crash simulation is to evaluate interesting parameter variations before extensive testing is done.

The main focus of the development results from the examined accident type and determined injury mechanism.

The restraint system of the driver side in frontal impacts includes the following components and subsystems.

- crossmember with interface to body structure
- mounting bracket of steering column
- steering column
- IP and kneebolster
- steering wheel
- driver air bag module
- floor and toe panel, pedals
- seat system (incl. mounting brackets / rails)
- seat belt system
- A-pillar and roof liners
- door panel

Independent of the development of the entire restraint system the optimization of one component must always take into account the entire vehicle system. This method of the scientific and systematic overall view of occupant safety is necessary to effectively develop function and cost optimized products. The following describes the principle steps of the development of an air bag integrated steering wheel as a restraint system component beyond the first prototype.

1. Automotive safety analyses

   1.1 Accident analyses

   Correlation between injury mechanism and the effect of vehicle subsystems or single restraint system components are the result of the evaluation of accident statistics and test results.

   1.2 Basic requirements

   All geometry data and characteristic values of the restraint system are determined. This includes all characteristic values of the restraint system which can not be altered, such as dependent geometry data and characteristic values of existing components.

2. Concept fixation

   First the occupant load limits are determined. This presupposes an extensive, realistic assessment with practicable development solutions based on the scientific expertise of the engineering team. Derived from the first step, the first design concepts are developed.

3. Development

   The three main departments, occupant crash simulation, CAD and crash testing, develop the component using the development loop shown in Figure 1. The development starts with the occupant crash simulation and design of the first functional samples.

4. Prototyping

   As a result of the development ,prototypes are built which meet or exceed the performance criteria.

5. Product development

   The performance criteria as well as design hardpoints for the air bag integrated steering wheel are handed over to the product development. The product development uses the numerical models and the test rigs from the concept phase for further refinement. The main task during this phase is the fine tuning of the component as well as the final design for a fully mechanized assembly line. The final prove out and validation of the developed air bag integrated steering wheel takes place in a full scale crash test.

OOP - PROBLEMATIC NATURE

During a vehicle collision, air bag modules have the task to fully inflate an energy absorbing cushion as quickly as possible before the occupant's forward excursion and subsequently support the occupant. The necessary restraint load is transferred on the occupant using the large area of the air bag. Compared to the seat belt, the restraint load application is essentially reduced. This fact is shown in accident analyses.

In the aggregate, the share of head and cervical spine injuries adds up to no more than 10%, and the statistically relevant AIS ratings of these injuries range between 1 and 2, while the proportion of chest injuries among belted occupants varies between 25 and 30%, at AIS ratings between 1 and 3 [10]. This accident analyses confirms known test results. At identical dummy load levels, belt related loads carry a greater injury risk than air bag related loads. [9]. The main task of occupant safety is the minimization of occupant loads during most accident types and to control the localization, the direction and the application area of the restraint load on the occupant to guarantee a high biomechanical quality and to prevent unnecessary injuries caused by the restraint system [3].

The air bag as a component of the restraint system has the potential, in cooperation with the seat belt, to fulfill this task. The problematic nature has to be analyzed and evaluated before the requirements can be defined.

How can the out-of-position (OOP) or Inflation Induced Injury (I^3) be defined?

OOP describes a situation where the occupant is positioned in the deployment space of the air bag and therefore an uncommon interaction between the head, neck and thorax region and the air bag cushion and module cover can be seen. The direct contact between

the occupant and the module cover is referred to as the worst case scenario. Severe injuries or even fatalities can be the consequence of this interaction. OOP situations in real world accidents can have following causes:

- delayed ignition of the air bag during the vehicle collision
- close by seating position
- forward movement of the occupant due to pre-impact braking

What type of loading mechanism can be seen in OOP situations?

Loading mechanism during the contact phase under OOP conditions have been broken down by Horsch et al. into "punchout" and "membrane loading" phenomena [4]. Punchout occurs in an early phase of the inflation, when the module swells because of the deploying bag until only a small portion of the bag has escaped from the module. Membrane loading denotes the phase when the fabric wraps around a body region as the bag becomes full, thereby exerting a relatively distributed force on the occupant. A third mechanism related with OOP injuries, the so called "bag slap" [11,13] occurs when the occupant is struck by a small but rapidly moving portion of the bag. Even if this effect does not result in critical injuries it can cause skin abrasions or eye injuries.

The following injury criteria are selected and further evaluated:

- Viscous Criterion (VC, thorax)
- Neck Extension Moment
- HIC

OUT-OF-POSITION (OOP) ANALYSIS

PRELIMINARY STUDY - A preliminary study was conducted by Malczyk and Adomeit [5]. This study analyzed the air bag folding pattern as a means for injury reduction for OOP occupants. Static OOP tests were carried out with driver air bag modules mounted to a rigid test rig and folded either according to the PF- or LF-pattern. A Hybrid III small female was placed on a seat in front of the module with two main test configurations: "chest centered on module" and "forehead centered on module" with varying separations from the module ranging from 0 to 100 mm. The test setup for the configuration "chest centered on module" is shown in Figure 2; Figure 3 shows the test setup for the configuration "forehead centered on module".

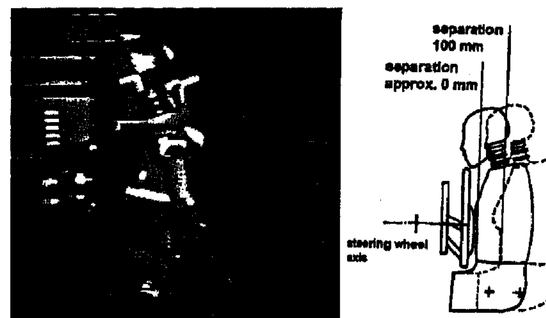

Figure 2: Test setup for configuration "chest centered on module"

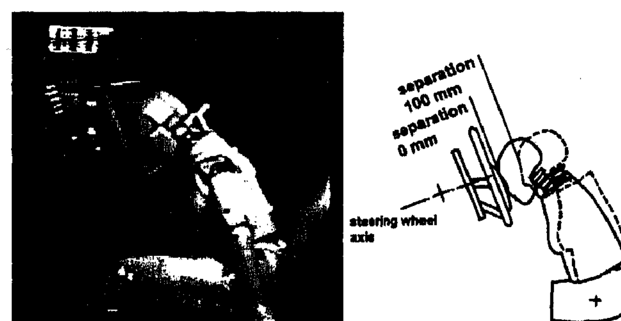

Figure 3: Test setup for configuration "forehead centered on module"

The following main conclusions have been drawn from this study. For the configuration "chest centered on module" values of all relevant injury criteria for the chest and the neck were significantly lower with the PF-pattern. For the configuration "forehead centered on module" neck loadings were lower with the PF-pattern in almost all cases except for neck tension and extension moment at separations of 0 mm and 20 mm. The geometry of the module cover tear seam was found to have negative influence here. Cosmetic markings applied to the dummy's face left far less smeared remains on the P-folded bag in comparison to the conventional folding. This indicates a reduced relative motion between the bag fabric and the skin during inflation. Tests conducted until now concentrated on extreme OOP configurations, with direct contact of parts of the body with the module cover. These configurations are based on the assumption of an unbelted occupant. It is certainly feasible, however, to imagine OOP scenarios with restrained occupants, although reliable information is not available with case figures or the distances between vehicle occupants and the air bag module [4,6]. In this sense, the possible configurations of occupant - module studied in OOP tests should include not only the "worst case position" aspect, but also greater separations between dummy and module.

The tables 1 and 2 provide details on the measured biomechanical loads (VC, neck extension moment, HIC, bold values indicate exceeding of injury threshold). For evaluation of occupant loading the scaled IARVs (Injury Assessment Reference Value) for the small female

Hybrid III given in [6] and [7] were applied. Calculation of the Viscous Criterion (VC) took place in accordance with the scaling formula presented by Mertz [8].

Table 1: VC and neck extension moment for configuration "chest centered on module"

	Separation from module [mm]	Chest VC [m/s]	Upper neck M_y Extension [Nm]
LF-pattern	100	0.28	**59.1**
	50	0.71	**65.5**
	20	**1.16**	**71.4**
	0	**1.78**	**62.6**
PF-pattern	100	0.11	2.4
	50	0.37	9.9
	20	0.9	13.1
	0	**1.46**	19.0
scaled IARV		1.0	31.0

Table 2: Neck extension moment and HIC for configuration "forehead centered on module"

	Separation from module [mm]	Upper neck M_y Extension [Nm]	Head HIC
LF-pattern	100	20.8	60
	50	23.6	96
	20	20.8	250
	0	19.2	359
PF-pattern	100	8.3	75
	50	8.8	81
	20	23.5	190
	0	30.1	235
scaled IARV		31.0	1113

The values are mean values from two tests conducted for each separation from the air bag module.

Regarding the measured injury criteria, the following conclusions for future developments can be drawn to furthermore reduce OOP occupant loads:

- Air bag module design concept to be adjusted to OOP condition (priority folding pattern).
- Distribute OOP loads to sufficient occupant body parts and mass.
- A "minimum distance" between occupant and air bag module of 30 to 40 mm must be provided.

SOLUTION APPROACHES - In order to reach optimal occupant protection the component function has to be developed from the entire restraint system point of view. To reach this goal the performance of the restraint system must not be lowered for the majority of cases to gain performance for the minority.

Taking that into account, the following fundamental solution approaches are possible:

1. Energy reduction of the air bag or "depowered air bags"

   Requirement: - reduction only in case of OOP configuration (advanced sensor system)
   Examples: - dual stage inflator
   - sensor system to detect accident severity
   - sensor system to detect occupant position

2. Optimized occupant load and load distribution on the occupant

   The ideal solution is an adjustable restraint system which can be controlled during the collision. Technically such a restraint system necessitates an inflator with an adjustable mass flow during the gas generation and a corresponding sensor system.

On the assumption that the injury risk for the occupant is a result of partial overload, the demand for the solution approach is specified as follows:

⇒ Reduction of occupant loads during air bag inflation and OOP conditions **without** lowering the occupant protection during in-position conditions using today's technology.

That means that the air bag performance and function is unchanged during all possible accident types. All requirements regarding the restraint system such as air bag inflation time, air bag volume and energy absorbing characteristics of the air bag are adjusted to optimize the restraint system for in-position conditions.

Derived from the OOP analysis and the solution approach analysis the following requirement for the air bag performance is specified:

⇒ Realization of a "minimum distance" between occupant and air bag module in all accident types through the retraction of the air bag module.

DEVELOPMENT OF A RETRACTING MODULE

The preceding analyses admit the conclusion that optimized design solutions can essentially contribute to reduce OOP risks.

In order to retract an air bag module it must be accelerated quickly over the necessary distance.

The following options are possible:

1. Passive retracting module - passive PRM

   The module is retracted by the reaction forces during the cover opening and deployment of the air bag in a direction toward the steering column axis.

2. Active retracting module - active PRM

   The retraction of the module is completed before the cover opening. To retract the module, the energy from the inflator gas escaping or a separate energy source is used.

A separate energy source must be adjusted to the inflator ignition and the complexity increases as the reliability decreases. Therefore the goal must be to use the available energy of the inflator.

Before the product development can begin the realization of the selected concepts must be proven.

TEST REQUIREMENTS - During the development of an air bag integrated steering wheel, numerous requirements of components of the restraint system as well as the entire restraint system must be taken into account, especially the peculiarities of the air bag integration and the retracting module.

The main requirements to be addressed are listed in the following:

1. Restraint System and Components

- FMVSS 201 (ECE-R21)
- FMVSS 203 (ECE-R12)
- FMVSS 208 (ECE-R94)

2. Design

- Environmental tests (includes the steering wheel)
- DOT, BAM (air bag and inflator)

3. Retracting Module

- Guaranteed fixation of the module in the initial and retracted position against head impact, reaction forces and misuse.
- OOP optimized module concept (PF-pattern, design of module regarding optimized deployment trajectory of air bag)

4. Generic requirements

- Availability of developed solution (long / short term)
- Low cost (development and product)
- Flexible design

VALIDATION - Before the product development begins, the realization of the retracting module concept regarding the function must be proven. In the first step prototypes are developed which represent the demanded function and can be used in static OOP tests as described in [5]. To compare the test results the same components are used as in the earlier study and the same test setup.

TESTS CONDUCTED - The first test series is used to verify the possible occupant load reduction under OOP conditions using a passive retracting module. The following tests were selected to be conducted with the retracting module.

1. Configuration "chest centered on module"
   Separation 0 mm and 50 mm

2. Configuration "forehead centered on module"
   Separation 0 mm

Each test is conducted twice.

The idea is to use the reaction forces during the cover opening and deployment of the air bag acting in the direction of the steering column axis, as an energy source to retract the module. The usable force is only available during the cover opening phase because it is the sum of inertia forces from the generated gas mass, the cover and the air bag fabric. The measurable reaction forces are in direct context with the characteristics of the inflator mass flow.

The available air bag steering wheel is modified to allow an unrestrained deformation of the module mounting. In order to hold the module in its initial position, two deformable brackets represent the mounting of the module to the steering wheel. The necessary energy absorption behavior of the deformable brackets was determined through an analyses of measured steering wheel reaction forces during a static air bag deployment test. In accordance with this analysis, simple deformable brackets have been developed and integrated in the air bag steering wheel. The deformable bracket is shown in Figure 4. Steel with a thickness of 1 mm was used to built the brackets. The maximum possible deformation of the brackets is 45 mm. The measured deformation force of one deformable bracket during a static compression test is shown in Figure 5. The possible energy absorption is approx. 36 Nm with two deformable brackets used as the module mounting. Figure 6 shows the mounted air bag module used for the configuration "chest centered on module". The same setup was used for the configuration "forehead centered on module".

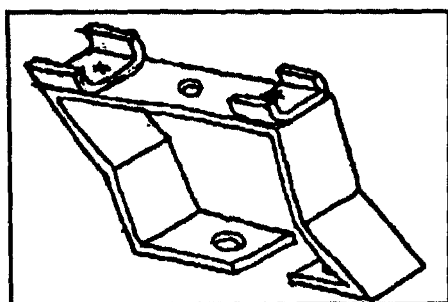

Figure 4: Deformable brackets to mount air bag module on steering wheel

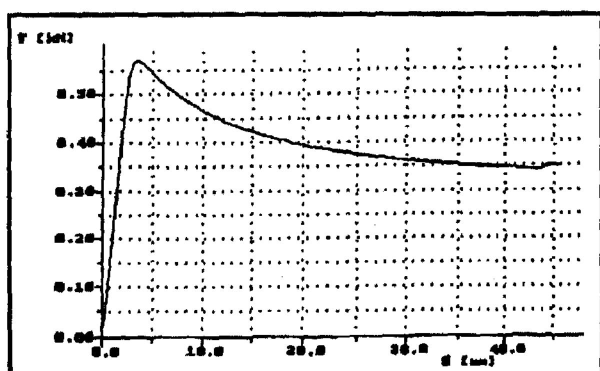

Figure 5: Deformation force of one deformable bracket during static compression test

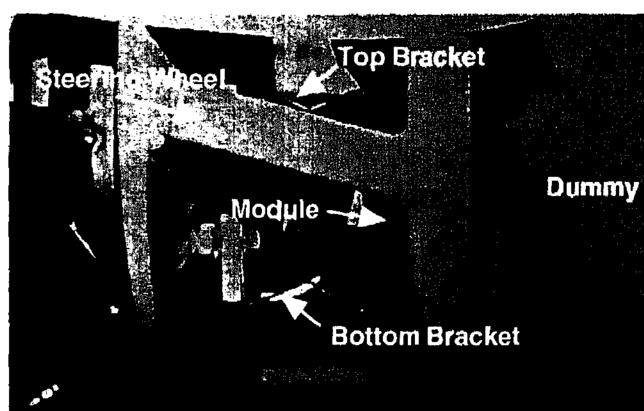

Figure 6: Test setup "chest centered on module" with deformable module mounting brackets

TEST RESULTS - "Chest centered on module" - During the tests with 0 mm separation between occupant and module the top bracket deformation starts directly after the cover opening at approx. 5 ms after air bag ignition. The deformation is finished after 3 ms. The bottom bracket deformation starts at approx. 10 ms after air bag ignition. The end of the deformation can not be seen due to the air bag coverage of this area. The entire deformation distance was used in both tests. The air bag uses the available area caused by the module retraction and the region behind the upper steering wheel rim for deployment.

During the tests with 50 mm separation between occupant and module the top bracket deformation starts shortly after the cover opening at approx. 7 ms after air bag ignition. The deformation is finished after 4 ms. The bottom bracket deformation starts at approx. 16 ms after air bag ignition. The end of the deformation can not be seen due to the air bag coverage of this area. The deformation of the top bracket was 35 mm and the deformation of the bottom bracket was 15 mm. Both brackets have not used the entire available deformation distance. The air bag uses the available area caused by the deformation of the top bracket and the region behind the upper steering wheel rim for deployment.

Table 3 and Figure 7 show the results for the VC and neck extension moment (bold values indicate exceeding of injury threshold) compared between the L-folding pattern (LF), the P-folding pattern (PF), and the P-folding pattern with the retracting module (PF / PRM).

Table 3: Comparison of VC and neck extension moment for configuration "chest centered on module" for LF-pattern, PF-pattern and PF-pattern with retracting module PRM

	Separation from module [mm]	Chest VC [m/s]	Upper neck M_y Extension [Nm]
LF	50	0.71	**65.5**
	0	**1.78**	**62.6**
PF	50	0.37	9.9
	0	**1.46**	19.0
PF /	50	0.30	13.5
PRM	0	**1.07**	21.8
scaled IARV		1.0	31.0

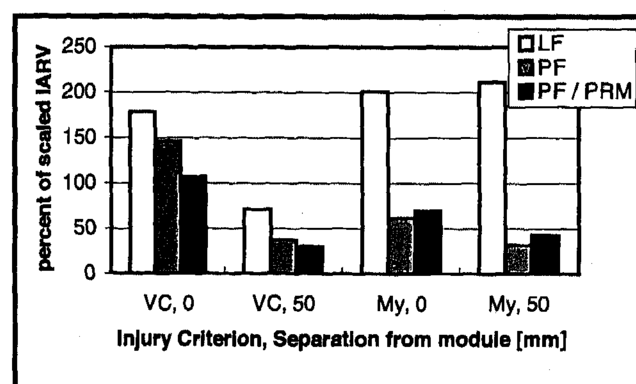

Figure 7: Comparison of VC and neck extension moment for configuration "chest centered on module" for LF-pattern, PF-pattern and PF-pattern with retracting module PRM

A comparison of the air bag deployment and occupant kinematics for the configuration "chest centered on module with 0 mm separation is shown in Figure 8 and for 50 mm separation in Figure 9.

Figure 8: Comparison of air bag deployment and occupant kinematics for PF-pattern with and without PRM, "chest centered on module", 0 mm separation

Figure 9: Comparison of air bag deployment and occupant kinematics for PF-pattern with and without PRM, "chest centered on module", 50 mm separation

"Forehead centered on module" - After the cover opening the air bag inflates towards the upper steering wheel rim for the first 10 ms. During that time the top bracket is deformed. In the beginning the air bag can escape behind the upper steering wheel rim. After approx. 30 ms the entire air bag is located in front of the steering wheel rim. The bottom bracket is deformed between 12 and 15 ms after the air bag ignition. The deformation of the top bracket was 35 mm and the deformation of the bottom bracket was 15 mm. Both brackets have not used the entire available deformation distance.

Table 4 and Figure 10 show the results for the neck extension moment and the HIC compared between the L-folding pattern (LF), the P-folding pattern (PF), and the P-folding with the retracting module (PF / PRM).

Table 4: Comparison of neck extension moment and HIC for configuration "forehead centered on module" for LF-pattern, PF-pattern and PF-pattern with retracting module PRM

	Separation from module [mm]	Upper neck M_y Extension [Nm]	HIC
LF	0	19.2	359
PF	0	30.1	235
PF/PRM	0	22.5	165
scaled IARV		1.0	1113

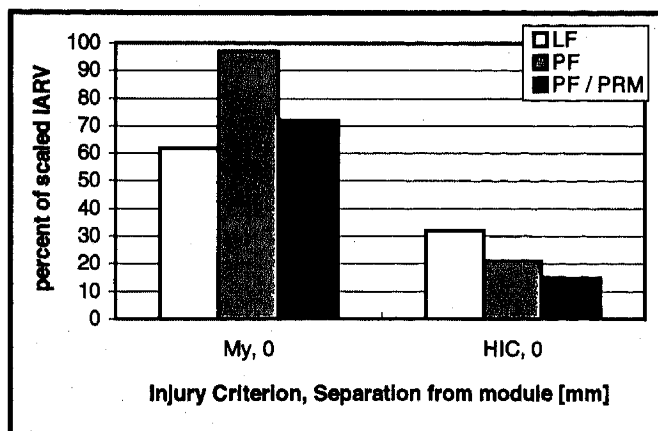

Figure 10: Comparison of neck extension moment and HIC for configuration "forehead centered on module" for LF-pattern, PF-pattern and PF-pattern with retracting module PRM

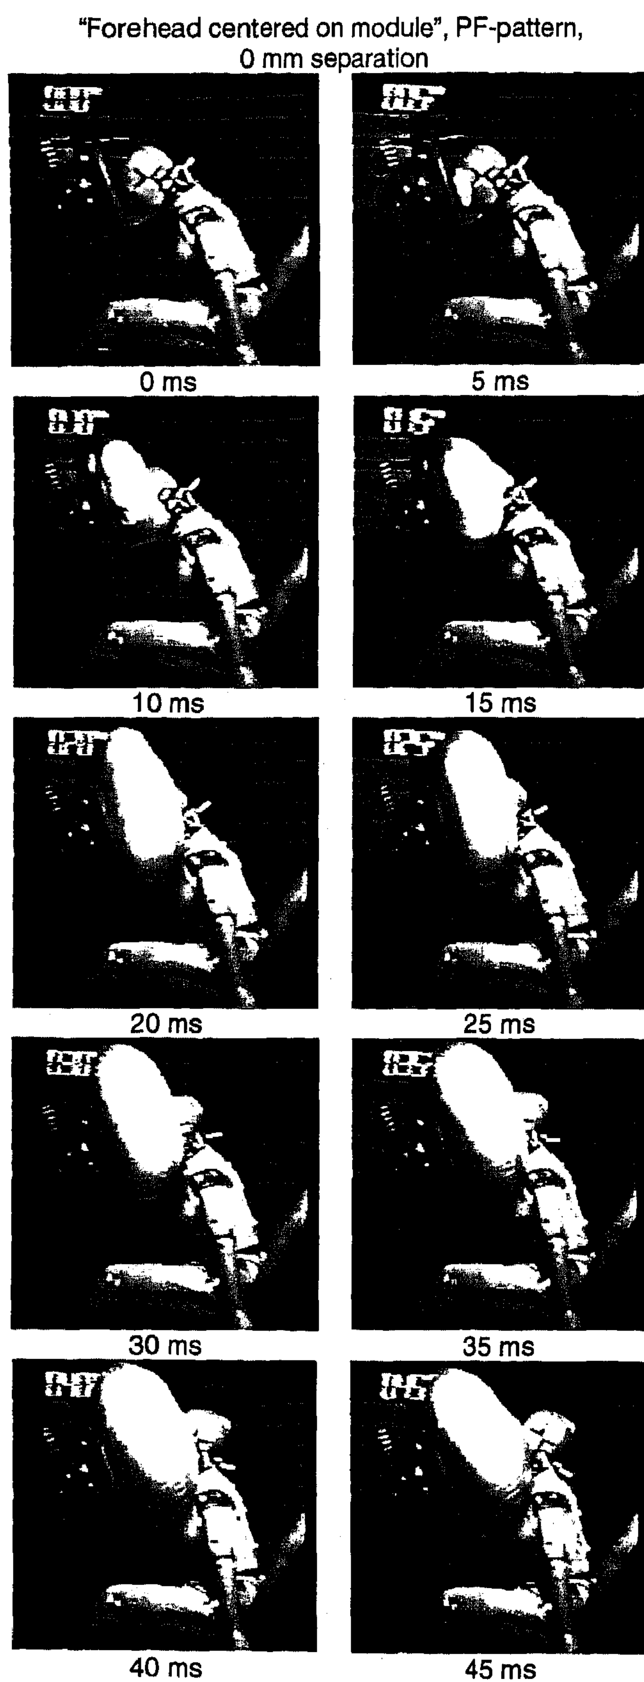

A comparison of the air bag deployment and occupant kinematics for the configuration "forehead centered on module" with 0 mm separation is shown in Figure 11.

TEST RESULT SUMMARY - "Chest centered on module" - The test configuration "chest centered on module" with the PF-pattern and the retracting module showed a significant reduction of the viscous criterion VC compared to the LF-pattern and the PF-pattern without the retracting module. With 0 mm separation the reduction was 26% and with 50 mm separation the reduction was 20%. With 0 mm separation all air bag module configurations exceeded the IARV, however, both tests with the retracting module resulted in VC values slightly above and under the IARV.

The test results with the LF-pattern far exceeded the IARV for the neck extension moment in all tests. The test results with PF-pattern remained far under the IARV for the neck extension moment in all tests. This benefit could not be increased with the retracting module. The neck extension moment in these tests increased slightly, however, they remained far under the IARV of 31 Nm.

"Forehead centered on module" - The test configuration "forehead centered on module" with the PF-pattern and the retracting module showed a significant reduction of the neck extension moment and HIC values compared to the PF-pattern without the retracting module. However, the neck extension moment with the retracting module is slightly higher than with the LF-pattern but remains 30% under the IARV. The increase in neck extension moment for the PF-pattern compared to the LF-pattern can be traced to the interaction of the folding scheme with the tear-open mechanism of the module cover. Analysis of the high-speed films reveals that the torn-open cover becomes wedged in between the deploying air bag and the dummy head situated in front of the module. When this cover finally slides away from the dummy chin and then flips downward, the potential energy of the bag portion located beneath the cover is suddenly transferred to the underside of the chin. As a result of the different bag folding scheme, this wedging of the module door was not so pronounced with the LF-pattern and the rearward rotation of the dummy head was likewise gentler [5]. This phenomenon was mitigated when using the retracting module and the PF-pattern. The neck extension moment with the PF-pattern and the retracting module was decreased by 25% compared to the tests without the retracting module and the PF-pattern. Furthermore, tear seam design may reduce the neck extension moment.

All tests showed HIC values far below the IARV, however, the test with the PF-pattern and the retracting module showed a 20% reduction of the HIC value compared to the test with the PF-pattern and without the retracting module.

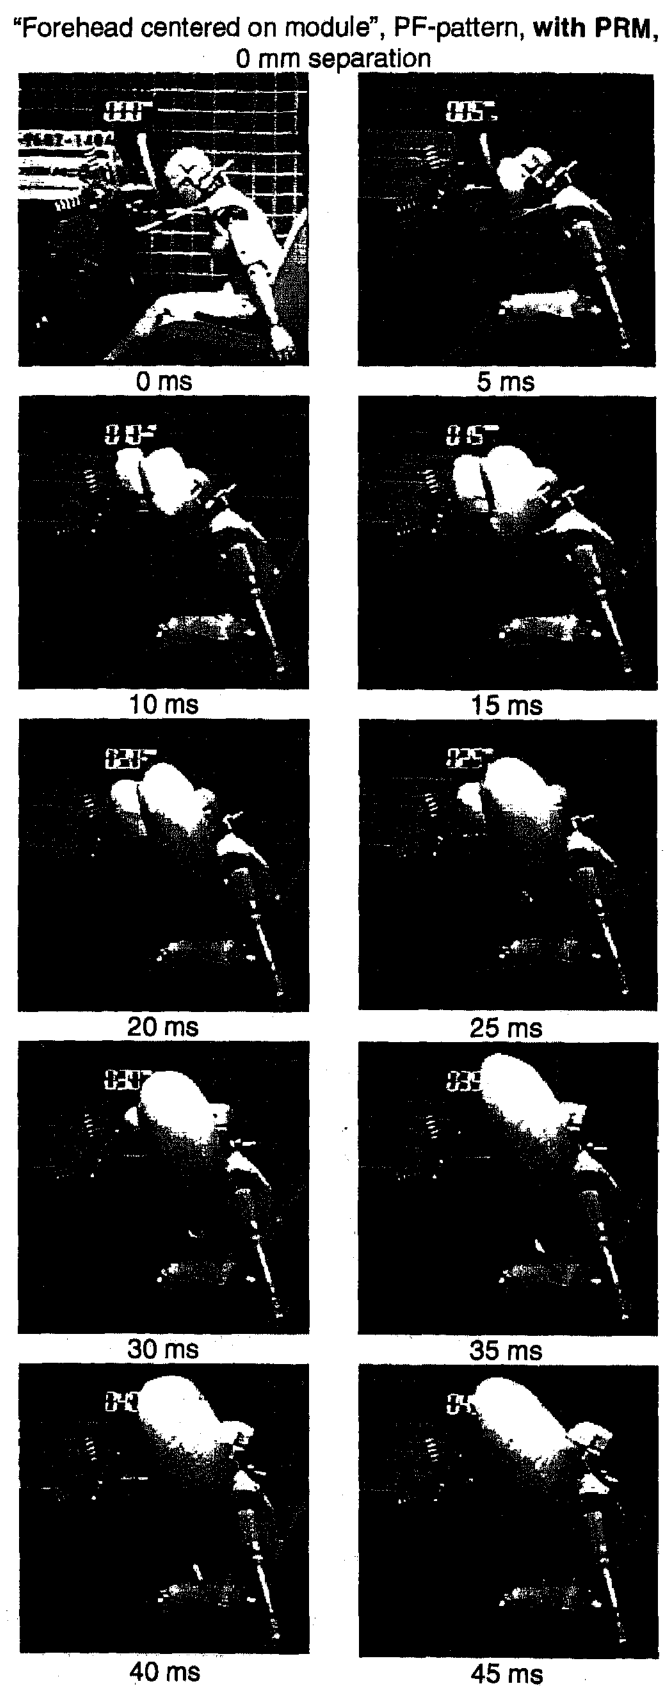

Figure 11: Comparison of air bag deployment and occupant kinematics for PF-pattern with and without PRM, "forehead centered on module", 0 mm separation

SUMMARY AND CONCLUSION

The effective usage of available scientific and systematic tools in the restraint system development requires methodical procedures. This study describes the methodical procedure to develop an air bag integrated steering wheel in order to optimize occupant protection balanced against OOP risks.

The close cooperation between the concept design, occupant crash simulation, crash testing and product development is emphasized. This guarantees the development of a restraint system component from the system point of view.

The evaluation of the OOP topic, analysis of preliminary OOP studies and a methodical solution approach lead to the development of a new component for an air bag integrated steering wheel. The development of a passive retracting air bag module - PRM - was achieved during the methodical procedure and performance of OOP tests.

Compared to OOP tests in [5] the usage of the retracting module - PRM showed a significant reduction for the configuration "chest centered on module" for the viscous criterion VC. The value for the neck extension moment was slightly increased, however, it remained far below the IARV. For the configuration "forehead centered on module" HIC value was reduced by 20% with the usage of the retracting module - PRM. The neck extension moment was reduced by 25%, however, the value was slightly higher compared to the LF-pattern.

It remains to be noticed that the energy absorption of the deformable module brackets was on a very low level. Increasing that level and producing a more even deformation for the module shows another safety potential of the passive retracting module for OOP conditions.

An additional advantage of the retracting module is the use of the mechanism to satisfy the head impact standard (FMVSS 201, ECE-R21). The mechanism is then functioning as a crash can implemented in the steering wheel.

These features included in an air bag integrated steering wheel in addition to the P-fold allow a seamless design of the steering wheel and a smaller package to gain more available distance for the retracting module.

In the future, the active retracting module may furthermore result in reduced occupant loads compared to the passive retracting module due to a mitigated punchout effect. The retraction of the module before the swelling and opening of the module cover may result in reduced punchout loads on the occupant.

Due to an optimized function for all occupant positions, the retracting module concept guarantees a safety potential increase for OOP occupants and no reduction for in-position occupants.

In summary, the test results showed the effectiveness of the retracting module concept - PRM and the analyses admit the conclusion that optimized design solutions can essentially contribute to reduce OOP risks.

The present study suggests that the use of the retracting module - PRM - leads to load reductions for OOP occupants. For the foreseeable future further developments regarding air bag module design, sensor systems and inflator technology show an increase for the safety potential of restraint systems

ABSTRACT

Vibrations induced by the internal flow in a typical seat valve used in mobile hydraulics are investigated under various extreme flow conditions. To reduce the noise associated with these vibrations, it is necessary to gain a thorough understanding of the flow in this particular hydraulic component and of the dynamic characteristic of the hydraulic system. The three-dimensional and turbulent flow in the valve is studied and characterized applying Computational Fluid Dynamics (CFD). Subsequently, dynamic phenomena, such as pressure pulsation, flow rate fluctuation, and body fixed acceleration, are analyzed from measurements on a hydraulic test assembly.

The combined method using CFD and direct measurements suggests itself as a very suitable approach to gain more understanding not only of the flow processes in the valve but also of the causes for the instability of the valve closing body.

INTRODUCTION

Seat valves are widely used basic components of hydraulic systems, especially employed in passenger cars and trucks. Some of these are antilock braking systems (ABS), traction control systems (TCS), continuously variable transmission (CVT), steering systems, dynamic level control systems, and fuel injection systems.

The current trends in development of these systems are smaller size, higher power density, better efficiency, and cost reduction. Therefore, each system component must contribute to satisfy these requirements.

In this paper, an example for a typical seat valve used in a plunger pump is presented. To study the flow in the valve and its influence on system dynamics, there are several methods as follows: flow visualization via enlarged models, numerical investigations (Computational Fluid Dynamics [1], [2] and one-dimensional parametrized behavioural simulation for hydraulic networks [3]), and direct measurements on a hydraulic test assembly.

Enlarged models are usually based on the principle of the same Reynolds number of both flow regimes (original and similar flows). Methods, such as Laser Light Sheet (LLS) and Particle Image Velocimetry (PIV), are generally used to visualize the flow in the enlarged models. They are quite useful for complicated geometries and extremely difficult flows involving strong curvature, swirl, and body force effects but rather expensive. However, it is very difficult either to visualize the three-dimensional velocity field experimentally or to measure pressure and temperature distributions on any sectional surface.

Alternatively, Computational Fluid Dynamics (CFD) is often applied to simulations of flows in the considered component of the system. In recent times, both computer capacities and simulation programs have quickly been developed so that we can calculate the flow for complicated geometries with a very fine grid and complex turbulence models. Unfortunately, CFD is presently not suitable to compute dynamic phenomema like pressure pulsation, flow rate fluctuation, etc. Thus, the one-dimensional behavioural simulation for hydraulic networks has to be carried out. However, some effects, such as cavitation and air release from the liquid that usually take place in the hydraulic components, have not correctly been modeled in CFD and in 1-D behavioural simulations for hydraulic networks.

Hence, direct measurements by means of pressure transducers, hot film anemometer, and acceleration pickup on the original component cannot be replaced yet. Analytical methods in the frequency domain, such as spectrum analysis via Fast Fourier Transformation (FFT), autocorrelation, and cross-correlation, have been used to analyze the measured results.

To study the internal flow in the valve, CFD and direct measurements are chosen in the product design and development phase. This combined method is very suitable to analyze and solve complex dynamic problems fast and economically.

DESCRIPTION OF THE SEAT VALVE IN THE PLUNGER PUMP

The cost-efficient plunger pump described in Figure 1 applies a very simple principle. The plunger is moved backwards and forwards by an eccentric wheel for the intake and the compression phase, respectively.

At the beginning of the intake stage, the pressure in the internal pump chamber decreases until it is less than the pressure at the pump inlet. Thereupon, the hydraulic liquid starts flowing from the inlet through the circular channel on the plunger into the internal chamber.

The pressure in the internal chamber continuously rises at the beginning of the compression stage until it is larger than the given pressure at the pump outlet. The closing body (further called „ball") is then opened and the pumping process continues as long as the plunger is moving forward.

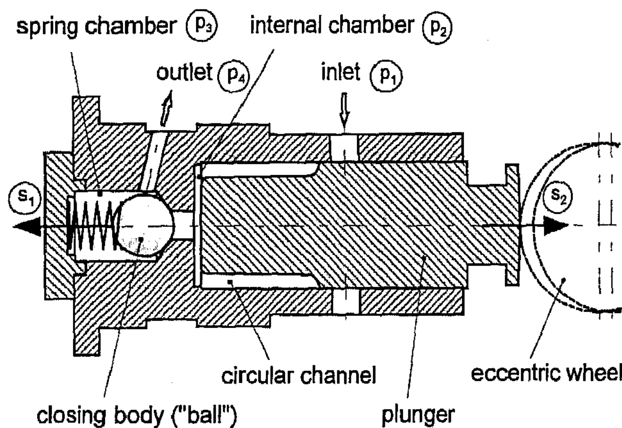

Figure 1: Schematical description of the plunger pump

NUMERICAL STUDY AND RESULTS

COMPUTATIONAL GRID - For the numerical study of the pumping process, it is necessary to model the flow in the outlet seat valve of the pump consisting of the internal chamber, the spring chamber behind the ball and the outlet bore (see Figure 1).

The simulated domain is one half of the seat valve because of the geometrical symmetry of the cases where the ball is axisymmetric or eccentric only in the direction towards the outlet bore. The computational grid is directly generated from the CAD geometry by using the code ICEM-CFD [4]. Figure 2 shows this grid for the seat valve.

Defining the degree of mesh refinement necessary to ensure a mesh independent numerical solution is quite difficult, particularly for three-dimensional problems. It depends on many factors, such as geometrical configurations, flow properties (viscous regions, separation, possible unsteadiness), mesh qualities (cell aspect ratio, cell skewness), numerical schemes, and turbulence models. Various types of structured or unstructured meshes can be applied, but in all cases, besides numerical schemes, mesh qualities will greatly influence accuracy and convergence of numerical solutions.

In general, finer meshes reduce discretization and truncation errors but cause rather high costs of the computation. Principally, the mesh must be fine enough to generate sufficiently accurate solutions but should not be finer than necessary. Much experience is required to determine the appropriate number of nodal points as well as their distribution for the computational problem.

A multiblock and structured mesh whose elements are trilinear and hexahedral is used for this numerical study. It includes 27 topological blocks and about 100,000 nodal points.

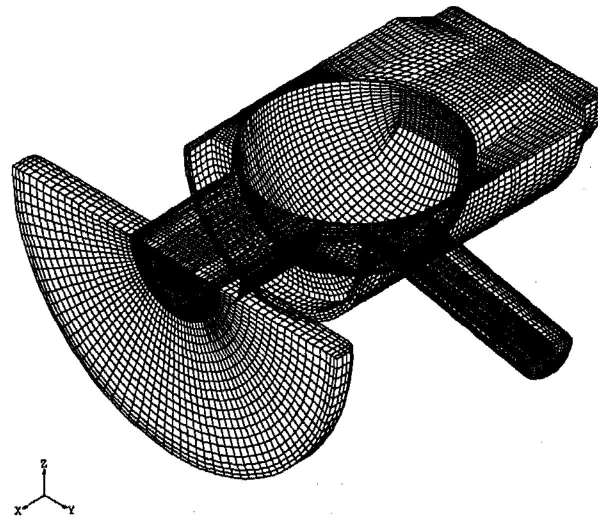

Figure 2: Computational grid for the seat valve

Grid generation nowadays takes most of the working time in CFD simulations, in particular for complicated geometrical configurations. Hence, there is a strong need for automatic mesh generation algorithms, especially for structured and unstructured meshes with hexahedral elements.

NUMERICAL SIMULATION - The flow in the valve is assumed as steady-state, isothermal, and incompressible. The simulation is based on the Reynolds Averaged Navier-Stokes equations (RANS) and the continuity equation [5].

At first, the continuous governing partial differential equations are discretized by the Galerkin approach, a weighted residual method. The principle of the Galerkin formulation, the finite element method, is that the integral of the weighted residual of the equation system over the computational domain is zero [6]. For the steady case, a system of algebraic equations is generated from the discretized equation system. This algebraic equation system connecting the solution nodal values is solved

either directly or iteratively [7]. In this paper, the commercial code FIDAP [8] has been used for the computation.

The considered numerical model is an elliptic boundary value problem for subsonic flows, i.e., Ma < 1. For this reason, boundary conditions for the computational domain have to be supplied.

The relationship between the lift of the ball and the plunger displacement can be determined from the one-dimensional behavioural simulation for hydraulic networks. The lift is defined as zero, when the valve is closed. Therefore, in the three-dimensional computation the flow in the valve is simulated for each given constant lift.

The velocity of the fluid used for the boundary condition at the valve inlet is assumed to be the speed of the plunger, which is easily calculated from the rotational velocity of the eccentric wheel and its eccentricity. The pressure boundary condition at the valve outlet is set to be zero as the reference pressure. On the wall of the valve body, all velocity components are equal to zero. Because of the symmetric boundary condition, the velocity component normal to the symmetric valve plane must be equal to zero as well.

The Reynolds number Re that defines the relation between the momentum force and the viscous force is generally used to determine the flow regime of the fluid. For the flow in typical valves in mobile hydraulics, the Reynolds number at the valve seats amounts to a value of the order of 10^3.

The valve geometry shown in Figure 1 induces an annular jet flow at the seat where the flow jet becomes mostly unstable even at lower Reynolds numbers, i.e., Re < 10^3.

In order to get accurate numerical solutions, either the total nodal points of the mesh must be in the order of $Re^{9/4}$ for 3-D problems, or the computation must be run with a turbulence model for the corresponding flow regime. Even though the flow is at relatively low Reynolds numbers, the first approach involving direct numerical simulation (DNS) cannot be carried out on workstations, because it would need immense capacities only available on fastest super-computers including optimized numerical algorithms. Hence, a turbulence model for low Reynolds numbers is usually applied to modeling the flow in the considered hydraulic valves.

In the standard k-ε turbulence model regarding the gradient-transport concept, the Reynolds stress is related to the mean-velocity gradient via a so-called turbulent eddy viscosity that is assumed to depend on the turbulent kinetic energy k and the turbulent dissipation ε. This assumption is quite suitable for high Re numbers but rather inaccurate for low Re number flows involving viscous boundary layers, transition, and separation.

Therefore, we apply an alternative approach to conventional closure schemes using the renormalization group theory (RNG), which has been developed by Yakhot and Orszag [9]. The RNG method uses dynamic scaling and invariance together with iterated perturbation techniques to evaluate the transport equations for the large-scale modes and their transport coefficients. Computations with the RNG turbulence model have shown a better agreement with experiments for complex flows (separation and swirling flows) where the standard k-ε turbulence model often fails [9]. Additionally, the main advantage of the RNG analysis is its independence of any experimentally adjustable coefficients.

The RNG approach is effective in both low and high Re number flow regions. Hence, it is generally available for near-wall areas as well as for highly turbulent flow regions. However, computation only with the RNG model requires a very fine mesh in the near-wall region. In order to save computation costs, the combination of the RNG turbulence model and the Reichardt's universal near-wall model has been used for the numerical calculation. With this approach, the so-called local Reynolds number y^+ on nodes next to the wall can be less than 30 instead of between 30 and 100 in case of the standard k-ε turbulence model with a near-wall model; i.e., the RNG model working with a high order of accuracy has directly been applied in viscous sublayers or in separation regions.

NUMERICAL SCHEME - In order to stabilize the numerical solutions, the streamline upwinding (SU) scheme developed by Hughes and Brooks [10] has been used in the computation. The high-order convection term resulting from the finite element Galerkin method can be unstable. Such instability may be alleviated by the SU scheme via explicitly adding numerical diffusion only along the flow direction. Practically, the combined scheme (Galerkin and SU) substantially stabilizes convection instabilities with only a minor loss of accuracy.

Due to the limited main memory of computers, the discretized system of equations, particularly for 3-D problems, is usually solved iteratively. The pressure projection scheme, a modified algorithm of the MAC (Marker and Cell) method [11], has been used where velocities and pressures are iteratively corrected in two steps [8].

The applied segregated algorithm requires the solution of both non-symmetric and symmetric linear equation systems at each iteration step. The conjugate gradient squared (CGS) and the conjugate residual (CR) iterative methods have been utilized to solve the non-symmetric and symmetric linear equation systems, respectively [7].

In order to substantially improve the convergence of conjugate gradient methods, the application of preconditioning is necessary. Gauss-Seidel and Jacobi preconditioning are available for symmetric and non-symmetric linear systems of equations, respectively.

In addition, for accelerating the convergence of the linear or nonlinear iterations, the residual projection on the subspace (RPS) scheme of Karamyshev et al. [12] is employed, where the solution vector is corrected by an adjustment vector consisting of a linear combination of the previous residual vectors.

NUMERICAL RESULTS - Some selected computational results are presented. The first calculation begins with a lift of the ball of 0.100 mm for the case of the axisymmetric position of the ball, i.e., the center of the ball lies on the valve axis. A second computation with a lift of 0.150 mm for the case of an eccentric ball position of 0.100 mm has been carried out. The velocity of the fluid at the valve inlet of 0.5 m/s and a zero reference pressure at the outlet have been chosen as boundary conditions.

Figure 3 shows the velocity field at the valve seat and on the valve plane of symmetry. At the edge of the entrance of the cylinder joining the internal chamber to the valve seat, flow separation takes place. Since the total pressure drop mainly occurs at the valve seat, the fluid reaches a maximum velocity in the valve seat region near the entrance of the outlet bore. Note that the fluid velocities in the spring chamber are very small due to its large dead volume. In the region located between the ball and the wall of the valve opposite to the outlet bore, recirculation flow (vortex) is observed.

In order to study the internal flow in the valve in more detail, the velocity vectors at several selected sectional areas perpendicular to the valve axis are displayed in Figure 4. The flow in the domain near the ball equator gradually changes from its axial direction at the side opposite to the outlet to the tangential direction along the ball equator. Therefore, most of the fluid flows to the outlet bore in front of the equator. However, a small part of the fluid first enters the spring chamber and then returns to the outlet.

At the inlet area, some fluid particles have been selected whose paths are shown from two different directions of view in Figures 5 and 6. The particles at the right side of the inlet area flow directly to the outlet bore. At the left side, the particles either change their directions behind the valve seat but in front of the ball equator and then move towards the outlet bore or recirculate from the spring chamber to the exit.

A pressure distribution in the valve is presented in Figure 7 where the dark and light shading values point out high and low isobaric domains, respectively. The maximum pressure at the valve inlet area is about 3 MPa, while the minimum occuring in the separation zone at the entrance of the outlet bore is approximately 0.4 MPa below the reference.

Since pressure energy is transformed into kinetic energy at the valve seat, most of the pressure drop takes place there, in particular near the outlet bore. The recirculation flow in the spring chamber accounts for its increased pressure being about 1 MPa above the reference.

Figure 7 shows that the pressure in the internal chamber is higher than the pressure in the spring chamber. Hence, a force on the ball is acting in the negative x direction. In addition, the pressure at the side opposite to the outlet exceeds the outlet pressure. Therefore, another force is acting on the ball in the y direction. Due to the symmetric boundary condition, the resulting force component on the ball in the z direction is of course equal to zero.

By way of integrating the normal (pressure) and shear stresses on the ball surface, a resulting force has been calculated. In this case, the force component in the negative x direction is 6 N, which is still greater than the return spring force, the component in the y direction is 2 N. This suggests that the ball will still be opened further resulting in a larger lift and simultaneously be drawn into the direction of the outlet bore, i.e., the position of the ball will be eccentric to the valve axis.

In order to determine whether the ball will be returned from the eccentric to the axisymmetric position, a second computation with a larger lift of the ball of 0.150 mm, an eccentricity of 0.100 mm from the valve axis to the outlet, and the same boundary conditions as in the first case has been carried out.

Figure 8 gives the pressure distribution in the valve for this case. Since the lift of the ball is larger than in the first case, the maximum pressure at the inlet area is reduced from 3 to 2.4 MPa. An additional throttling effect at the entrance of the outlet bore is created due to the ball eccentricity. Therefore, the pressure in the spring chamber increases from 1.0 (in the axisymmetric case) to 1.8 MPa.

The pressure distribution on the ball accounts for the change of direction of the x-force component from -6 to 1.5 N and the increase of the y-force component from 2 to 5 N. This implies that the ball has been stabilized at a lift between 0.100 and 0.150 mm leaning against the wall of the valve body near the entrance of the outlet bore.

The movement of the ball from the valve axis to the outlet bore causes the quasi-closing of the spring chamber. This effect is further called „ball turnover". Because of the additional throttling effect, the pressure not only in the spring chamber but also in the internal chamber rapidly rises. Due to the pressure increase in the spring chamber, the ball is pushed back into the valve seat. Thereupon, the internal pressure goes up further and the ball moves forward again. The movement of the ball is repeated until it stabilizes at the wall near the outlet entrance. Thus, pressure pulsations not only in the spring chamber but also in the internal chamber and the whole hydraulic system accordingly develop. The quasi-incompressibility of the liquid accounts for the high frequency and amplitude of the pulsations. That causes the vibration of the ball directly at the beginning of its lift before it stabilizes at the outlet bore. The instability of the ball will be discussed in the next section in more detail.

In order to get converged numerical solutions, well-estimated starting values are required. Hence, the solutions with the k-ε turbulence model have been used as starting values for the subsequent computation with the RNG turbulence model.

The computation for the valve with a grid consisting of about 100,000 nodal points requires a main memory of 75 Mbytes as well as 11 and 15 CPU minutes per iteration step on a workstation HP 9000-J200 for the k-ε and the RNG turbulence model, respectively.

For the applied segregated solver, a solution convergence tolerance of 10^{-3} has normally been employed for 3-D problems. For this convergence tolerance, 50 and 75 iteration steps for the k-ε and the RNG turbulence model, respectively, are required for the computation.

EXPERIMENTAL STUDY AND RESULTS

To supplement the computational investigations, the pressure characteristic at the inlet p_1, in the internal chamber p_2, in the spring chamber p_3, and at the outlet p_4 and the acceleration of the valve body in three directions have directly been measured on the hydraulic test assembly (s. Figure 1). The plunger movement s_2 has been determined by means of an inductive displacement pickup.

In this study the pressures at the inlet p_{in} and the outlet p_{out} are 1 and 10 MPa, respectively for all investigated cases.

At first, we investigate the vibrational characteristic of the valve at a low rotational speed of the eccentric wheel of 1500 rpm, then at a relatively high rotational speed of 3500 rpm.

The plunger movement s_2 and the vibrational characteristic of the pressures p_2, p_3, and p_4 at the rotational speed of 1500 rpm are presented in Figure 9. During the intake stage, the plunger moves backward from the top dead center (TDC) to the bottom dead center (BDC) and reversely for the compression stage.

During the intake stage, the pressure in the internal chamber p_2 is a little less than the inlet pressure p_1. However, the internal pressure p_2 is much larger than the vaporisation and the air saturation pressure at the operating temperature. Therefore, neither cavitation nor air release occurs in this stage. The internal pressure p_2 increases quasi-linearly with time at the beginning of the compression stage until the ball of the outlet valve is opened.

The resulting radial force on the ball determined in the computational study is relatively small at the low flow rate for this rotational speed. It is not strong enough to draw the ball to the outlet bore. For this reason, it is assumed that the ball vibrates mainly in the axial direction after the valve has opened. Thus, the pressures in the internal chamber p_2, the spring chamber p_3, and at the outlet p_4 are evanescently oscillating with a frequency of approximately 1.7 kHz until the beginning of the next intake stage. Note that the pressures in the spring chamber p_3 and at the outlet p_4 are nearly the same but the internal pressure p_2 is different from the outlet pressure p_4, i.e., the main pressure drop is at the valve seat. These results indicate that the ball stabilizes in the valve axis.

Figure 10 shows the vibrational characteristic of the pressures p_2, p_3, and p_4 and the plunger displacement s_2 at the rotational speed of 3500 rpm. Differing from the previous case, the internal pressure p_2 drops to nearly zero (vacuum) due to the high velocity of the plunger in the intake stage. Thus, air release and cavitation take place in the internal chamber. Even though the compression stage has begun, the internal pressure p_2 is still nearly vacuum for a while, before it suddenly shoots up to a pronounced spike. This characteristic can be explained as follows: the existing air and vapour bubbles in the fluid in the internal chamber must be compressed until they completely vanish. Thereupon, the pressure of the single-phase fluid (i.e., without air and vapour bubbles) in the internal chamber rapidly increases in the compression stage.

At this rotational speed corresponding to a high flow rate, the resulting radial force on the ball is strong enough to move it to the outlet bore. For the reason discussed in the previous section, a strong pressure pulsation occurs in the spring chamber and the internal chamber directly at the beginning of the ball lift. In this case, the pressures in the internal chamber p_2 as well as in the spring chamber p_3 are nearly the same because the additional throttling effect due to the ball turnover covering the outlet bore is stronger than the flow resistance at the valve seat. Hence, the pressure drop between the internal chamber and the outlet is substantially increased compared to the previous case. These results confirm that now the ball stabilizes leaning against the wall of the valve body near the entrance of the outlet instead of oscillating in the valve axis.

The instability of the ball at the high rotational speed of 3500 rpm has two consequences. First, the high pressure pulsations in the internal chamber p_2 and the spring chamber p_3 cause vibrations in the valve body associated with noise. Second, the additional throttling effect accounts for the low efficiency of the pump and therefore its high electric power input. This is particularly critical in winter when the increased fluid viscosity due to low temperatures raises the electric power requirements even more.

In order to characterize the vibrations induced by the flow in the valve, accelerations of the valve body have been measured in various directions. The Fourier analysis has been applied to transform the acceleration vs. time function into frequency function [13].

To suppress the pump frequency, accelerations of the valve body perpendicular to the plunger displacement are presented for two investigated cases with 1500 and 3500 rpm in Figures 11 and 12, respectively. At the rotational speed of 1500 rpm, the ball turnover effect has not happened yet; the pressure pulsation is very small. This results in a low excitation of the valve body that is visible through a peak of the acceleration signal at the frequency of nearly 1.7 kHz (s. Figure 11). Quite conversely, at the rotational speed of 3500 rpm, high pressure pulsation occurs because of the ball turnover. Thus, the maximum acceleration of the valve body is also seen at the frequency of about 1.7 kHz in Figure 12.

To analyze the correlation between the pressure pulsations and the accelerations of the valve body in more detail, the cross-correlation method has been used [13]. The resulting cross-correlation function of two signals contains only those frequency components common to both waveforms.

The cross-spectrum of the internal pressure p_2 and the acceleration of the valve body at the rotational speed of 3500 rpm is displayed in Figure 13. A good correlation is indicated at the pump frequencies of the first (0.058 kHz) and second order (0.116 kHz) and at the higher frequency of 1.7 kHz. This result indicates that the internal pressure pulsation is a major noise source in the valve with the high excitation frequency of 1.7 kHz.

CONCLUSIONS

The presented methods allow us to better understand the flow and the dynamic characteristic in the valve. Furthermore, the causes of the flow induced noise and of the low pump efficiency have been explained. This thorough understanding is necessary to develop, design, and optimize new valves for low noise, high pump efficiency, and low costs.

In order to verify the assumptions on the ball movement, we will try to develop a method to measure it. Further direct insight will be gained when the 3-D, turbulent, and unsteady-state flow computation is coupled with the 1-D behavioural simulation of the other mechanic and hydraulic system components.

Measured and Predicted Effects of Air Flow Non-Uniformity on Thermal Performance of an R-134a Evaporator

Aidan M. Ryan and David J. Timoney
University College Dublin

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Tests have been carried out over a wide range of operating conditions on a single circuit plate-finned tube type of refrigerant evaporator, exchanging heat between ambient air and refrigerant R134a. Uniform and non-uniform air flow distributions were applied with the objective of studying the effects of non-uniformity on heat transfer.

The experimental results revealed that, for a given total volume flow of air, heat transfer performances could be up to 15% better with a non-uniform flow where turbulence levels were also high.

Extensive comparisons were also made between these measurements and predictions from a computer model. This was designed to simulate the thermal behavior of cross-flow heat exchangers on a tube segment-by-segment basis, allowing for flow non-uniformity. Predictions were found to match measurements satisfactorily for test cases involving uniform air flows and a relatively large temperature difference between fluids. In contrast to the measured trends, the simulation results predicted a degradation in heat transfer performance for non-uniform air flow cases.

INTRODUCTION

Refrigeration and air conditioning system designers often consider the air flow velocity distribution across compact heat exchangers to be uniform when estimating heat exchanger performance. In practice, the flow profile can be highly non uniform. Space limitations and ducting arrangements often lead to mal-distributed air flow profiles, particularly in domestic and automotive applications. Use of axial and centrifugal fans in forced draught mode may also give rise to non-uniformity in the air flow.

A program of experimental and analytical work is underway at University College Dublin, aimed at the development of a reliable performance simulation model for cross-flow evaporators. This paper presents some results from experimental and analytical studies of the performance of one particular evaporator under conditions of (i) low turbulence uniform air flow (provided by a wind tunnel), and (ii) high turbulence, non-uniform air flow from a centrifugal fan. These results give some insight into the mechanisms by which air flow velocity and turbulence profiles can affect the overall performance.

The overall objective of the work is to establish whether design changes could usefully be made to an evaporator so that benefits could be obtained from a non-uniform air velocity distribution. Once adequately validated, the simulation software is intended for use as a design optimization tool.

REVIEW OF PREVIOUS WORK

Kitto & Robertson [1] suggest that the causes of mal-distribution in heat transfer equipment fall into one of the following categories;

1. Non-uniformities induced by mechanical design.
2. Flow self induced non-uniformity.
3. Two-phase flow effects.
4. Fouling.

In practice, the effects of these non-uniformities manifest themselves as degradation of thermal

performance or interruption of mechanical operation (i.e. failure).

For the type of evaporator being studied here, mal-distribution could be expected to affect thermal performance because;

(1) Tube side fluid property variations occur continuously throughout the heat exchange coil. Transformation from two-phase to single phase flow is unavoidable, thereby introducing significant variations in local tube-side heat transfer coefficients.

(2) Choice of fan and ducting arrangements will introduce non-uniform air flow, with consequent variations in local gas-side heat transfer coefficients.

A number of the published studies of the effects of non-uniform air flow have been based entirely on computer simulation. For example, Fagan [2] investigates the effects of parabolic, linear and step air flow distributions on the performance of a plate finned tube heat exchanger, assuming the refrigerant pressure drop to be negligible and the tube-side heat transfer coefficient to be constant. He suggests that mal-distributions of up to 75% of the average face velocity can produce evaporator capacity losses of 3 to 16%.

Chiou [3] proposed a numerical method to determine deterioration in heat exchanger effectiveness due to non-uniformity. He suggests that a generalized relationship between "flow non-uniformity factor" and performance deterioration could be developed. Two subsequent publications [4,5] are concerned with application of this method to studies of the performance of condensers and evaporators.

The work of Berryman & Russell [6] looks at the effects of forced and induced-draught air flow on air cooled heat exchangers. They suggest that mal-distribution will lead to loss in thermal performance of only a few percent. Their results also suggest that induced air flow can be as non-uniform as forced flow.

The effects of non-uniformity of inlet air temperature and velocity profile were investigated by Rabas [7] who used an analysis procedure similar to that of Fagan [2]. The results show that degradation of effectiveness increases with increasing non-uniformity of the air velocity profile. Temperature variations can have positive or negative effects but are less important than the effects of two dimensional flow mal-distribution.

Kondo et al [8] suggest that the *rms* value of the air flow distribution and thermal performance deterioration rate can be simply related. The space-averaged *rms* value of the entire velocity profile or degree of non-uniformity *K* is defined by;

$$K = \sqrt{\frac{1}{A}\int_A \left(\frac{V(A) - \overline{V}}{\overline{V}}\right)^2 dA} \qquad (1)$$

A is the total frontal core area, *V(A)* is the local velocity and $\overline{V}$ is mean frontal core velocity. This definition was also used in the present work.

Simulation studies were carried out as part of the present work. The results were in general agreement with those presented in these published works. However, the present authors have also undertaken extensive experiments to provide validation data and to clarify the experimental effects of air flow non-uniformity.

Simulation of Heat Exchanger Thermal Performance

General Description

The simulation modeling approach used for the present work was based on that used in the "EVSIM" program published by Domanski [9, 10]. This is based on a tube-by-tube analysis of a compact evaporator and accounts for local variations in tube-side heat transfer coefficients. On the air side, two-dimensional flow distributions can be specified at entry to the evaporator, providing a basis for evaluation of local heat transfer coefficients. The original EVSIM model has been altered significantly. Its workings are now in S.I. units and subroutines have been written to calculate the thermodynamic and transport properties of R-134a. The modified program has been named "EVSIM-2D" and all predicted results presented in this paper are based on this version.

The tube-side convective heat transfer model considers three regimes; (a) annular, (b) dispersed two-phase flow or (c) superheated vapor flow. The refrigerant-side heat transfer correlation of Wattelet et. al. [11] was used for the present work. The air side heat transfer coefficient is computed using equations from Gray & Webb [12] and the fin-tube contact resistance uses the correlation of Sheffield et. al. [13]. The formation of liquid on the tubes as a result of

condensation of ambient water vapour is represented with a continuous film model which takes account of the increased thermal resistance of the condensate film and of the associated latent heat transfer.

The pressure drop through the tubes is estimated using the Pierre [14] correlation for two phase flow and that of Fanning for single phase. Note that the refrigerant pressure drop is caused by (i) the frictional effects and (ii) the momentum change of the refrigerant it changes from liquid to vapor.

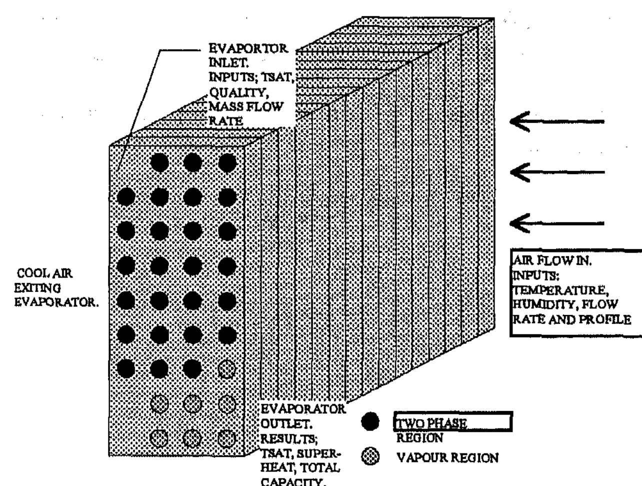

Figure 1: Geometric layout of single circuit plate-finned-tube evaporator - showing computer simulation input and output parameters. Note that the refrigerant flows in series through 33 tubes.

Properties of R-134a

Correlations for thermodynamic properties of R-134a have been published by a number of research groups, including [15-20]. The correlations of Kabelac [21] have been used for the present work.

Transport properties of R-134a are less widely publicized than the thermophysical properties and the data from different sources show less agreement. For the present work, liquid viscosity is calculated using an equation from Jung & Radermacher [22] whilst the vapor phase viscosities are found using data from I.C.I. Klea [20]. The liquid thermal conductivity is determined using a correlation from Jung & Radermacher [22] and that of the vapor is based on the correlation of Tanaka et. al. [23], the latter having been developed and validated with experimental data using R-134a.

Program Input / Output

Input and output data formats have also been revised from the original EVSIM format. *Refrigerant mass flow rate is now specified as input* rather than computed and the refrigerant exit pressure and temperature are computed rather than required as inputs. The air flow analysis has been changed so that less orthodox tube arrangements can be specified (e.g. vacant tube slots) and the program now provides for 2-dimensional air flow non-uniformity. Each tube is considered as a series of short segments where the heat transfer and condensation for each segment is influenced by the local variations in velocity and consequent variations in temperature, humidity and local heat transfer coefficient.

The program input and output parameters are illustrated in Figure 1.

Experimental Work

Refrigeration circuit

The evaporator under test formed part of a specially constructed refrigeration circuit, as shown in Figure 2. This was designed to provide maximum flexibility in the range of operating conditions achievable and was comprehensively instrumented.

The single circuit plate-finned tube type of heat exchanger tested (Figures 3, 4 & 5) had 33 tubes arranged horizontally in a 4 x 9 matrix (with 3 vacant slots). These were configured in a 25 mm in-line layout with a fin block length of 300 mm, a fin spacing of 4 mm and an external tube diameter of 9.5 mm. The total air side heat transfer surface area was 3.194 m^2. The refrigerant flows in series through 33 tubes, as illustrated in Figure 4.

The air temperature and humidity were determined in most cases by the ambient conditions in the laboratory. Air Inlet temperatures varied between 16 and 23°C and relative humidities ranged from 25 to 60% during the tests reported here.

An over-sized refrigerant compressor was used in conjunction with a hot gas by-pass loop. This provided evaporator mass fluxes in the range 40 to 400 kg/m^2s. Measurements of instantaneous refrigerant mass flow rate were made using a Pelton wheel type flow meter, installed in the liquid line. The condenser and hot gas by-pass flows were water cooled using plate heat exchangers. Flow through the evaporator was initially controlled with an internally equalized thermostatic expansion (TX) valve (Test Group A) but this was found to hunt unless the level of superheat was kept unreasonably high. Note that testing was carried out only when steady state refrigerant mass flow conditions prevailed. High superheat levels give rise to inefficient use of the available heat transfer area.

This is because a large number of tubes are involved in superheating. Overall heat transfer coefficients are low for these tubes and refrigerant pressure drop can be high. The situation was improved markedly when the an externally equalized (TEX) valve was fitted (Test Groups B, C & D).

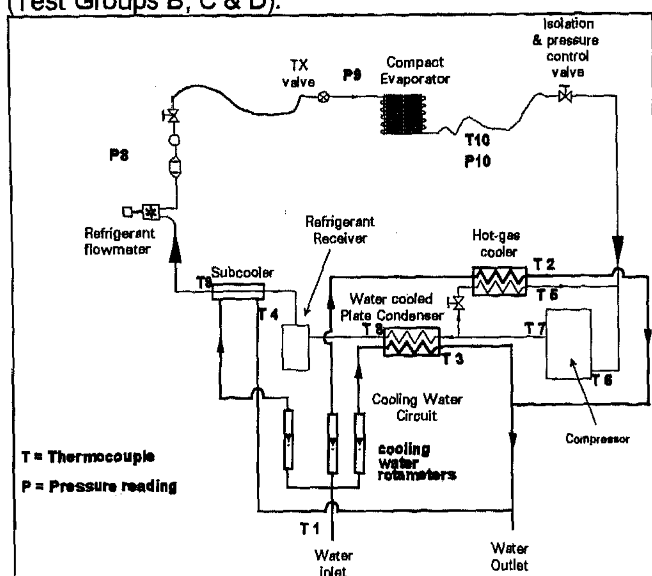

Figure 2: Schematic diagram of refrigeration circuit incorporating test evaporator.

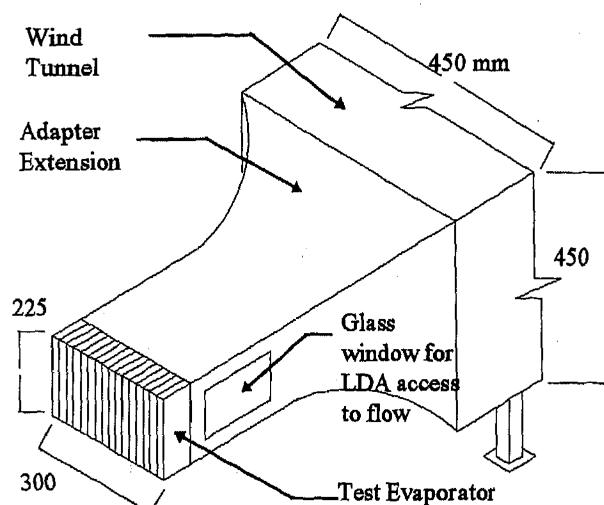

Figure 3: Evaporator mounting on open circuit wind tunnel.

Uniform Flow Test Rig

Air flow for the uniform case was provided by a blower wind tunnel (Figure 3). A converging duct was used to reduce the tunnel area to that of the evaporator and Plexiglas panes were inserted into this to provide optical access for LDA measurements. Also, holes were drilled at regular intervals, 50 mm upstream, to allow for insertion of a hot wire anemometer probe.

The hot wire was used to measure the flow velocity and turbulence characteristics whilst the LDA was used for calibration only. With this arrangement, the non-uniformity was 3.3% with average turbulence levels of 0.7%.

Non-Uniform Flows

The work discussed here has been directed at study of non-uniform air flow cases. Arbitrary profiles were produced by a dual inlet, forward bladed centrifugal fan (Figure 5). The fan is powered by a 3-phase 0.75 kW induction motor, fitted with a continuous speed control system. The duct connecting the fan outlet to the heat exchanger was fitted with Plexiglas side plates through which LDA and hot wire measurements were taken.

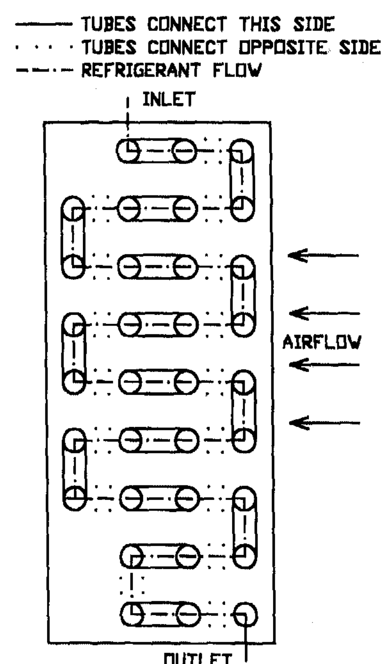

Figure 4: Refrigerant flow path through evaporator.

Air Flow Surveys (Non-Uniform Flow Tests)

Hot wire anemometry was used to measure both uniform and non-uniform velocity profiles. Measurements were made using a Dantec constant temperature anemometer system with a 5 micron x 1.25mm probe wire, supported on a long tube of 6 mm OD which was inserted into the flow stream in a plane, 50 mm upstream of the evaporator inlet.

The hot wire measurement system was calibrated before every test batch using a laser Doppler Anemometer (LDA) system. This was done in a wind tunnel under conditions of low turbulence. A best fit to Kings Law was effected by regression analysis.

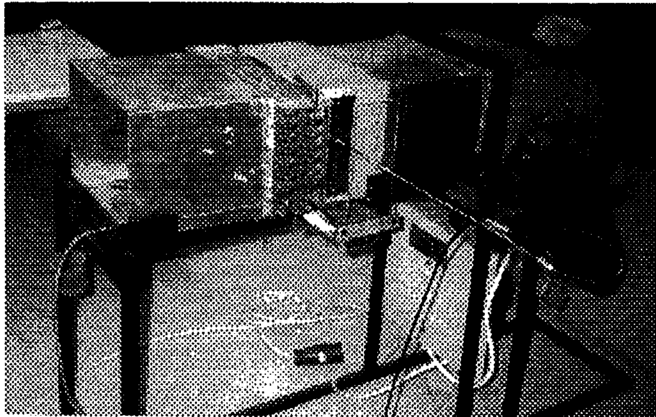

Figure 5: Photograph of centrifugal fan rig.

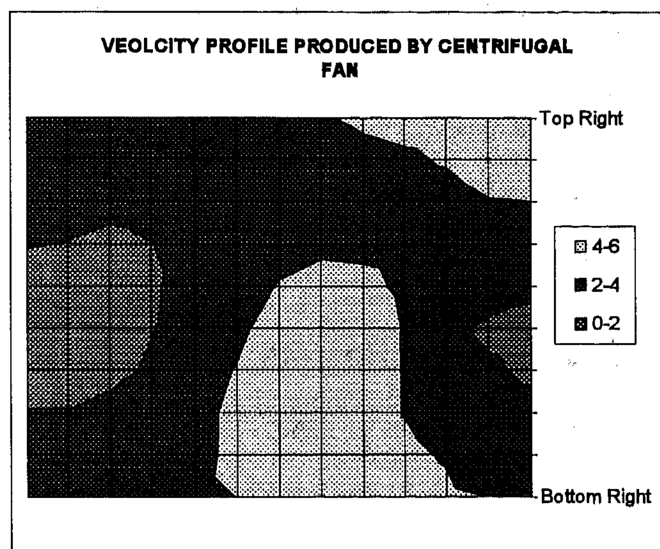

Figure 6: Two dimensional velocity distribution across the evaporator inlet - produced by forward bladed centrifugal (velocities in m/s). Mean velocity = 3.28 m/s. Non-uniformity = 31.5%.

The velocity profile produced by the fan is highly non-uniform (Figure 6), with a non-uniformity factor, *K*, of 31.5%, for this case where the mean velocity was 3.28 m/s. Air is induced from the two inlets at either side which meets centrally in the duct creating high flow velocities at the center of the duct. This is slightly asymmetrical due to the presence of a fan belt and guard on one side.

Figure 7 illustrates the turbulence intensity profile 50 mm upstream of the evaporator. For this test, the average turbulence intensity (over 130 measurement positions) is 30.3 %, with a local maximum of 70% and minimum of 10%.

Figure 8 summarizes the non-uniformity of the air flow velocity profile produced by the centrifugal fan over the full range of average velocities tested. Non-uniformity is calculated using equation (1).

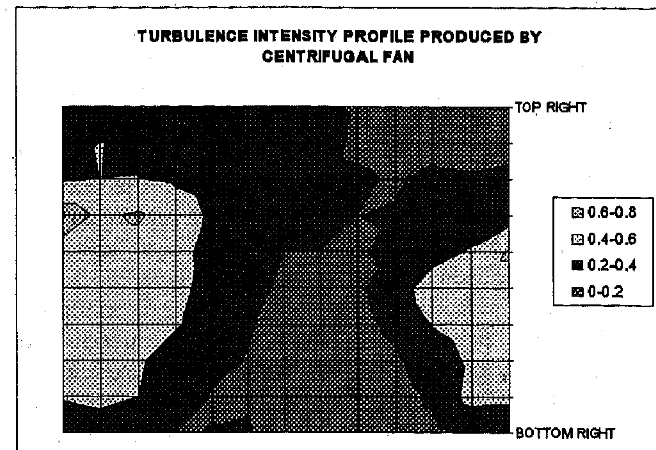

Figure 7 Profile of turbulence intensity created in centrifugal fan air flow profile for mean velocity of 3.28 m/s.

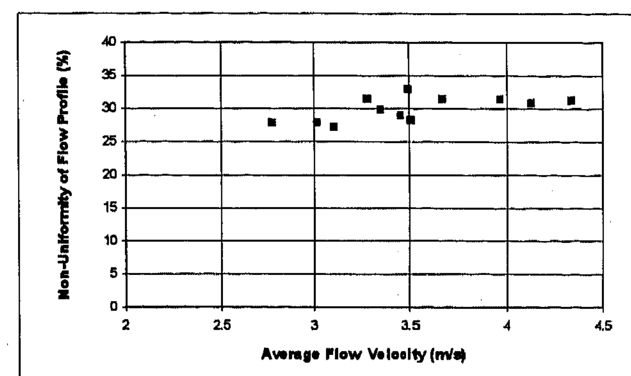

Figure 8: Non-uniformity (*K*) of velocity profiles produced by centrifugal fan at different flow rates.

Oil Concentration in Refrigerant

The presence of lubricant oil from the compressor flowing in the refrigeration circuit can alter the heat transfer process occurring in the evaporator. The mechanisms that cause this include alteration of the thermodynamic and transport properties, changes in the saturation profile due to pressure, temperature & concentration relations and to the retention of liquid refrigerant/oil mixture at outlet of the evaporator.

Measurements were made of the oil concentration in the refrigerant liquid line. The method used was similar to that described by McGovern [24] The results showed oil concentrations to be small, typically of the order of 0.2-0.4%. The effects of these quantities of lubricant on evaporation should be negligible.

Tube-by-Tube Refrigerant Temperature Profiles

Sixteen type K thermocouples were attached to the ends of various tubes in the coil. These facilitate detection of the onset and rate of superheating and study of the pressure profile (via saturation temperatures) along the coil. The thermocouples were secured mechanically and heat conductive paste was used to ensure good thermal contact with the tube surface. The temperature profiles along the coil were recorded using a sixteen channel 12 bit data logger, linked to a PC.

Since the quoted accuracy of type K thermocouples is relatively poor, the thermocouples used were individually calibrated over the temperature range of interest (-10° to +20°C). The measurement system errors were estimated to be ±0.2°C over the required range.

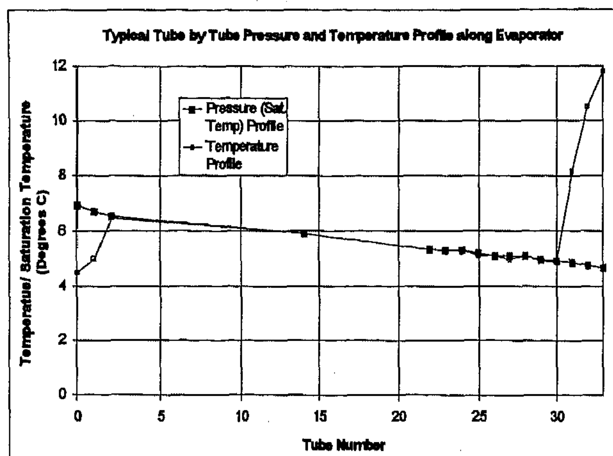

Figure 9: Tube-by-tube saturation pressure and refrigerant temperature profile along heat exchanger.

Results of the temperature profile from a typical test are shown in Figure 9. The temperature profile in the first few tubes is unexpected. The trend shown suggests the existence of a non-equilibrium sub-cooling effect, the refrigerant temperature being below the saturation temperature for the measured pressure. It is postulated that this is due to the under-pressure effect that has been observed for short tube and capillary tube refrigerant flow restrictors [25,26,27]. An important consequence is that local temperature differences are greater than might be anticipated, presumably increasing local rates of heat transfer.

Data Reduction

For the purposes of simulation verification the performance of the evaporator was evaluated in terms of the cooling capacity (kW) and the refrigerant pressure drop. The latter was determined by direct measurement of inlet and exit pressures. The cooling capacity $\dot{Q}$ was computed from the measured refrigerant mass flow rate $\dot{m}$ and change in specific enthalpy, i;

$$\dot{Q} = \dot{m}.(i_o - i_i) \qquad (2)$$

The specific enthalpy at inlet i_i is assumed equal to that of the liquid line and is evaluated at the prevailing liquid temperature. The inlet quality is calculated, assuming constant enthalpy across the expansion valve.

All other refrigerant properties were determined from measured data with the aid of correlations by Kabelac [21]. It has been assumed that the evaporator contains pure R-134a. The presence of oil or other impurities which may affect the properties of the working fluid are thereby ignored.

Experimental Results

Results are presented here from four distinct test groups, designated A, B, C & D;

Test Group A (Uniform Air Flow, TX Valve)

Measurements were made at 95 test conditions under conditions of uniform air flow, using the wind tunnel. These were based on one particular experimental rig configuration, using (i) a thermostatic expansion (TX) valve without external equalization, (ii) a relatively small compressor hot gas by-pass valve, and (iii) heating of ambient air before intake to the wind tunnel. All tests were confined to conditions of stable refrigerant mass flow, i.e. without 'hunting'. Refrigerant flow ranged from 1.7 to 14.5 g/s representing mass fluxes of 35-300 kg/m^{2}s. Typical superheat levels were 10-12 °C.

Test Group B (Uniform Air Flow, TEX Valve);

A total of 124 tests were carried out on a later rig configuration which used (i) an externally equalized expansion valve (TEX), (ii) a larger hot gas by-pass valve and (iii) no intake air heating. This arrangement allowed greater control of the

operating conditions and much lower levels of superheat (e.g. 5-7 °C) at outlet whilst retaining stable refrigerant flow conditions. As a consequence, overall temperature differences were generally lower and ambient water vapour condensation amounts were generally higher. Also, the nozzle hole size used in the TEX valve was smaller than that of the TX valve. This seemed to yield a more pronounced non-equilibrium refrigerant temperature profile in the first few tubes. Uniform air flow profiles were provided by the wind tunnel for this test group.

Test Group C (Non-Uniform Air Flow, TEX Valve);

97 additional tests were performed on the same refrigeration circuit and heat exchanger as Group B but with a highly non-uniform air flow, supplied from the centrifugal fan. The test data cover the range of average air flow velocities from 2.6-4.4 m/s, refrigerant mass fluxes of 180-320 kg/m^{2}s, air inlet temperatures of 17 to 23°C and relative humidity of 25-55 %.

Test Group D (Uniform Air Flow, TEX Valve);

40 tests were performed with the same rig configuration and similar conditions as for Group C but with uniform flow. In particular, care was taken to achieve similar total volumetric air flows or average velocities. The objective was to facilitate straight-forward comparison of results between uniform and non-uniform situations.

Experimental Comparison of Uniform vs. Non-Uniform Test Conditions.

Comparison of experimental results obtained from uniform and non-uniform test cases (Groups D & C respectively) are presented in Figures 10 and 11. These show overall heat transfer coefficients as a function of refrigerant mass flow rate at two different mean air velocities, 2.71 and 4.34 m/s respectively. These tests were all conducted with similar air inlet temperature and humidity conditions and equal volumetric flow rate (or average air flow velocity). The overall heat transfer coefficients are based on the following definition of temperature difference;

$$\Delta T = T_{air,in} - T_{ref,in} \qquad (3)$$

$$U_A = \frac{Q}{\Delta T . A_o} \qquad (4)$$

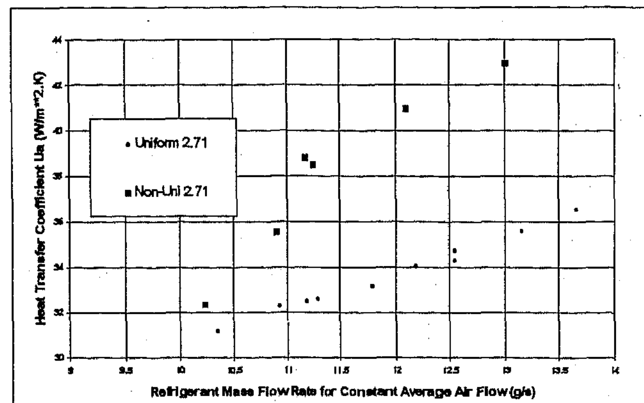

Figure 10: Experimental results showing overall heat transfer coefficients with uniform and non-uniform air flow at an average velocity of 2.71m/s. (Test Groups D & C). Air inlet temperatures were 18.9°C and 16.7° C for the uniform and non-uniform cases respectively. Relative humidity was 47% for all cases.

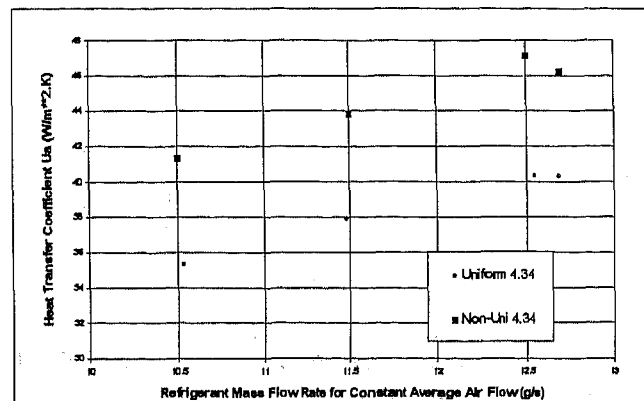

Figure 11: Experimental results showing overall heat transfer coefficients with uniform and non-uniform air flow at an average velocity of 4.34m/s. (Test Groups D & C). Air inlet temperatures and relative humidities were 21.0°C, 50% and 20.8°C, 44% for the uniform and non-uniform cases respectively.

These results show that the performance of the evaporator is superior by about 15% for the case of non-uniform air flow at a given volumetric flow rate. Note that the degree of outlet superheat was approximately constant for each of these test cases and that, for a given refrigerant mass flow, very similar amounts of heat transfer (kW) occurred. This was achieved with a lower temperature difference between fluids for the non-uniform flow conditions. The air inlet temperatures were determined by ambient conditions in the laboratory and the refrigerant evaporating temperatures were therefore proportionately higher for the non-uniform air flow cases.

The superior heat transfer characteristics observed with non-uniform flow seems to be primarily due to the enhancement of the air side heat transfer coefficients. These seem to be largely the result of the high levels of turbulence that are associated with the air flow pattern generated by the centrifugal fan.

Simulation results comparing uniform and non-uniform cases suggested that the performance of the evaporator would be *degraded* by the same distribution of air flow, if the effects of turbulence are ignored. With levels of non-uniformity in the region of 30%, the simulated performance degradation was of the order of 2 to 3.5%.

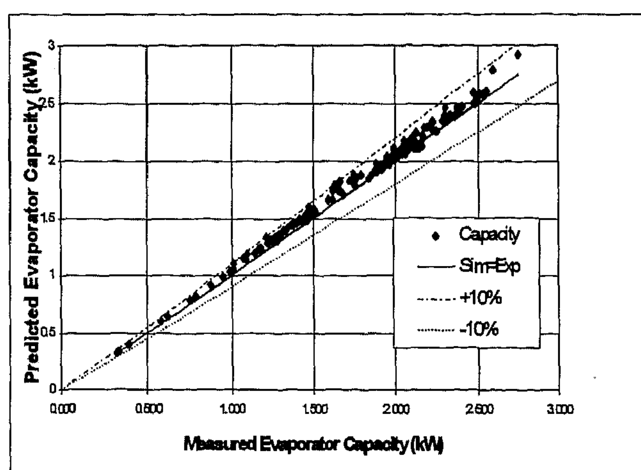

Figure 12: Simulated v measured evaporator capacity for uniform flow tests with TX Valve. (Test Group A, 95 test points).

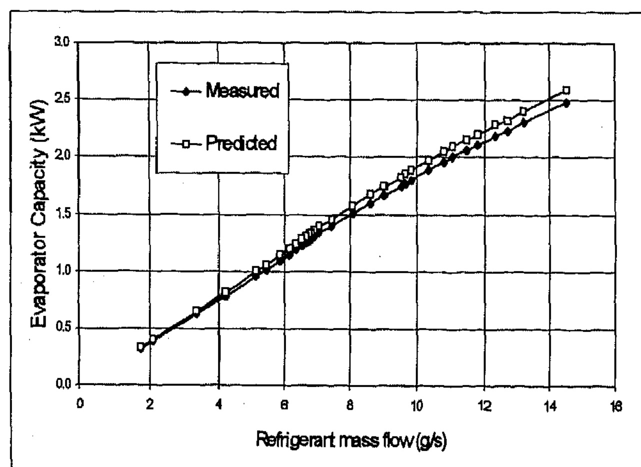

Figure 13: Simulated v measured evaporator capacity as a function of refrigerant mass flow rate at a constant uniform air flow velocity of 2.9 m/s, TX valve (33 data points, sub-set of Group A).

Comparison of Measured and Predicted Results

Test Group A (TX Valve, Uniform Air Flow)

Figure 12 shows a comparison of measurements and predictions of thermal capacity for the 95 test points of Group A. These cover a very wide range of operating conditions. All of the predicted data lies within -10% and +10% of the measured values, with an average over-prediction of 5%.

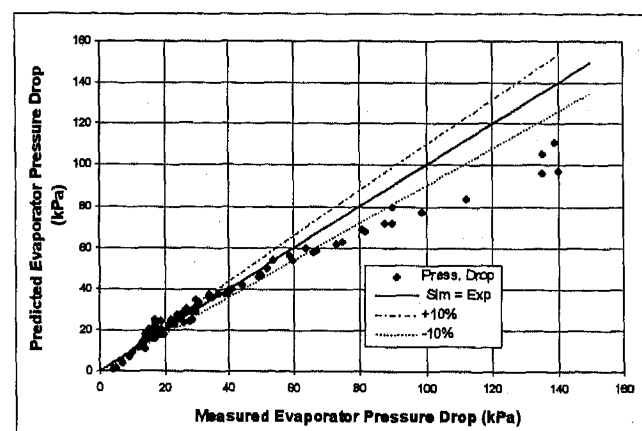

Figure 14: Simulated v measured refrigerant pressure. (Test Group A, 95 points, TX valve).

Results from a 33 point sub-set of the Group A tests are shown in Figure 13, where measured and predicted data are plotted as a function of refrigerant mass flow rate, for a constant mean air velocity of 2.9 m/s (uniform), with inlet air temperature of 22.5°C and relative humidity of about 29%.

The mean ratio of simulated / measured capacity is 1.044 for the test batch shown in Figure 13. Maximum and minimum ratios are 1.049 and 1.025 respectively and the standard deviation is .0005 about the mean. The agreement between modeled and experimental trends is clearly satisfactory. As discussed below, study of the refrigerant exit conditions yields some further insights into the reasons for the over-prediction.

Figure 14 shows the trends in both measured and predicted refrigerant pressure drop between evaporator inlet and exit for Test Group A. Absolute values of predictions are very close to the measured values for refrigerant mass flows up to about 12 g/s (250 kg/m^2s) and measured pressure drops below 70 kPa. Above this, the simulation underestimates the pressure drop significantly. The ratio of simulated to measured pressure drop has a mean value of 0.97.

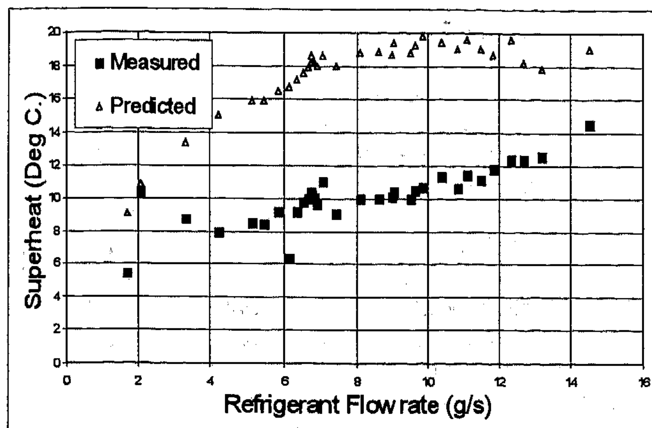

Figure 15: Simulated v measured refrigerant superheat at evaporator exit, as a function of refrigerant mass flow rate with constant uniform air flow velocity of 2.9 m/s, TX valve (33 data points, sub-set of Group A).

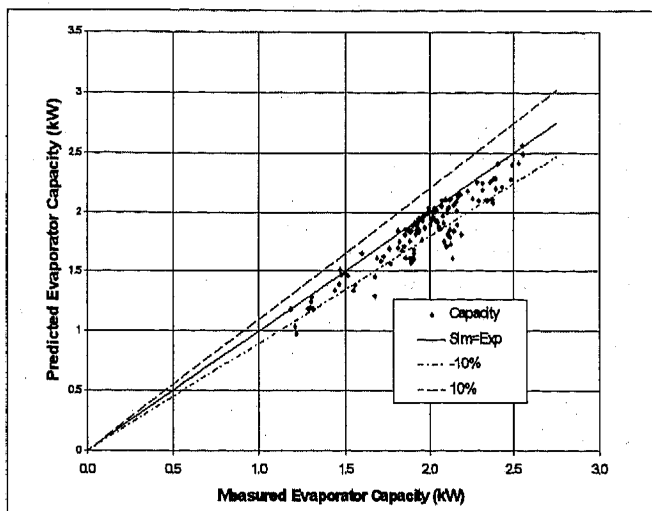

Figure 16: Simulated v measured evaporator thermal capacity for Group B Tests (124 points, uniform air flow, externally equalized TEX valve).

Figure 15 gives additional insight into over-prediction of thermal capacity for test Group A. Steady operation of the heat exchanger with the TX valve could only be achieved under conditions of relatively high superheat (typically 10-12°C). The 'minimum stable signal' for the TX valve is higher than that of the externally equalized TEX valve used in later tests (superheat 5-7 °C). As a consequence, a large number of tubes are dedicated to superheating in Test Group A and the heat exchanger is being used in an unrealistic and inefficient manner. Overall heat transfer coefficients in the later tubes are relatively low and the thermal capacity of the air side is far greater than required.

Test Group B (TEX Valve, Uniform Air Flow)

The results of the thermal performance predictions for test Group B (Figure 16) show a contrasting trend with those presented for Group A. The simulation under-predicts the data for this rig configuration, with an average predicted / measured ratio of 0.94 for the 124 Group B test points. The minimum ratio was 0.76 whilst the maximum was 1.04.

The refrigerant pressure drop was over-predicted by an average of 8% for Test Group B. Significant scatter is evident in Figure 17 but the more severely over-predicted points tend to occur at lower refrigerant flows. Note that significantly fewer tubes are involved with superheating in Test Group B than with Group A. The difference between air inlet and refrigerant evaporation temperatures is also lower for the Group B tests (typically 17-24°C for Group A and 14-19°C for Group B) and the ratio of air mass flow to refrigerant mass flow is lower, thus reducing the ratio of air-side to tube-side thermal capacities.

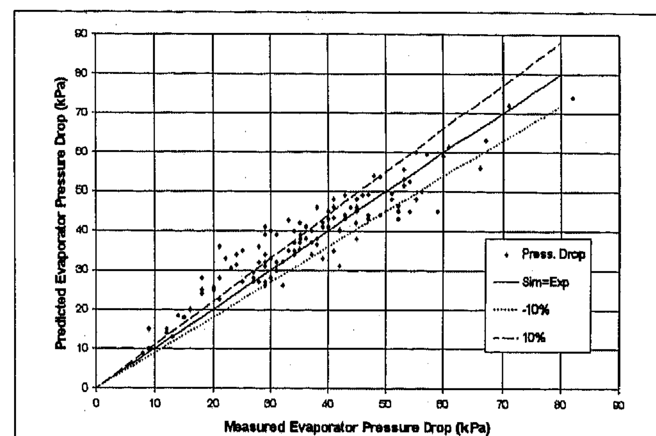

Figure 17: Simulated v measured refrigerant pressure drop across for Group B Tests (124 points, uniform air flow, externally equalized TEX valve).

The humidity levels hence the amount of condensation occurring are higher test Group B. Also, test cases involving larger temperature differences (and hence lower saturation temperatures) also tend to yield predictions which are in closer agreement with the measurements. The precise definition of log mean temperature difference used in the simulation for individual tube segments has a significant influence on the estimated heat flux. Uncertainties here, combined with possible inaccuracy in the air-side heat transfer correlation may be responsible for the poorer prediction accuracy. Also, the non-equilibrium inlet sub-cooling effect, illustrated in Figure 9, was observed to be more pronounced for tests in Group B.

This may not have been accounted for adequately in the simulation.

Test Group C (TEX Valve, Non- Uniform Air Flow)

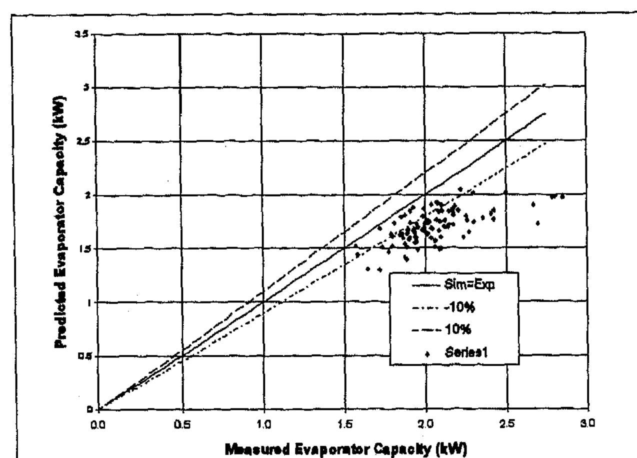

Figure 18: Simulated v measured evaporator thermal capacity for Group C Tests (97 points, non-uniform air flow, externally equalized TEX valve).

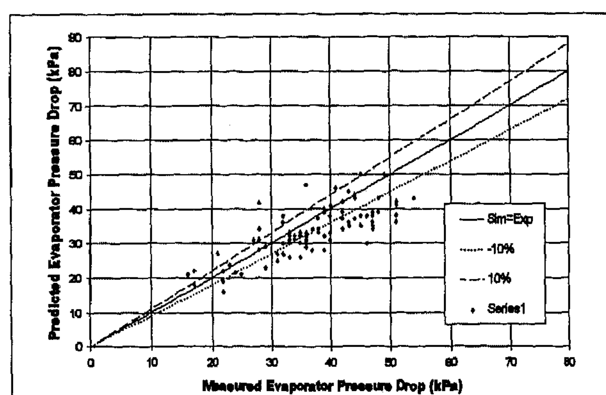

Figure 19: Simulated v measured refrigerant pressure drop across for Group C Tests (97 points, uniform air flow, externally equalized TEX valve).

Prediction of thermal capacity and pressure drop (Figures 18 & 19) for cases involving the non-uniform air flow profile created by the centrifugal fan is less satisfactory than that observed with the uniform flow cases. The simulation under-predicts consistently and the average ratio of predicted to measured capacity is 0.84, with minimum and maximum ratios of 0.64 and 0.98 respectively. The best matches between predictions and measurements were obtained for situations involving relatively high ambient air humidity. In these cases the latent capacity predicted is noticeably high despite experimentally observed levels of condensation being low.

CONCLUSIONS

An extensive series of tests have been carried out over a very wide range of operating conditions on a single circuit plate-finned tube type of refrigerant evaporator, exchanging heat between ambient air and R134a. Tests were confined to situations where the refrigerant flow was stable with time. Uniform and non-uniform air flow distributions were applied with the objective of studying the heat transfer effects of non-uniformity. Uniform flows were supplied from a wind tunnel whilst a centrifugal fan and duct were configured to provide forced flow with complex velocity and turbulence distributions. The latter were characterized experimentally using hot wire anemometry.

The experimental results revealed that heat transfer performances were 15% better with a turbulent non-uniform flow than those observed at the same volume flow of air with a uniform velocity distribution.

A computer simulation program is also being developed for ultimate use as a tool capable of assisting with design optimization in cases involving non-uniform flow. Extensive comparisons were made between predictions and measurements for a number of different rig builds. Predictions matched measurements satisfactorily for a group of tests (Group A) where the air flow was uniform and under conditions of relatively high average temperature difference between the two fluids. These experimental conditions were achieved with a thermostatic expansion valve which used internal pressure equalization.

A change to a different expansion valve configuration, which involved use of external pressure equalization, permitted experiments to be conducted at lower overall temperature differences and with higher ratios of air-side to tube-side thermal capacities (Groups B,C,D). Predictions matched measurements to a less satisfactory degree for these cases where a uniform air flow was retained.

The experimentally observed enhancement in heat transfer performance for non-uniform flow cases was not reflected in the simulation results (Group C). In fact, a slight degradation in performance was predicted. The reasons for these discrepancies are under investigation. The theoretical treatment of condensation on the air side requires many simplifying assumptions. However, the latent heat transfer has been kept to a minimum and the under-prediction observed with Group C cannot be adequately explained by this phenomenon alone. It

should be noted that the air-side heat transfer correlation used did not take account of the turbulence characteristics of the incoming air stream. This is thought to be the most significant reason for the observed enhancement under non-uniform conditions.

Optimization of Fin Louver Design Based on CFD

S. Bouzida and C. Mignot
Valeo Engine Cooling

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper presents an optimization methodology for the design of fin louvers of compact heat exchangers based on 2-D CFD calculations. The mesh generation and its automatization is described. The validation of the methodology and the results of this validation are presented. Finally, an example of application is given.

INTRODUCTION

Compact heat exchangers, like the ones commonly used in the car industry (radiators, condensers, ...), are based on the following technology: two fluids (air and water, air and oil or air and air) exchange energy by conduction and convection through surfaces (usually aluminum or copper). The first fluid, usually liquid, flows through pipes, which represent the direct surface of the exchanger and can be modelized by its internal thermal resistance (Y_{int}). The second fluid, usually air, flows externally around those pipes to exchange heat via convection which is modelized by the external thermal resistance (Y_{ext}). Looking at the order of magnitude of both resistances, it turns out that

$$Y_{ext} >> Y_{int} \quad \text{and} \quad Y_{ext} \cong 10\, Y_{int}$$

For that reason, the external surface is increased by a factor 10. This is done by adding a row of fins between the tubes of this exchanger (*fig.*1).

In most cases, this indirect surface represents between 70 to 90% of the total exchange area. More over, this surface is louvered to increase the flow circulation of the fluid. Again, depending on which particular heat exchanger we have, the louvered surface represents up to 90% of the indirect surface (*fig.*2). In other words, almost 80% of the total exchange surface is louvered.

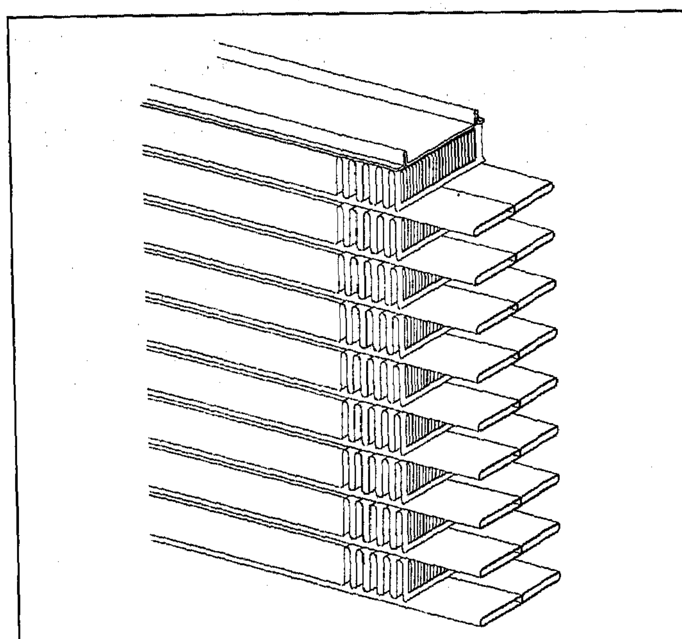

FIG. 1 - Fins in a heat exchanger

The thermal resistance is mainly external, so improving the performances of an exchanger implies improving its external surface and in particular, its louvers geometry (*fig.*3). In order to do so, we need to have a better understanding of the flow structure in between these louvers and on the phenomenon that occur at these small scales. Typically, the length of a louver is between 1 and 2 mm long and local experimental measurements are hard to set up. A lot of questions concerning the flow pattern still remain unanswered. For example, is the flow steady or unsteady (unsteadiness comparable to a Karman vortex street in the case of a flow past a cylinder)? Is there a boundary layer separation on each louver or only on a few of them? Is the recirculation of the flow good for the heat exchange or is it something that should be avoided?

Clearly, the lack of information on what is happening between the louvers makes predictions very difficult.

Unfortunately, too many parameters are involved in a proper study and the systematic design of a new prototype becomes too costly and time consuming.

We selected a C.F.D. approach in order to optimize the geometry and lower the cost and time of development. If it's true that CFD can turn out to be cheaper and faster and at the same time give satisfying results, it's also true that it can sometimes be the opposite: if it takes 3 persons on a full time basis to built a 3-D model, in a period of 6 months, with an expensive code and computer and, in the end, get a couple of results that never get validated, we can be very septic concerning the added value of CFD in a project development and the saving of time and money previously mentioned. To avoid this, we have limited ourselves to the study of a 2-D case. Of course, a 2-D modelization is not always possible due to a geometry which is purely three dimensional but with some reasonable assumptions, we show that in most cases of our applications, these assumptions hold. Also, the 2-D approximation might be less accurate than a full 3-D model but the gain in time is tremendous.

A full validation of the methodology was conducted using experimental results of two types of condenser fins. This methodology does not pretend giving the absolute performances of an exchanger that has never been tried but does give the rate of improvement of a new geometry as compared to the old one.

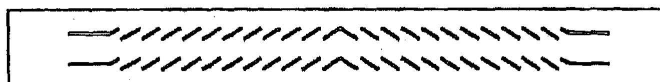

FIG. 3 - cross section normal to the fin surface

MESHING / PRE-PROCESSING

A REALISTIC MODELIZATION - In a C.F.D. study, the most time consuming part is with no doubt the pre-processing: creating the geometry and meshing the domain of interest is usually, depending of course on the geometry we are dealing with, a task that can take up to several weeks. So the idea of the study that we wanted to make was to reduce this time by as much as possible via an "automatic model generator" so that not only we could spend more time on the post processing which is the only part of interest really for the engineer but also extend the study to a bigger amount of cases and applications. At the same time, it would allow us a higher reactivity so that we can meet the development team needs in terms of time and schedule. Also the validation stage could be made in a shorter time by comparing the numerical results with the experimental results. Our main concerns and constrains were as follows:

-Create a model that would make a minimum of assumptions so that we simulate a more realistic geometry (too many modelizations are idealistic and therefore suffer the confrontation with the experiment).

-Adjust the meshing so that the boundary effects are well predicted without ending up with huge models that would take weeks in terms of CPU time.

-Reduce the pre-processing time by at least a factor 10.

To fulfill all these requirements, the idea of a parametric meshing program came. A first program written in FORTRAN was done. This program generates a serie of commands (stored in a file) which gradually builds up the model. At the beginning, we had to choose the parameters that we wanted to leave free for the user to change knowing that at this point the only difficulty was to integrate these parameters in the program. After having gathered all the potential parameters that were of interest for us in our applications (there are 18 of them), we were ready to create the meshing itself built on the geometry defined by the vertices. Those 18 parameters or "degrees of freedom" that are completely defining the geometry are: (*fig.* 4, 5 and 6)

- The flat plate length : that's the part of the domain which is not louvered.

- The number of louvers

- The stretching coefficient of the first louver: for the case where we want the first louver to be longer or shorter. Indeed, in almost all cases, the very first and very last louver of the geometry is half the size of a louver. This is due to the fact that the first and last louvers are cut on only one side. Nevertheless, it is also possible to design the louvers in such a way that these louvers are actually longer or shorter than the standard half louver length. (figure 5 shows the case where this louver is equal to the louver length). This parameter allows the user to control this particular length.

- The stretching coefficient for the central louver: for the case where we want the central louver to be longer or

shorter. This is exactly the same thing than seen previously. This parameter allows the user to have control of the central louver length.

- The core thickness

- The fin pitch: distance between 2 fins

- The gage: thickness of the metal sheet

- The mean angle of the first row of louvers

- The mean angle of the second row of louvers

- The half-louver angle for the first row

- The half-louver angle for the second row

- The central-louver angle for the first row

- The central-louver angle for the second row

- The central flat length

3 more parameters were defined for the conditions of the problem itself:

- Upstream mean velocity

- Wall temperature

- Upstream temperature

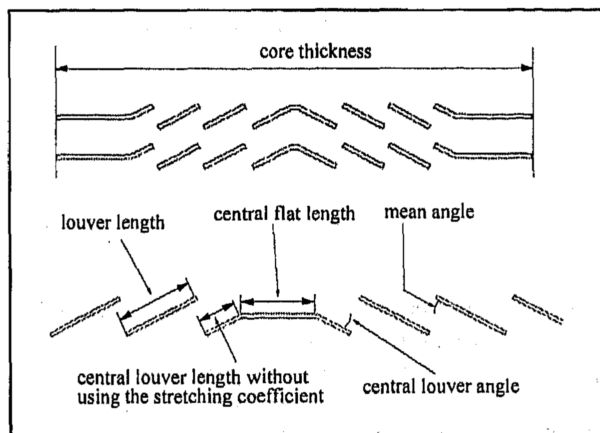

FIG. 4 - geometrical parameters

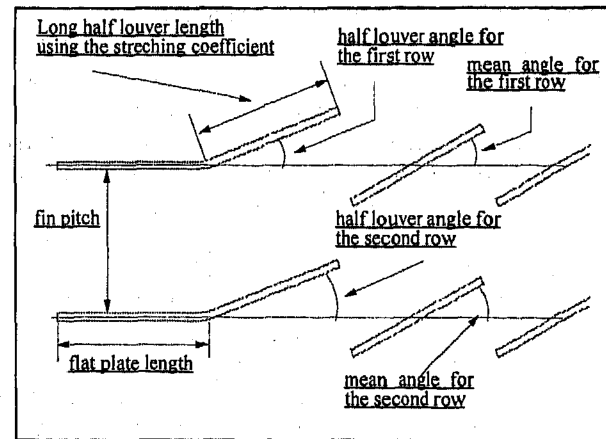

FIG. 5 - geometrical parameters

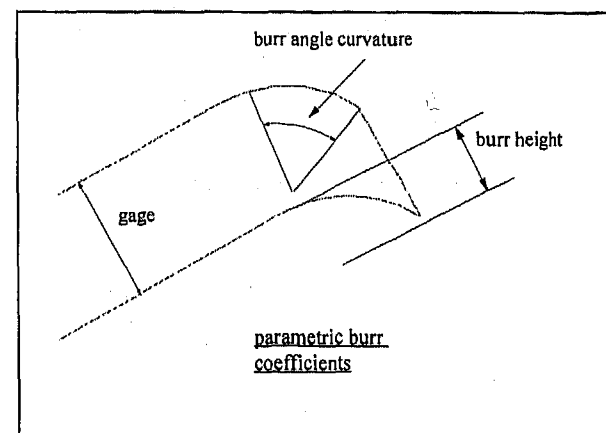

FIG. 6 - parameters related to the burrs

Now, other parameters were introduced. Their purpose was, as we mentioned previously, to fit reality as much as possible. A close observation of the production helped us identify the potential degradation modes. Taking into account these degradation modes would quantify their effects and give an estimation on the consequences they have on the performances of the exchanger. Those parameters and what they represent can be described as follow:

- The burr angle curvature: when we represent the burrs, they are represented by a radius (which is the burr height itself) and the burr angle curvature which gives the rate of "distortion" of the burr.

- The angle dispersion by default (ADD) and angle dispersion by excess (ADE): We have noticed that during the fin manufacturing, a small dispersion of the angle distribution could occur. Indeed, if on "paper" the angle was, say α, a close observation of what the angle really was after manufacturing showed that the angle was never exactly α. In fact, the value of the angle was $(\alpha + \Delta\alpha)$ where $\Delta\alpha$ could be positive or negative. A general law of this dispersion couldn't be drawn, in other words, if in the first row of louvers the first 3 louvers had a negative $\Delta\alpha$ and the next 4 a positive $\Delta\alpha$, the second row of louvers would show a totally opposite distribution. We have also noticed that the magnitude of this dispersion

was closely related to the age of the industrial tools, the older the tools, the bigger it was. The conclusion was that the angle dispersion was random and the question that arose from this observation was the influence of this angle dispersion. Therefore, we have introduced those two parameters which represents precisely this random angle dispersion. The user can, after having selected all the angles of his geometry, decide on the magnitude of the angle dispersion but has no control on which louver is going to be affected by the dispersion and by how much within the specified range. As an example, let's consider a heat exchanger whose fins have 2 blocs of 6 louvers. "On paper", all the angles were given equal to 25°. Looking closely at how the prototype really turned out to be, the angle measurements gave respectively:

24.0° 25.0° 23.0° 24.0° 27.0° 25.5°

and from the same prototype another measurement on different louvers gave:

23.5° 26.5° 24.0° 23.0° 25.5° 25.0°

now, the program that we present takes this random distribution into account with the two parameters mentioned. The user has to set a value for the mean angle and then set the values of the angle dispersion by default and the angle dispersion by excess. In this particular example, those values were:

mean angle = 25.0 °
ADD = 2.0 °
ADE = 2.0 °

Once the model was built, the angle distribution was:

24.2° 26.2° 25.3° 23.7° 24.8° 25.9°

At this stage, the user knows that the model represents the manufacturing dispersion, knows its order of magnitude but does not know exactly beforehand which louver is affected and by how much exactly. Of course, it is also possible to modelize a geometry with no dispersion at all. But the idea of modelizing reality by introducing a random angle distribution according to the dispersion specified by the user is, although it sounds like a paradox, a way to stick more to reality to a certain extent. The manufacturing dispersion (even small) exists? Let's modelize it.

- The louver burr: Another imperfection of manufacturing is the burr on the edge of the louver created when the tools cut the metal sheet (*fig.*7). We have noticed here again that the older the tool, the bigger the burr and the question was to find out what consequences they had. Were they improving the efficiency of the exchanger or were they making things worse? In other words, is it really necessary to spend money on maintenance or it's not worth it after all. We tested them and we found out that some burrs were "good ones" and others "bad ones". Without really understanding why, we thought that taking them into account in our modelization was necessary.

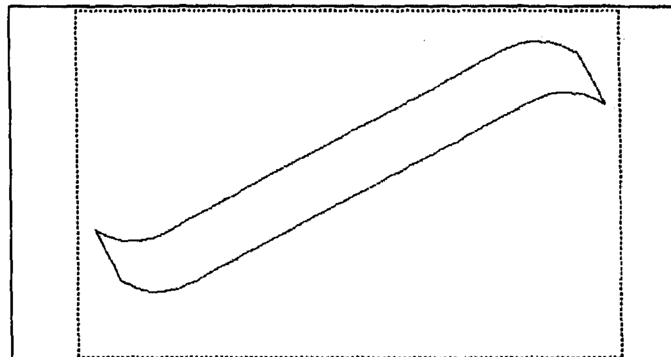

FIG. 7 - modelized louver with burr

- The burr height by default (BHD) and burr height by excess (BHE): Here, we have exactly the same approach than before. The burr height is random and so we have introduced its random distribution in the modelization. The user can specify the maximum height that the burr can have above its reference value and the maximum height that it can have below its reference value. But the actual value of the burr height is not directly none by the user. Again we have modelized the unknown of manufacturing imperfections.

- Two rows of louvers: Another aspect of the degradation of the manufacturing tools is the variation of the angle dispersion from one row to another. Indeed, we have observed that in a few cases, the fins would have one row of louvers at a constant angle α and a second row at a constant angle β with $\alpha > \beta$ (*fig.*8). This is due to the fact that one roll is a driving one and the other roll is a driven one, and so the stresses in the metal are different from one row to the next one.

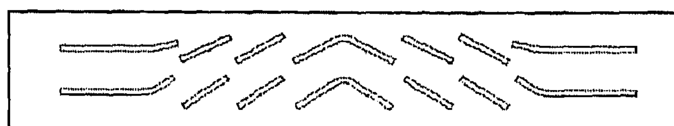

FIG. 8 - Two rows of louvers with angle dispersion

Therefore the modelization of two rows of louvers would allow us to anticipate the behavior of an exchanger in this particular degradation mode. This is the reason why all the simulations that we present in this paper are based on two rows of louvers instead of one

THE MESHING - Five more parameters were introduced and are related to the meshing itself. The idea was to allow the user to modify certain aspects of the meshing by just modifying the value of these parameters.

- The number of cells in the boundary layer (NCBL): To predict the heat transfer at the boundary with accuracy, it is necessary to get an accurate solution of the velocity field itself. Indeed, the heat transfer coefficient h, just like

the friction coefficient Cf, is proportional to the velocity gradient at the boundary. Therefore, the quality of the mesh in this region is of primary importance. This implies that close to the boundary, the mesh must be finer than in other parts of the model where the mesh can be left coarse. The program we present makes a first calculation of the boundary layer thickness based on a blasius solution for a flat plate. It is given by:

$$\delta = 5\sqrt{\frac{\nu L}{U}}$$

where L represents a characteristic length scale which for us could either be the pitch or the louver length and U the upstream velocity. Then we build a "skin" of cells, of thickness d, surrounding the louver in which we put the "appropriate" number of cells (*fig.*9&10). This "appropriate" number of cells was determined comparing the solution given by the code in the simple case of the flow over a flat plate with the exact solution. But, instead of fixing its value once for all, we decided to leave this new parameter free so we could adjust better to each new problem.

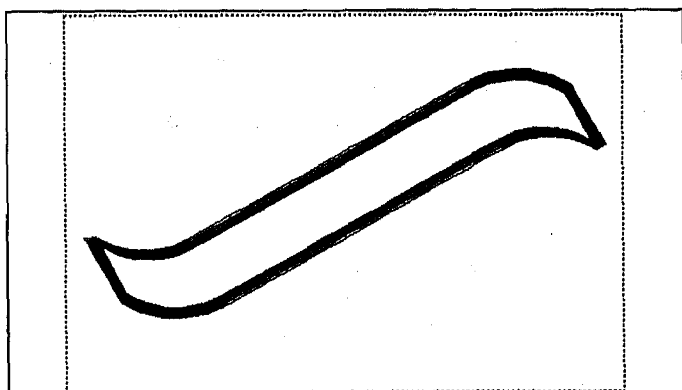

FIG.9 - layer of cells around the louver

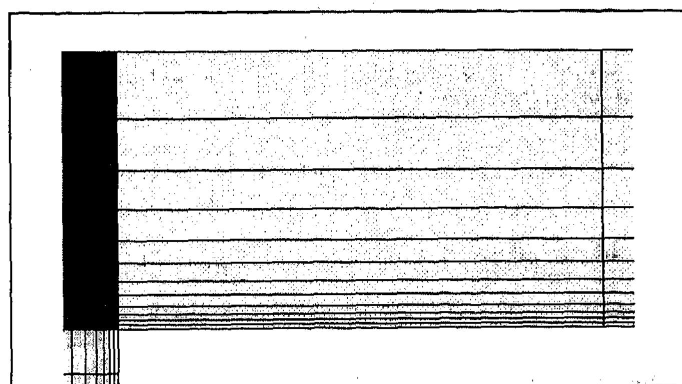

FIG. 10 - Non-linear repartition of cells within the boundary layer.

-The boundary layer thickness coefficient (BLTC): We saw that the last parameter could allow us to put a large number of cells in the boundary layer (B.L.) but the problem is that the numerical models usually do not accept transitions from large cells to small cells which induce numerical instability and convergence problems. Therefore the trick was to increase the value of the B.L. thickness by a factor chosen by the user (usually between 1 and 3) and at the same time keeping the number of cells within the B.L. constant. This way the size of the cells is increased and the transition from small cells to large cells is smoother. But again, this technic had the disadvantage of increasing the size of the first cell at the boundary, and therefore to lose accuracy. This problem was avoided by introducing the next parameter.

- Non-linear repartition of cells within the boundary layer (LRC): This parameter is simply a function defined in the code and allows a non linear repartition of cells along a direction. This is possible with practically all meshing code but here this parameter is fixed by the user in a file and the non-linear distribution of cells is applied throughout the model. In practice, it means that close to the boundary the cells are very small (which is good for the accuracy) and at the edge of the B.L the cells are almost as big as the external coarse mesh (good for the smooth transition).

- Number of cells along the curvature: The burr that we have is defined by its height and its radius of curvature. If its height is small its radius of curvature is small. This parameter simply defines the number of cells that we should put along the curvatures.

- The concentration of cells throughout the model: This last parameter allows the user to increase the total number of cells uniformly throughout the model. Increasing its value implies refining the mesh. Its purpose is to increase or reduce the number of cells and therefore the CPU time depending on the level of accuracy expected.

Some of these parameters may not sound of primary importance but they turned out to be very useful. With very little effort, we could determine things like the effect of the meshing on the solution, the effect of the number of cells within the boundary layer, avoid quite easily the problems due to the size of cells and so on...The important thing is that now that the program is written, very little time is spent on building the model. The user just has to give the values of the different parameters in a separate file, the program creates the files of the model in 0.8 second (CPU time). And then it takes the code another two hours (more or less depending on the number of nodes) to completely achieve the model.

EQUATIONS, BOUNDARY CONDITIONS AND FURTHER ASSUMPTIONS - We solve the Navier-stokes equations, with the viscous term, in steady state. Two types of flow are considered: Laminar flow and turbulent flow. In the case of the compact heat exchanger the flow is for low inlet velocity ($\cong$ 2 m/s) laminar with Re < 1000 and for higher flow rates where the inlet velocity is about 6 m/s the flow can be turbulent with Re > 1000. For this last case, the turbulent model used is a K-ε with a mixing length assumption. It is

argued by a lot of people that the K-ε is known to be wrong but we decided not to spend time on validating which model was best adapted because for one it was difficult to check with experiment since local measurements are almost impossible and for two we were not looking at absolute values but at the differences between two values given by the same turbulent model. Nevertheless, all the results presented in this paper were established using a laminar flow. The reason is that the Reynolds numbers are not "big" enough and even in the range 1000 - 2000 it is not obvious that turbulence plays an important role. In our applications, we believe that we are in the transition between a laminar flow and a turbulent flow and that the use of a turbulent model might not be well suited. Turbulence increases the heat transfer but using a turbulent model if the flow is laminar might lead to wrong results. The louvers are there to start a boundary layer at their leading edge where the heat transfer coefficient is the most important (*fig.*11-a). This is precisely this property of the heat exchange coefficient that we use when we increase the heat exchange by increasing the numbers of louvers. This is also clear when we represent the heat flux along the louvers as shown in figure 11-b where we see the areas and the parts of the louvers that are thermally speaking the most active : the louver leading edges.

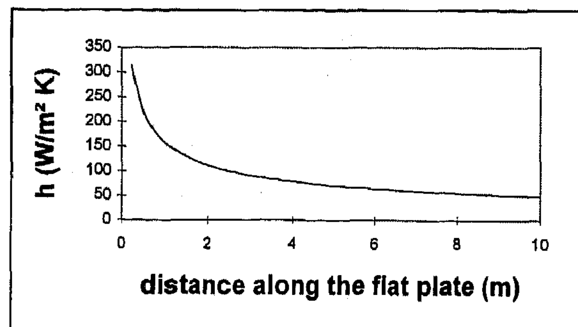

FIG. 11-a - heat exchange coefficient along a flat plate

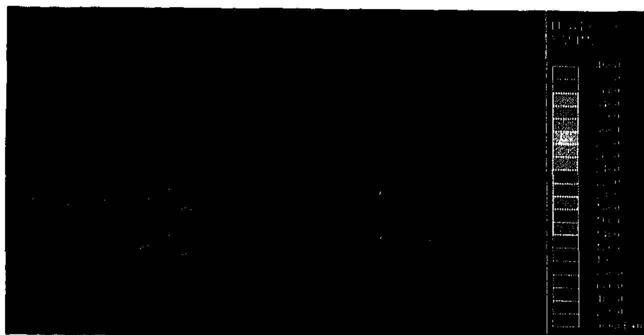

FIG. 11-b - heat flux along the louvers

We also solve the energy equation to get the temperature distribution in the flow field. Moreover, the flow is considered incompressible so that density is not a function of pressure but a function of temperature only:

$$\rho = f(T)$$

There are 5 types of boundary condition in the model:

- Inlet boundary condition: we prescribe the upstream velocity

- Outlet boundary condition: we insure the conservation of mass

- Cyclic boundary condition: traduces the periodicity of the model

- Symmetric boundary condition: condition for the modelization to be 2D

- Wall boundary condition: with no-slip + fixed constant temperature (*)

(*) the fixed temperature at the wall is an assumption. Unless we decide to mesh the metal, which would imply solving the conduction equation in the metal as well, we couldn't prescribe what the heat flux was at the boundary otherwise we would have been giving the solution in the B.C. since the heat exchange is an unknown that we are looking for. But in our case, the biot number (Bi) is small enough which implies that conduction is much greater than convection so that in first approximation we can consider the fin at a constant temperature.

$$Bi = \frac{L\,h}{k}$$

L = characteristic length scale
h = heat transfer coefficient
k = conductivity in the metal

(example: l=0.001 h=100 k=200 $\Rightarrow$ Bi= 0.0005 << 1)

Also, from experiment we know that the fins efficiency is close to 1 which again confirms this assumption. Another assumption is to claim that the flow is 2D. Indeed, it is true when the ratio

$$r = \frac{(\mathit{fin\ pitch})}{(\mathit{fin\ hight})} \ll 1$$

(example: pitch = 1.3 mm and fin height = 11

$\Rightarrow$ r = 0.118)

this approximation is no longer valid for r > 0.3 or 0.4 where the flow is purely 3D (*fig.* 12).

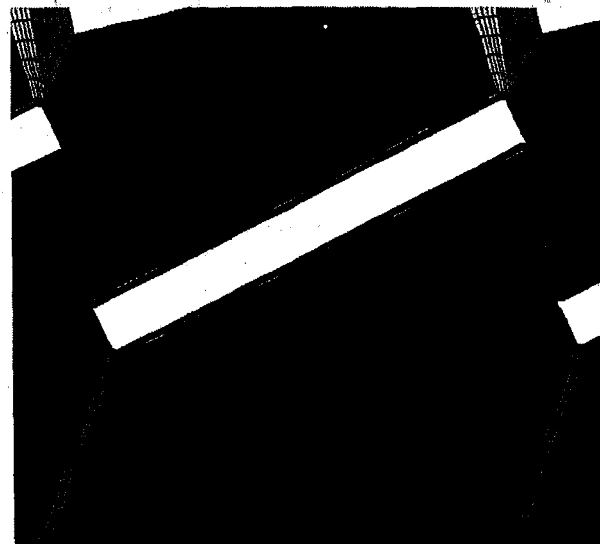

Figure 13 represents the boundary conditions. For convenience and clarity the symmetric boundary conditions are not represented

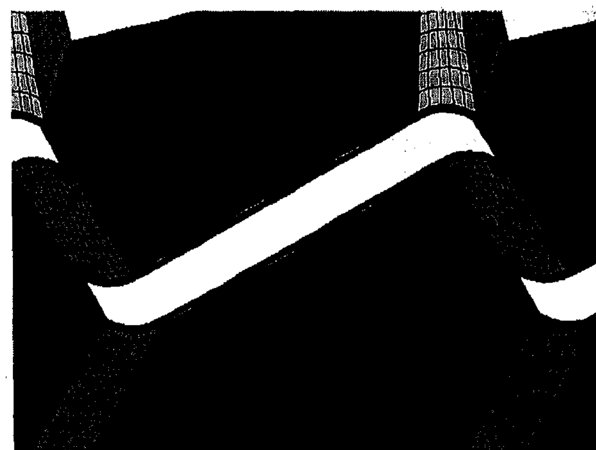

METHODOLOGY, VALIDATION AND RESULTS

FROM EXPERIMENT TO MODELIZATION-The validation was done on two different sets of condensers. We present here the results for condensers in the 22 mm range. We purposely took a "clean" condenser (meaning with no burrs) and a "burred" one (meaning with quite important burrs on the louvers that we did using very old tools). (figures 14 and 15 are photographs of these louvers in both cases, whereas Figures 16 and 17 represent the modelized geometry and the mesh around it). We cut them and reduced them to one pass having 12 tubes each.

FIG. 14 - louvers with burrs (real geometry)

FIG. 15 - louvers without burrs (real geometry)

FIG 16 - modelization of a louver with no burr

FIG.17 - modelization of a louver with burrs

We tested these condensers as if they were radiators and ran the analysis the same way we would have for a radiator. Results showed that they there was a non negligible difference in terms of performances between the two. Figure 18 shows a difference of 10 % on the friction coefficient and 7 % on the value of the heat exchange coefficient.

	Cf	h
clean	0.1223	221.5
burred	0.1348	205.5
Δ	+ 10 %	- 7 %

FIG. 18 - experimental results of the 22 mm condenser

note: all the results presented are for the same Re number (Re = 900)

The goal of the validation was to find this differences numerically.

METHODOLOGY - Now, it is important at this point to notice that since we have a 2-D modelization, we are not expecting results to match experiment in absolute values. Nevertheless, we do expect to find results going the right way in terms of general tendency. The methodology can be described as follow: We start with a geometry which is well-known, that's to say we know its dimensions, all its geometric characteristics, we have all its results from the test bench from which we have computed all its dimensionless coefficients, namely the friction coefficient (Cf) and the heat exchange coefficient (h). Those coefficients are determined using global measurements on the test bench such as the total pressure drop, the inlet and the outlet temperature of the liquid in the exchanger, the air velocity at inlet and so on. Then, we modelize the indirect surface of this exchanger and we run a first calculation which gives us a value for Cf and h. we call these values: Cf_{2D} and h_{2D} Then we modify the geometry, whatever this may be, and we modelize this new geometry. A new calculation gives us new values for Cf and h, we call them: Cf_{2D}^* and h_{2D}^* Comparing the last 2 sets of results gives us a variation for these coefficients that we write: ΔCf_{2D} and Δh_{2D} Finally, the last step is to find the variation of the performances of the real geometry in terms of the variation of the performances of the numerical variation (the whole procedure is described in figure 19). If we take into account the fact that only a percentage of the total exchange surface was modelized we can establish the following relations:

$$\Delta(Cf) = F1\,(\Delta Cf_{2D})$$
$$\Delta(h) = F2\,(\Delta h_{2D})$$

The 2 functions F1 and F2 are deducted from the direct confrontation of the experimental results with the numerical results during the validation of the method.

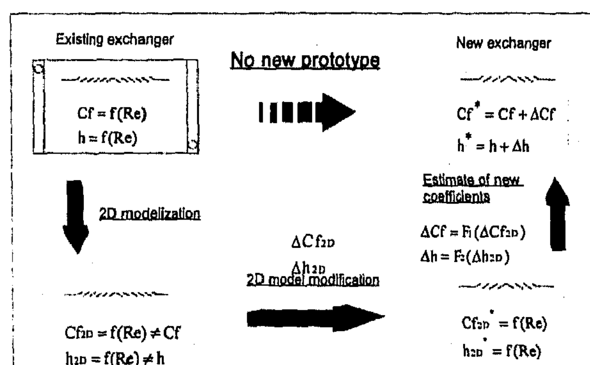

FIG. 19 - general methodology

POST-PROCESSING - That's one of the most important part but also one of the most difficult of the whole modelization process. The code will give us all the quantities that we want but the interpretation and manipulation of these datas is certainly not a trivial task. In particular, we must find a way to express the Re number, The hydraulic diameter D_H , the friction coefficient Cf and the heat exchange coefficient h so that it would be relevant with the experimental datas. As far as the hydraulic diameter is concerned, we calculate it the same way we do for the 3D geometry. It has to be homogeneous to a length. It is the ratio between the passing surface and the "wet" perimeter. The passing surface is a surface through which the fluid flows and the "wet" perimeter is the perimeter of that surface which is directly in contact with the fluid. More or less, it has the same order of magnitude than the louver length. Its calculation is straightforward but tedious. It includes complicated geometrical considerations that are not worth including in this paper.

$$D_H = \frac{4 \times passing\ surface}{wet\ perimeter}$$

The Reynolds number is built on that hydraulic parameter and is defined as follow:

$$Re = \frac{U\ D_H}{\nu}$$

The friction coefficient is a dimensionless expression of the pressure drop. The code does compute a value for Cf but the results were not satisfying. Instead, we used the pressure drop given by the code and we divided it by the relevant datas:

$$Cf = \frac{(\Delta P)\,(\frac{D_H}{4})}{(\frac{1}{2}\rho U_l^2)\,L}$$

where L represents the relevant length scale for the pressure drop: the core thickness. The factor 4 is just there to be consistent with the definition of the hydraulic diameter. U_l is not the upstream velocity but the average velocity between the louvers. Indeed, the velocity U_l is greater than the upstream velocity because the passing section for the fluid decreases as the flow enters the compact exchanger (conservation of mass) and the difference between the two is not negligible. Also, strictly speaking, the density is a function of temperature but since its variations are very small, we neglect its variations and we assume its value to be constant and we take it at the average temperature (T_a) which itself is defined as:

$$T_a = \frac{T_\infty - T_w}{2}$$

Finally, the h coefficient is a quantity directly given by the code. Just like the pre-processing, the post processing is completely done by a program written in FORTRAN

which computes all the quantities just mentioned, except the values given by the code itself.

VALIDATION AND RESULTS - The numerical results are presented in figure 20.

	Cf	h (W/m² K)
burred	0.206	168.0
clean	0.170	172.3
Δ (%)	+21	- 2.5

FIG. 20 - numerical results of the 22 mm condenser

As these Figures show, the absolute values are not directly comparable which is not surprising since the direct surfaces are not taken into account and because of the few assumptions that we made along the way. More interesting though is to compare the variations between the clean and the burred geometries for both the experimental results and for the numerical results (see figure 21).

	Δ(Cf)	Δ(h)
experimental	7.5 %	7.7 %
numerical	20 %	2.5 %

FIG. 21 - comparison of the experimental and numerical variations

We see that the numerical predictions overestimate the friction coefficient but underestimate the gain in heat exchange. But in any way results go the right direction. The visualization of the flow field helps understand why the burrs are degrading the performances. We see precisely where there is the boundary layer separation on the edge of the louvers and the surfaces that are not thermally active clearly appear. (figure 22 shows the iso-velocity lines for a "clean" exchanger i.e. with no burrs and figure 23 shows the iso-velocity lines for a "burred" exchanger i.e. with important burrs and 23-b shows the recirculation due to the burr).

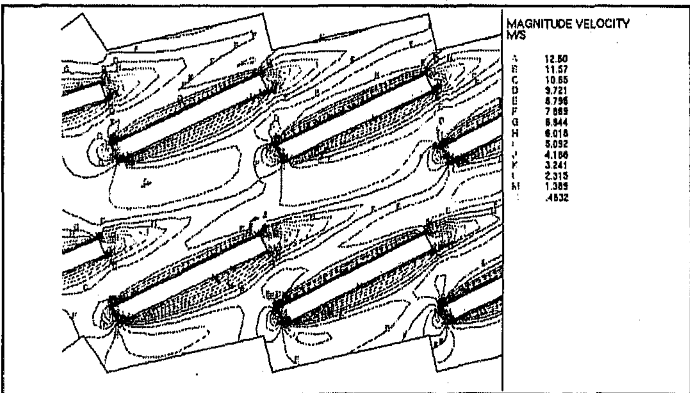

FIG. 22 - iso-velocity lines around louvers with no burrs

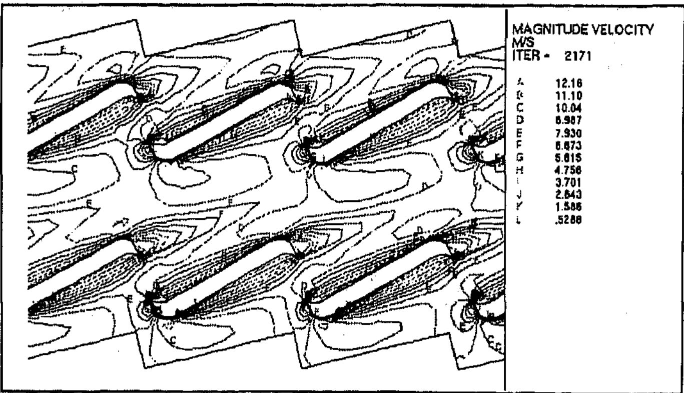

FIG. 23 - iso-velocity lines around louvers with burrs

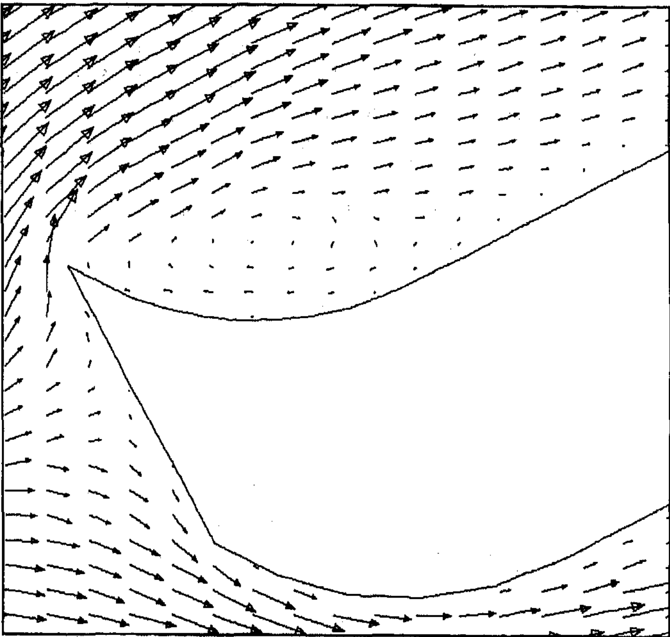

FIG. 23-b flow recirculation around the burr

The conclusion is that we can express the variations of the experimental results in terms of the variation of the numerical results in a general form:

$$\Delta(\text{experimental results}) = F\ (\ \Delta(\text{numerical results})\ )$$

where the function F takes into account the ratio of the indirect modelized surface over the total surface of the exchanger. Finding an analytical expression for F was possible only after having confronted a lot of numerical results with the experimental results. Using the same notation than before, we can write:

$$\begin{cases} \Delta(Cf) = F_1(\Delta Cf_{2D}) \\ \Delta(h) = F_2(\Delta h_{2D}) \end{cases}$$

or,

$$\begin{cases} Cf^* = Cf_{ref} + F_1(\Delta Cf_{2D}) \\ h^* = h_{ref} + F_2(\Delta h_{2D}) \end{cases}$$

where the upper script * denotes the value of the new geometry and the subscript "$_{ref}$ denotes the value of the known geometry.

$$\begin{cases} F_1 = \dfrac{(\ louvered\ surface)}{(total\ surface)} \times C_1 \times \Delta Cf_{2D} \\ and \\ F_2 = \dfrac{(total\ surface)}{(\ louvered\ surface)} \times C_2 \times \Delta h_{2D} \end{cases}$$

where C1 and C2 are constants which values are improved after each calculation we make. This form for the function F is explicitly independent on the Re number but implicitly depends on it since the two quantities ΔCf_{2D} and Δh_{2D} are themselves implicit functions of Re (they are the numerical solution of the Navier-stokes equations). The reason why F1 is proportional to the ratio between the indirect surface over the total surface is that most of the external pressure drop in a compact heat exchanger is due to the louvers and since what we modelize represents only the louvers, it is not surprising to find a higher prediction in pressure drop. The final form for the expression of the new geometry coefficients is:

$$\begin{cases} Cf^* = Cf_{ref} + \left[\dfrac{(louvered\ surface)}{(total\ surface)} \times C_1 \times \Delta Cf_{2D} \right] \\ and \\ h^* = h_{ref} + \left[\dfrac{(total\ surface)}{(louvered\ surface)} \times C_2 \times \Delta h_{2D} \right] \end{cases}$$

The next plot (*fig.24*) is the temperature distribution in between the louvers for a normalized velocity of 5 m/s (Re ≈ 900)

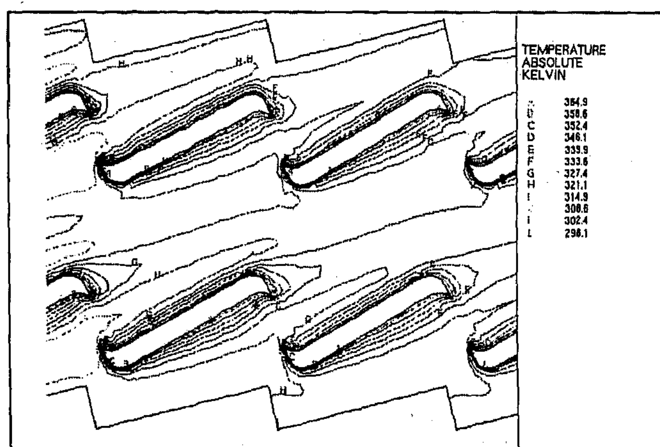

FIG. 24 - temperature distribution around louvers with burrs.

AN EXAMPLE OF APPLICATION

This was applied to the design of fins in the case of a mechanical radiator. Three different geometries were tried numerically and in the end one was chosen on the numerical results basis. One of the objective of the study was to determine the number of louvers required given a core thickness and whether it was necessary or not to leave unlouvered the central part of the surface. (The three different geometries are represented on figure 25). The first geometry has twelve louvers of 1 mm and no central flat length. The second geometry has the same number of louvers, each louver having the length of 1 mm but there is a central flat length of 0.9 mm. The third geometry has 14 louvers of 0.9 mm and a central flat length of 1.5 mm. The fin pitch, the core thickness, all the angles and the gage have the same value for the three models. So, this study allowed us to measure the influence of the central flat length and of the number of louvers in this particular example.

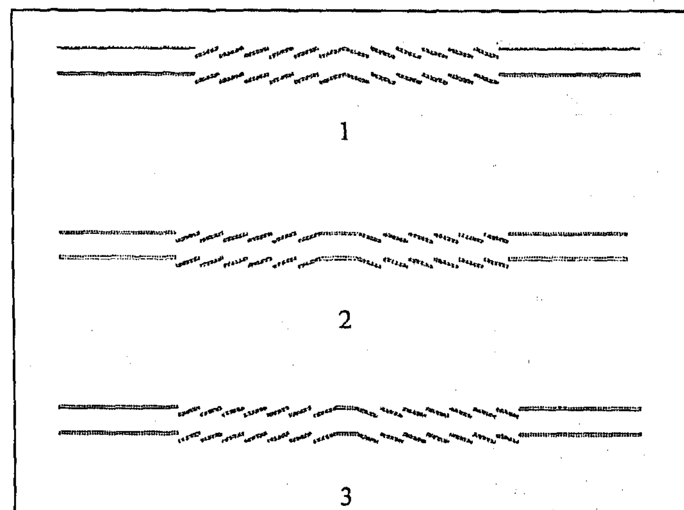

FIG. 25 - Three different modelized geometry.

Unlike the methodology previously described, we do not start from a known geometry but still we could determine which geometry was best adapted for this particular project. The numerical results were: (*fig.* 26)

	geometry #1	geometry #2	geometry #3
Cf	0.149	0.135	0.1490
h	294	295.1	294

FIG. 26 - numerical predictions for a mechanical radiator.

The best geometry turned out to be the second one. It's true that the variation in terms of the heat exchange coefficient is not important but they are two reasons for that: for one, the velocity is not very important (≅ 2.5 m/s) and therefore the variations are less obvious, we usually get more important variations when the inlet

velocities are higher (≅ 5 or 6 m/s) and for two, we saw during the validation of the procedure that the code underestimate the variation of h. Same remark applies to the friction coefficient Cf but we still get a variation of about 10 %. The conclusion was that a long central flat length was much better in terms of pressure drop and slightly better in terms of heat exchange. The visualization of the velocity field around the central flat length helps us understand why the central flat length brings better performances. (*fig.* 27, 28 and 29)

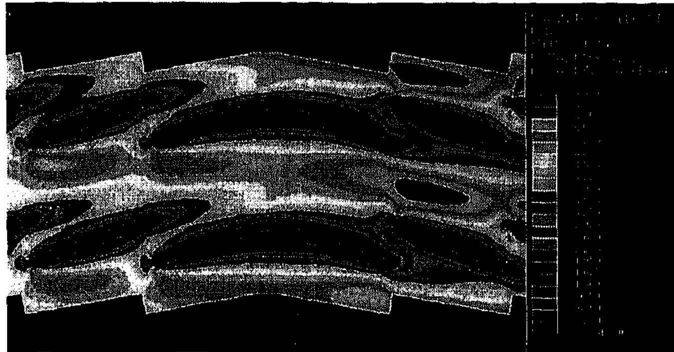

Fig. 27 - velocity field around a central louver without a flat length

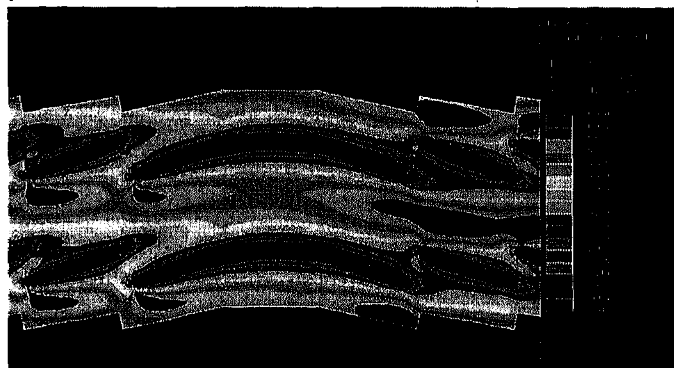

FIG. 28 - velocity field around a central louver with a long flat length.

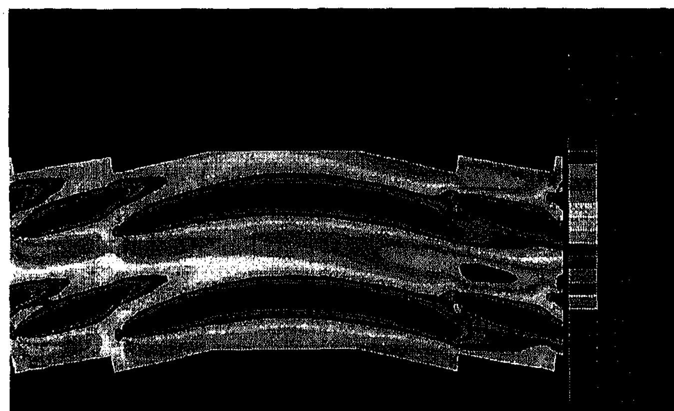

FIG. 29 - velocity field around a central louver with a short flat length

CONCLUSION

This method allows the optimization of the louvers geometry for a wide range of applications. An "ideal" optimized geometry can always be defined in a reasonable time. But more important is the possibility to quantify the effects of the degraded modes on the performances of an exchanger. We know that the aging of the tools is an unavoidable process. Taking into account these "imperfections" in the performance predictions is very important because it will define in a rigorous manner the dispersion that can be tolerated and the parameters of the geometry which variations have an important (or negligible) effect on the performances. It will enable us to tell the risky geometry (which cannot bear production dispersions) from the "safe" geometry (which can stand production variations). This way, we will be able to anticipate the behavior of the exchangers as the industrial tools get old and therefore to maintain a level of quality through a better control of dispersion.

ABSTRACT

An exhaust air fuel ratio sensor (A/F sensor), which is applied to a 1997 model year LEV vehicle was developed. This sensor enables the detection of the exhaust gas air fuel ratio, both lean and rich of stoichiometric. This A/F sensor was developed from a lean mixture sensor, which has a proportional output to the exhaust gas air fuel ratio in the lean region only, by widening the detection range to rich air fuel ratios to 12:1. This sensor is comprised of a zirconia solid electrolyte and a platinum electrode with a ceramic coating used as a diffusion layer. As a result of improvements, it has a effective air fuel ratio range from 12 to 18 as required for LEV vehicles with model based air fuel control systems. It has a fast light off, -- within 20 seconds -- to minimize exhaust hydrocarbon content. Further, it has fast response times, less than 200 msec., to improve air fuel ratio controllability.

INTRODUCTION

Social demands for environmental improvement is increasing. For the automobile, exhaust gas criteria pollutants are required to be reduced under various regulations. Limits continue to decrease because air quality standards have not yet been met. The state of California has already introduced an LEV program and an EU-III program is under development in Europe.

Various exhaust gas control systems have been introduced to meet these emission regulations, and three-way-catalytic converter / oxygen sensor systems have been widely adopted. In the beginning, these systems had one catalytic converter and one oxygen sensor upstream of the catalytic converter. Toyota introduced the two-oxygen sensor system in 1987. This system allows more precise control of air fuel ratio. It consists of oxygen sensors both upstream and downstream of the catalytic converter. This system has

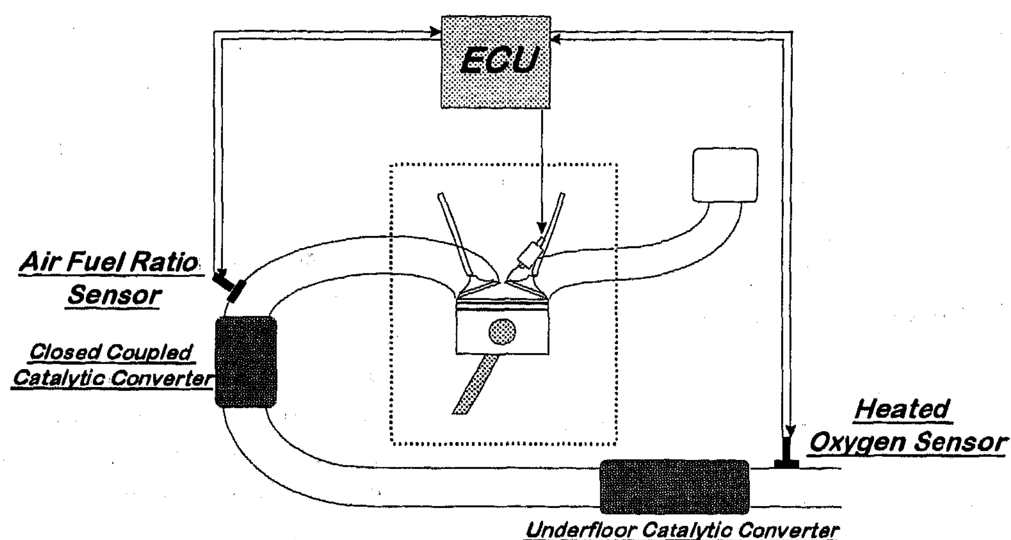

Fig. 1 : Exhaust System for 1997 Model Year 2.2 liter inline 4 engine for LEV vehicle

the following exhaust emission, durability, and reliability advantages:

(1) feed-back for variation of fuel composition
(2) compensation for deviation of the upstream sensor from the stoichiometric point
(3) tighter control within the window air fuel ratio range of the catalyst

The aim of the two oxygen sensor system is to maintain the air fuel ratio near the stoichiometric point, by detecting whether the oxygen content in the exhaust gas is only rich or lean. Since even deteriorated catalytic converters have reasonable efficiency in a narrow air fuel ratio window, system performance is improved.

Beginning in 1994, the California OBD-II regulation required detection of catalytic converter deterioration. To meet this requirement, most automobile manufacturers have designed their exhaust emission control system with an oxygen sensor downstream of the catalyst. By comparing the upstream and downstream oxygen sensor signals, catalytic converter efficiency can be inferred.

As emission regulations continue to tighten, it may seem easy to use a greater amounts of the noble metal (typically: platinum and/or palladium and rhodium) in catalytic converter to improve the system performance. However, availability, cost and deterioration require improved air fuel ratio control to better utilize the catalytic converter. In this context, new exhaust emission control systems have been under development.

SYSTEM CONFIGURATION

At steady running conditions, the air fuel ratio can be precisely controlled around the stoichiometric point using a conventional oxygen sensor. However, transient conditions such as acceleration or deceleration require more accurate air fuel ratio control to meet LEV level exhaust emission standards.

For the 1997 Model Year, Toyota has introduced vehicles which comply with the California LEV classification. In comparison with the 1996 Model Year TLEV vehicle, this system (Fig.1) consists of the items listed below:

(1) An exhaust A/F sensor is used instead of the oxygen sensor upstream of the catalyst at the exhaust manifold
(2) A close coupled catalytic converter with a low thermal mass metal foil substrate is used for the reduction of hydrocarbons during cold starts
(3) The under floor catalyst is enlarged to reduce emissions during hot engine conditions, and an oxygen sensor is set downstream

This system is designed to control air fuel ratio precisely around the stoichiometric point under steady conditions, and to quickly stabilize the air fuel ratio around the stoichiometric point during transient conditions.

Ohata et.al [1] and Nasu et.al [2,3] have developed a model based air fuel ratio feedback control system with counter control of fuel injected to the engine. This counter control requires quantitative measurement

of the exhaust gas air fuel ratio which an oxygen sensor cannot measure. An output proportional to the exhaust gas air fuel ratio must be used. Using this control, the integrated value of exhaust gas air fuel ratio into the catalytic converter is controlled to be stoichiometric. This results in maximization of the gas conversion in the catalytic converter.

(CONVENTIONAL) OXYGEN SENSOR

The oxygen sensor is widely used to control the air fuel ratio within a narrow range or window to optimize the efficiency of the three-way catalytic converter for both oxidation and reduction of exhaust pollutants. It consists of a zirconia solid electrolyte with platinum electrodes on both surfaces. One side is exposed to exhaust gas and the other to the atmosphere. This sensor is characterized by an output signal discriminating only rich or lean operation. This is a simple method which leaves much room for improvement and for optimizing air fuel ratio control.

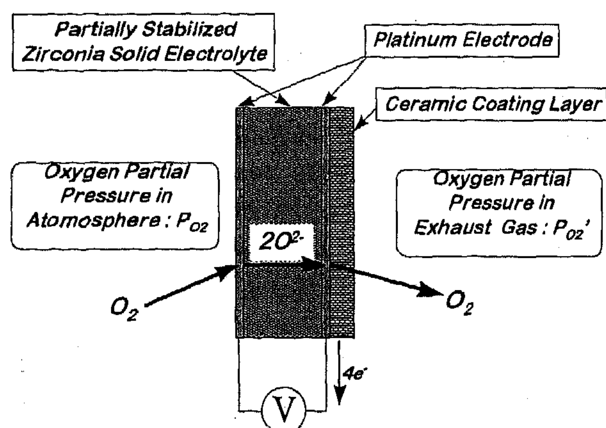

Fig. 2 : Detection Principle of (Conventional) Oxygen Sensor

Figure 2 shows the principle of a conventional oxygen sensor. The oxygen sensor is considered to be an "oxygen concentration cell." Depending on the difference in the oxygen partial pressures between the two surfaces of the platinum electrode, an electromotive force (E.M.F.) is produced according to the Nernst's Equation:

$$E = \frac{RT}{4F} ln\left(\frac{P_{O2}}{P_{O2}'}\right) \quad (1)$$

where

R: gas constant

T: absolute temperature

F: Faraday's constant

Po_2: oxygen partial pressure of the atmosphere

Po_2': oxygen partial pressure of the exhaust gas.

When the air fuel ratio is lean, E is about 0V, and when air fuel ratio is rich, E is about 1V. Near the stoichiometric point, small amounts of NOx, HC, CO and O_2 are present in the exhaust gas. Because of the catalytic ability of the platinum electrode of the sensor, these species are converted to stable compounds. This is why the difference of the stoichiometric point between the catalytic converter and the oxygen sensor is almost negligible.

Figure 3 is the output characteristic of this sensor. The output voltage changes abruptly at the stoichiometric point, so that the oxygen sensor can indicate only a rich or lean state. Using this sensor, fuel injection control is performed by reducing the fuel injection when the sensor output is above 0.45V and increasing the fuel volume when the output is below 0.45V.

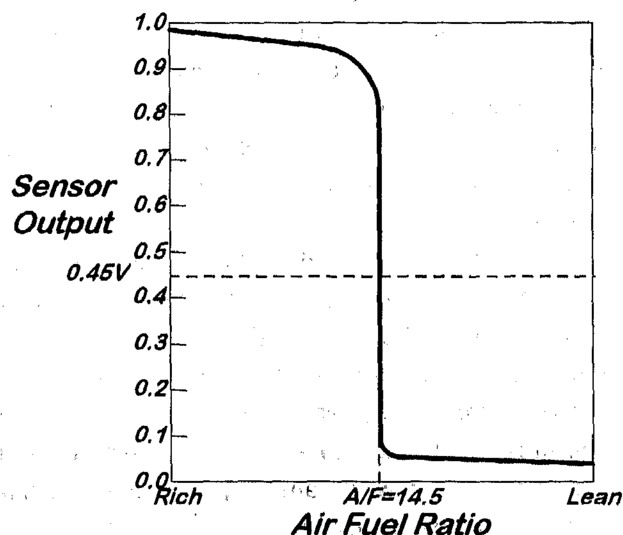

Fig. 3 : Output Characteristics of (Conventional) Oxygen Sensor

LEAN MIXTURE SENSOR

Lean mixture sensor was developed for lean combustion systems. It was the first production exhaust gas sensor to have a proportional output characteristic. This system allows the maintenance of an air fuel ratio of approximately 23, the optimal value for NOx emission reduction and fuel consumption. The electrochemical

reaction of the lean mixture sensor is shown in Fig.4 In this sensor, the ceramic diffusion layer is used to create a current output proportional to the air fuel ratio. This is represented as follows:

$$I = C\frac{D_{O2}}{T}\frac{PS}{\ell}\ln\left(\frac{1}{1-P_o/P}\right) \tag{2}$$

where

C: constant

D_{O_2}: diffusion coefficient at the diffusion layer

T: absolute temperature

S: electrode surface area

ℓ: length of diffusion layer

P_0: oxygen partial pressure of inner (atmosphere) electrode

P: absolute pressure

The diffusion layer consists of $MgAl_2O_4$, called "SPINEL", which has micro pores from 100Å to 1000Å radius. This diffusion layer restricts molecular diffusion according to the oxygen partial pressure.

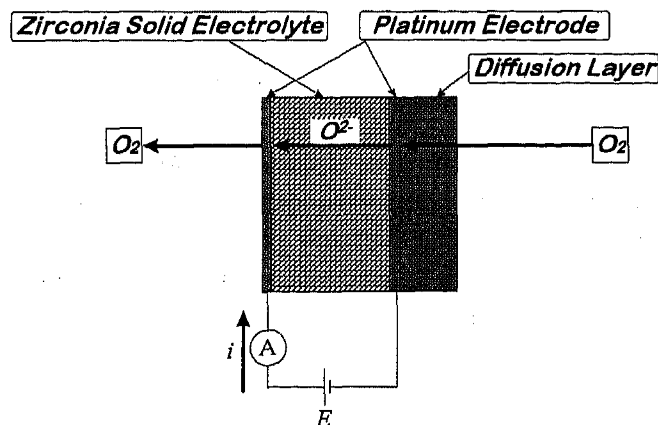

Fig. 4 : Detection Principle of Lean Mixture Sensor

According to Kamo et.al. [4], diffusion at the diffusion layer can be obtained with the character of "Temperature Independence" or "Pressure Independence" based on the radius of the micro pore. For the automotive application, the "Temperature Independent" type diffusion layer is used.

The output characteristic of the lean mixture sensor is shown in Fig.5. It varies based on the exhaust gas air fuel ratio and the applied voltage. This current curve shows a plateau region for an applied voltage of 0.2V to 0.9V. When a constant voltage (shown in figure by the dotted line) is applied to this sensor, e.g. 0.8V, the current flow is nearly proportional to the exhaust gas air fuel ratio. (Fig.6)

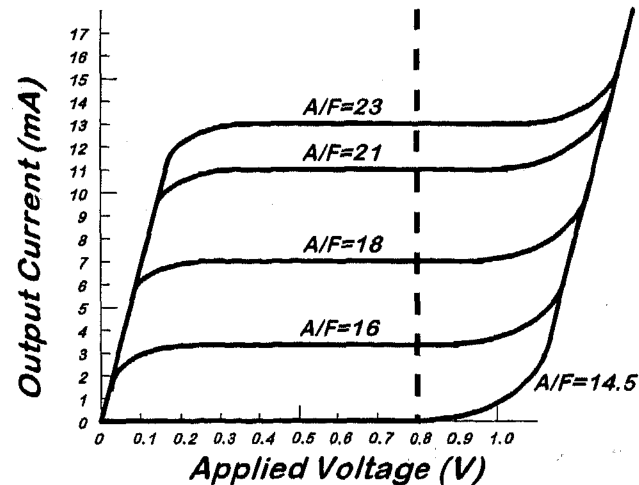

Fig. 5 : Output Characteristics of Lean Mixture Sensor

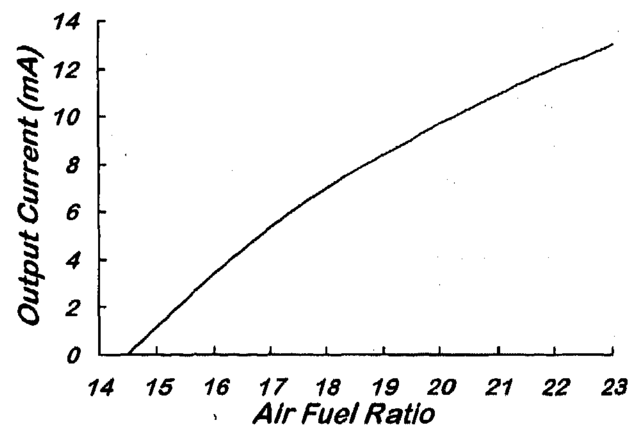

Fig. 6 : Output Current of Lean Mixture Sensor

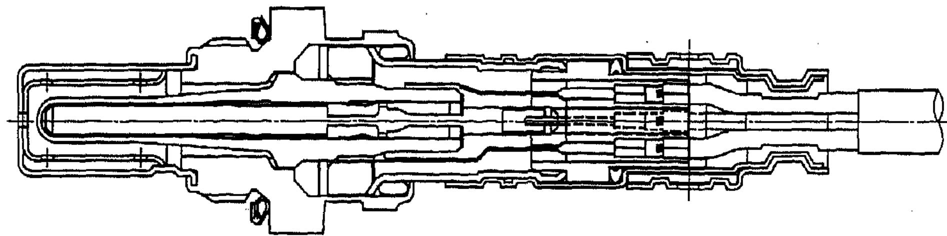

Fig. 7 : Schematic Illustration of Air Fuel Ratio Sensor

AIR FUEL RATIO SENSOR

Since the introduction of the oxygen sensor, most oxygen sensors and lean mixture sensors have had an element of cylindrical shape with one closed end. This configuration has high durability and reliability, because of its thermal strength against internal stress.

The A/F sensor's development was based on the lean mixture sensor. Its basic construction is shown in Fig.7. The required specification of the A/F sensor for LEV vehicles is as follows:

a) Functional air fuel ratio range from 12 to 18
b) Activation time from cold start of less than 20 seconds
c) Response times in the entire air fuel ratio range of less than 200msec

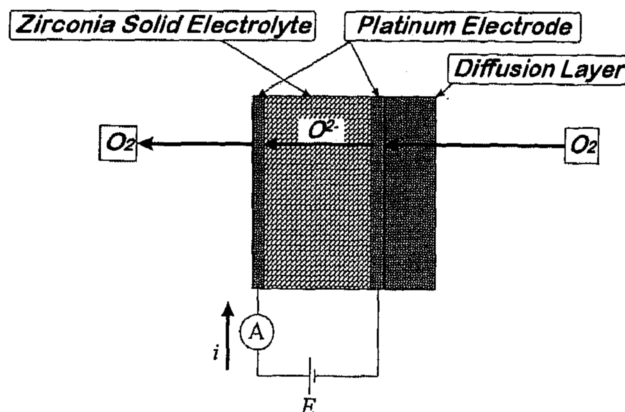

Fig. 8 : Detection Principle of Air Fuel Ratio Sensor in Lean Exhaust Gas

Since the electrochemical reaction at the sensing element is the same as that of the lean mixture sensor in the lean region, then, of course in the lean region, the output characteristic is also the same (Fig.8). This reaction is considered to be oxygen pumping from the exhaust gas (outer electrode) to the atmosphere (inner electrode). [5]

On the other hand, in the rich region, ion movement is in the opposite direction. The electrochemical reaction at the exhaust gas surface (outer electrode) is the combination of hydrocarbon and carbon monoxide with oxygen to form water and carbon-dioxide (Fig.9).

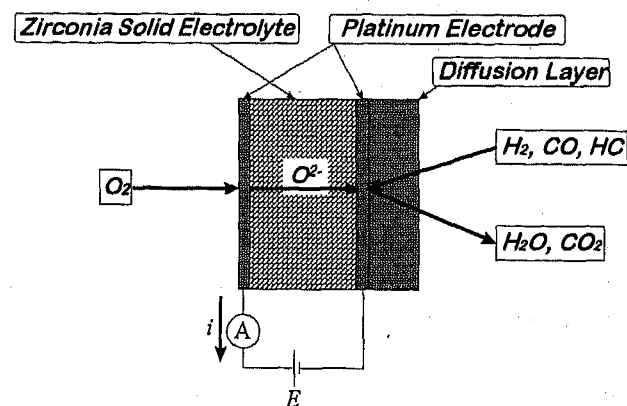

Fig. 9 : Detection Principle of Air Fuel Ratio Sensor in Rich Exhaust Gas

The diffusion layer is used to restrict molecule movement of both water and carbon-dioxide. From the mass and the partial pressure of the molecules, the velocity of molecule transportation in the diffusion layer is calculated from the following equation: [6]

$$\frac{|I_p(lim)|}{P_e} \propto \frac{n}{\sqrt{M}} \qquad (3)$$

where

- $I_p(lim)$: limit current obtained with A/F sensor
- P_e : partial pressure of each component in exhaust gas
- n : number of electrons for electrode reaction of each gas
- M : mass of molecule

To verify this relation with hydrocarbon, the case for propane is examined. For propane, n=20 and M=44, then we obtain $n/\sqrt{M}$ as 3.015. The observed

I_p(lim) and $n/\sqrt{M}$ is summarized in Table 1, and is shown in Fig.10.

	$n/\sqrt{M}$	I_p(lim) [mA]
C_3H_8	3.015	17.2
H_2	1.414	7.0
O_2	0.707	3.4
CO	0.378	1.8

Table 1 : Calculated $n/\sqrt{M}$ and observed output current of each gas

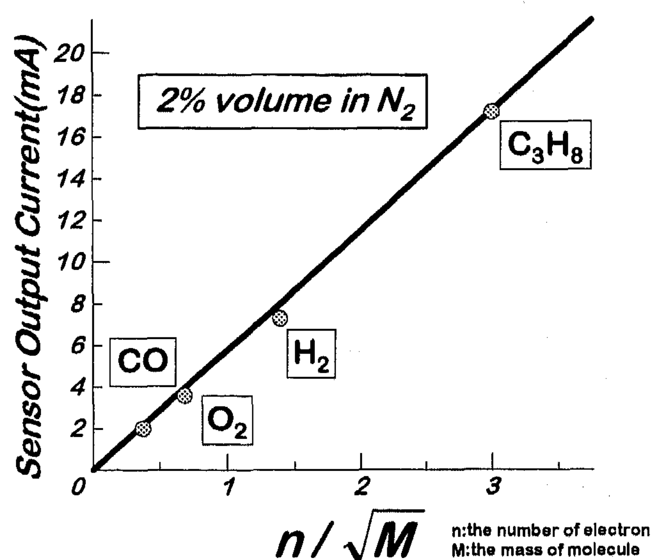

Fig. 10 : Air Fuel Ratio Sensor Output Current for Various Gas Molecule

DETECTION RANGE

The Lean mixture sensor is designed for detection of air fuel ratios around 23, based on the needs of the lean burn engine. Considering the electrochemical reaction at the lean region, oxygen molecules are pumped from the exhaust gas to the atmosphere. The pressure inside the sensor housing goes up, but there is no problem releasing oxygen to the atmosphere. Test results using ambient air (oxygen content about 21%) show no problem (Fig.11).

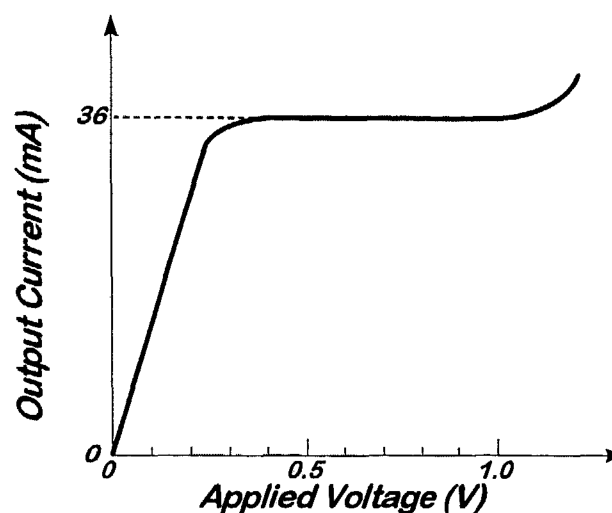

Fig. 11 : Output Characteristics of Lean Mixture Sensor in Atmosphere

In the rich region, however, the output current is saturated at an air fuel ratio of 13 (Fig.12 and 13). As described by Chujo et.al [7], oxygen flow determines the rich detection limit. During rich operation of the A/F sensor, oxygen is provided from the atmosphere to the exhaust gas through the path between the sensing element and the heating element. Assuming that the oxygen path between the sensing element and the heating element is a simple diffusion process and calculating the transport of oxygen molecules, there is insufficient path for detecting an air fuel ratio of 12. Additional detail is described in Appendix I. In order to widen the path between the sensing element and heating element, the inner radius of the sensing element was widened (Fig.14).

Experimental results with a 2.2 liter inline-4 engine, shown in Fig.15 and 16, has proven this improvement to be very effective in expanding the detection range to air fuel ratios of less than 12.

FAST LIGHT OFF

With regard to California's LEV Program, the hydrocarbon requirement is the most difficult to meet. HC emissions at cold start are nearly 70% of the total FTP cycle. Fast light off is required for both the catalytic converter and the A/F sensor.

Activation temperature for the A/F sensor is about 650 °C, instead of 400 °C for the conventional oxygen sensor. The optimization of fast light off without loss of durability is critical.

To improve the light off time, numerous methods to improve thermal conductivity from the heating element to the sensing element, improve activation temperature of the sensing element, and improve heating element capability have been considered. Because this A/F sensor's development was based on the lean mixture sensor, we first chose to improve the heating element.

Material

A heating element laminated on alumina was adopted for the lean mixture sensor. This heating element was designed only to maintain the sensing element in its active temperature region and is insufficient to meet the requirement of activation from a cold start in 20 seconds. The alumina heating element, requires more than 1200 °C to activate the A/F sensor within 20 seconds. This will cause problems such as cracking or oxidation of the heating material. Figure 17 shows the temperature rise of the A/F sensor with the alumina heating element. The A/F sensor is activated at a temperature greater than 700 °C, and the temperature above which the durability of heating element deteriorates is about 1200 °C. When sufficient power to activate the A/F sensor within 20 seconds is introduced to the heating element, its temperature exceeds 1200 °C. Therefore, it is not feasible to have both fast activation and durability using the alumina heating element.

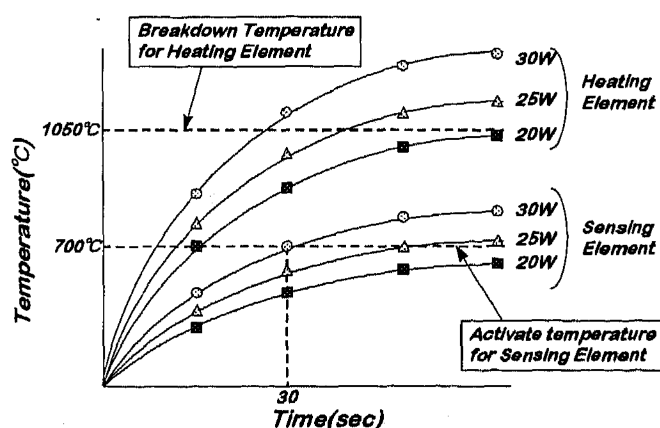

Fig. 17 : Heating Element and Sensing Element Temperature Rise after Cold Start

A silicon nitride substrate can be made using a hot press method to create a rigid structure. This material is widely used in oil stoves to quickly evaporate fuel after being switched on. It is also used in the turbine of turbo chargers which are exposed to high temperature.

Figure 18 shows the temperature rise of the silicon nitride heating element. Its breakdown temperature is greater than 1300 °C. This data shows that the A/F sensor can be activated using the silicon nitride heating element within 25 seconds. Farther, changing the input power control (100% duty cycle at cold start, 30W continuous after activation) for the heating element results in a faster light off. The final result is that the A/F sensor is activated within 20 seconds.

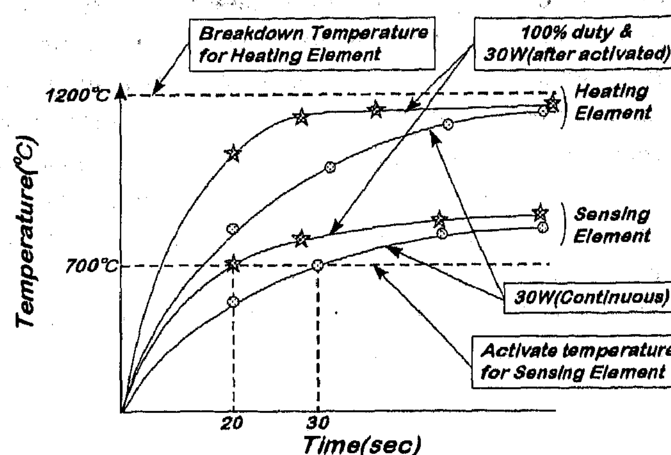

Fig. 18 : Cold Start Temperature Rise with Silicon Nitride Heating Element

Figure 19 shows the durability of the silicon nitride heating element at high temperatures. This graph shows that the silicon nitride heating element's durability can still be maintained to about 15,000 hours at 1300 °C, while the alumina heating element has reached the deterioration limit after only 9,000 hours at 1050 °C.

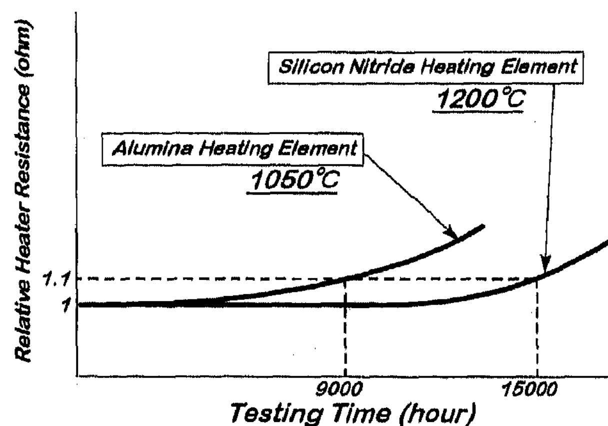

Fig. 19 : Durability of Silicon Nitride Heating Element with Continuous High Temperature Test

Geometrical Arrangement

The heating element is also required to have a geometrically constant heating ability to maintain the sensing electrode at a constant temperature. Also, for fast light off, the heater resistance should be around 1 ohm. Unfortunately, the heater material is a tungsten carbon composite, which has a relatively high electronic resistance. Another design requirement that must be considered is a uniform distribution of temperature around the heating element. To satisfy all the requirements, the geometric arrangement of the heater is designed as shown in Fig.20. Two heaters are placed in parallel to obtain a lower resistance.

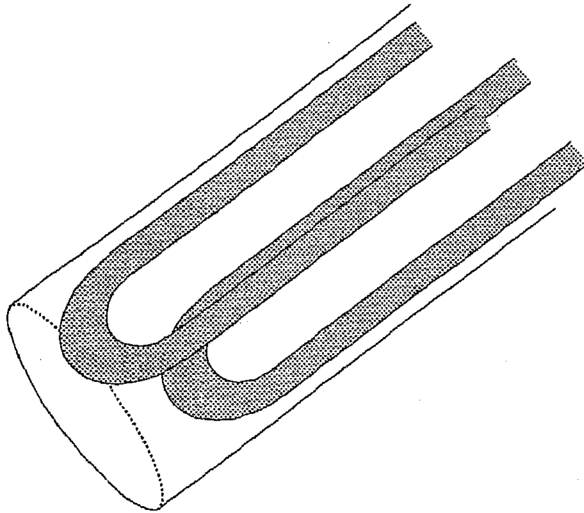

Fig. 20 : Heater Coil Arrangement for Silicon Nitride Heating Element

RESPONSE TIME

According to Nasu, et. al. [2], A/F sensor response time is critical to the model based control method. Response of the A/F sensor is defined as a 63% change in output current (Fig.21).

The response to various step changes in air fuel ratio was measured. Results are shown in Fig.22. The slowest responses were observed when there was a small air fuel ratio change across stoichiometric, either lean-to rich or rich-to-lean. We chose to concentrate on the response time of the sensor from air fuel ratios of 14 to 15 and 15 to 14.

Figure 23 shows the response of a prototype A/F sensor that has the same protection cover as the lean mixture sensor. As shown in Fig.24, this cover has 2 rows and 4 columns of gas apertures. The gas apertures are designed to avoid poisoning from oil contents. This sensor's response is not sufficient for the LEV application because it causes hunting in the air fuel ratio control.

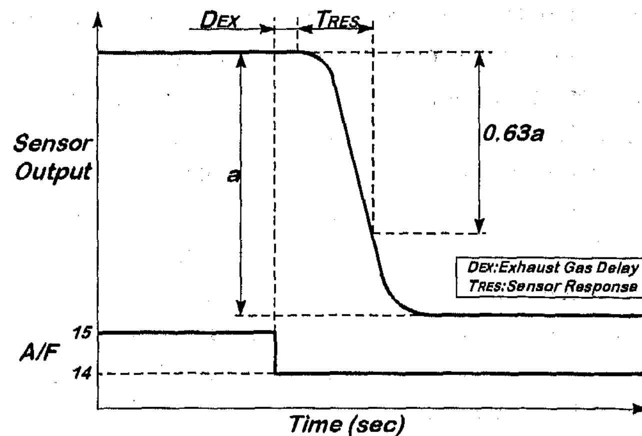

Fig. 21 : Response Definition of Air Fuel Ratio Sensor

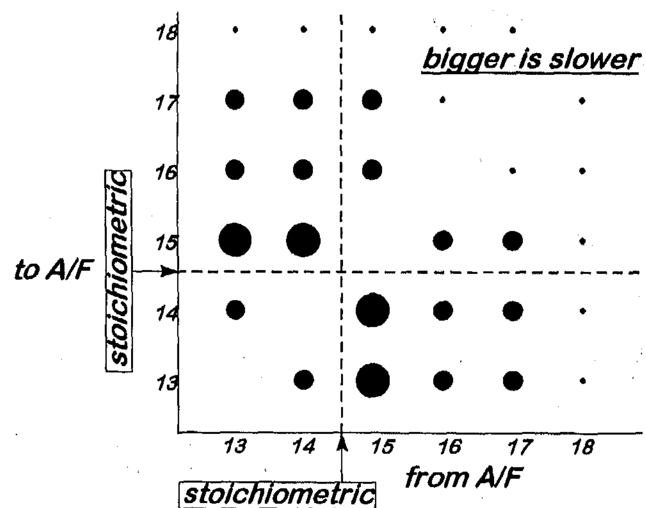

Fig. 22 : Response of Air Fuel Ratio Sensor at various Air Fuel ratio Stepwise Change

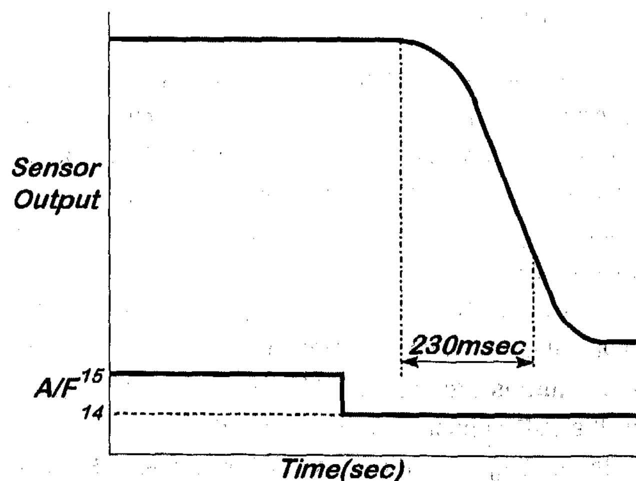

Fig. 23 : Response of Prototype Air Fuel Ratio Sensor

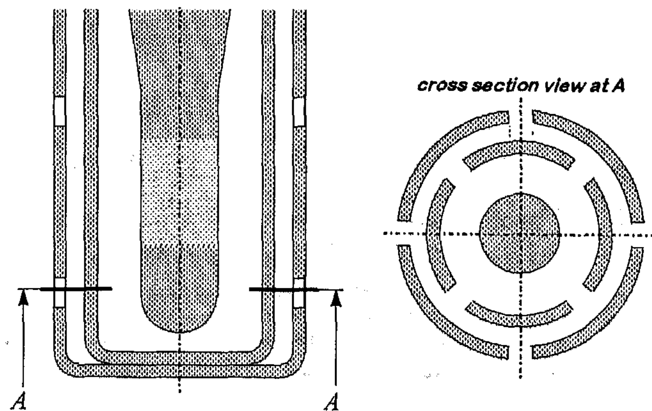

Fig. 24 : Aperture Arrangement of Protection Cover for Lean Mixture Sensor

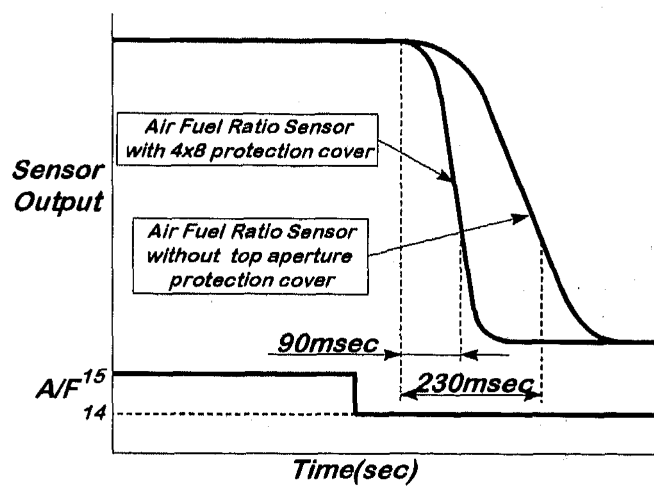

Fig. 25 : Aperture Arrangement of Protection Cover for Conventional Oxygen Sensor

Figure 25 shows the A/F sensor response using a conventional oxygen sensor protection cover, with 4 rows and 8 columns of gas apertures. This aperture arrangement is shown in Fig.26. The response using this cover is nearly the same as that of the sensing element itself, without a cover. This also shows that if gas flow is insufficient, there will be a delay in the response of the sensor.

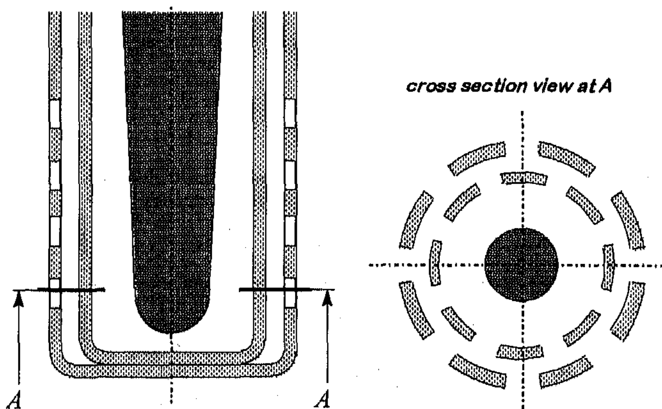

Fig. 26 : Aperture Arrangement of the Protection Cover for Conventional Oxygen Sensor

Gas flow analysis was carried out using an oil film method and a smoke tracing method [see Appendix II]. Figure 27 shows the result of these analyses. The main gas flow around the sensing element is directly across the sensing element resulting in insufficient gas exchange. To improve the gas exchange around the sensing electrode, an additional gas aperture was added at the top of the protection cover (Fig.28).

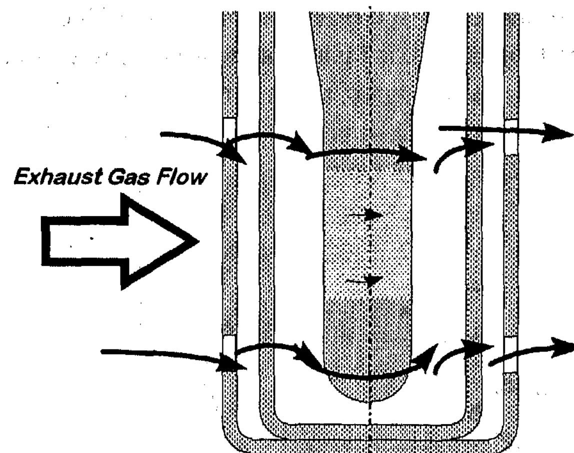

Fig. 27 : Gas Flow with Protection Cover (without Top Aperture)

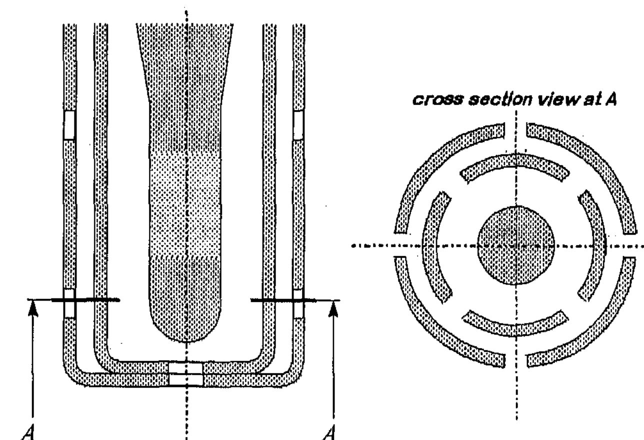

Fig. 28 : Aperture Arrangement of the Protection Cover with Top Aperture

Figure 29 shows the gas flow at the sensing element using the protection cover with the top aperture. The gas flow along the sensing element was obtained by adding the gas flow through the top aperture. The response of the sensor with the protection cover with the top aperture is shown in Fig.30 and 31. The worst case response time value is about 150 msec, which is sufficient for the required specification. These results are summarized in Table 2. The response of the cover with the top aperture is faster than that with 2 rows and 6 columns of gas apertures, and is almost the same as that with 4 rows and 8 columns.

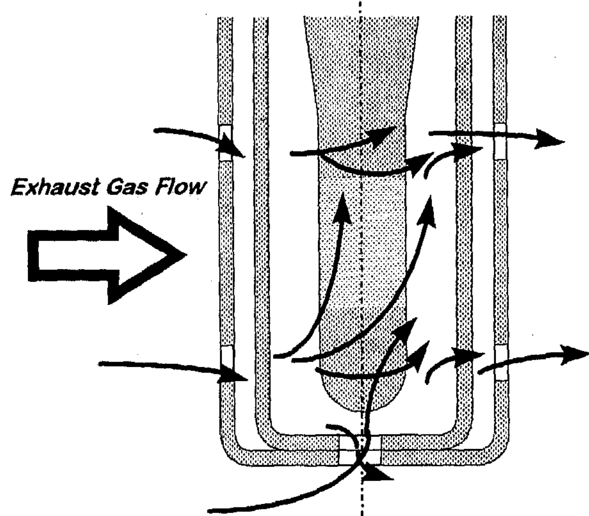

Fig. 29 : Gas Flow with Protection Cover (with Top Aperture)

FUTURE DEVELOPMENT

Regulations requiring further reductions of exhaust emissions will continue into the future. The main obstacle in meeting these regulations is hydrocarbon emissions, which, as described in the introduction, hydrocarbon is emitted mainly during cold starting. In the future, much faster light off will be required of both the sensor and catalytic converter.

To improve fast light off, a new sensor that has a planar construction is being widely investigated because of its low thermal capacity. The cylindrical shaped sensing element is advantageous due to its low internal thermal stress. The challenge we face will be in developing a faster light off sensor while maintaining high durability and reliability.

Another theme for sensor development is high temperature durability to improve tolerance to little or no fuel enrichment at high load conditions.

We are trying to improve the exhaust gas sensor to meet these challenges. However, there are still many countries that allow leaded gasoline which deteriorates both exhaust gas sensors and catalytic converters. If global air pollution is to be reduced, all countries will need to adopt programs where leaded gasoline is outlawed and emission are strictly regulated.

CONCLUSION

The A/F sensor was developed with the following improvements: (1) expansion of the rich detection region using analysis of the gas flow between the sensing element and heating element; (2) improved light off using a silicon nitride heating element; (3) improved response time by using gas flow analysis to optimize the sensor protection cover aperture arrangement. This A/F sensor, to be used for air fuel ratio control in LEV and ULEV vehicles, represents a break through in environmental improvement.

APPENDIX I : CALCULATING OXYGEN PATH WITH SIMPLE DIFFUSION PROCESS

According to the diffusion equation, the output current of the A/F sensor is expressed as follows,

$$I\ell = C\frac{S}{\ell}D_n \ln\frac{1}{(1-P_{O_2})} \qquad (4)$$

where

$I\ell$: output current

C : constant (=4FP/RT)

S : area of diffusion path

ℓ: length of diffusion path

Dn : diffusion coefficient for oxygen molecule in the atmosphere (0.178)

PO2 : partial pressure of oxygen in atmosphere.

and, the s/ℓ is integrated with

$$\frac{S}{\ell} = \frac{1}{\frac{\ell_1}{s_1}+\frac{\ell_2}{s_2}+\frac{\ell_3}{s_3}+\frac{\ell_4}{s_4}+\frac{\ell_5}{s_5}\ldots\ldots} \qquad (5)$$

Calculating with the geometric value, we can obtain the output current limit value for both unimproved and improved element. The results are summarized in Table 3.

	Output Limit	A/F Limit
Unimproved	7mA	12
Improved	12mA	11

Table 3 : Rich Detection Improvement Result

APPENDIX II : VISUALIZATION OF GAS FLOW

Many methods have been reported for visualization of gas flow. We selected 2 methods which were, "Oil Film Method" and "Smoke Tracing Method".

With the oil film method we detected the gas flow around the surface of the outer cover and between the outer and the inner cover, and by the smoke tracer method, the gas flow around the sensor element itself.

OIL FILM METHOD

The oil film method is carried out as follows: First coat the surface of test objects with a thin layer of oil emulsified with TiO2 powder. Second take it into the gas flow. When the oil is blown off and drained away, the powder is stretched into lines along the gas flow line. Then, the gas flow can be seen as the lines on the objects.

SMOKE TRACING METHOD

The smoke tracer method is carried out as follows: All of the experimental apparatus is made using a clear material such as acrylonitrile plastic for components such as the cover and element. They are assembled and inserted into the gas flow. Then, smoke is added to the gas flow. The gas flow can be seen as the lines of smoke.

Ignition System-Embedded Fiber-Optic Combustion Pressure Sensor for Engine Control and Monitoring

Thomas J. Poorman, Liangdao Xia, and Marek T. Wlodarczyk
Optrand Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

We report a low-cost fiber-optic combustion pressure sensor integrated with an ignition system of a passenger car. A miniature sensor is attached to a shaft extending from the spark plug boot. Simultaneously with the boot mounting on the spark plug the sensor shaft is pressed into a cylindrical hole of a modified production spark plug. The sensor cable is combined either with the boot, or boot and high voltage cable, depending whether a coil-at-plug or a Distributed Ignition System is used, respectively. The sensor optical and Application Specific Integrated Circuit (ASIC) components are packaged inside a miniature module, embedded either in a coil-at-plug package or a Distribute Ignition System module. Engine test results are reported for a single-cylinder, gasoline fueled stationary gen-set engine. When optimized for high linearity and reduced thermal shock, the spark plug-mounted sensor demonstrates approximately +/-1.5% pressure reading accuracy, comparable to that of a laboratory-grade piezoelectric transducer. With the life-time of 200 Million pressure cycles and targeted price of $7 to $10, the sensor meets the performance, durability, and cost requirements for production car applications.

1. INTRODUCTION

Cylinder pressure is the fundamental variable that determines a combustion engine's operating state. If available for all cylinders, combustion pressure information can be used in advanced engine applications ranging from diagnostics and testing through monitoring to closed-loop control systems. Based on cylinder-specific pressure information, engine control applications have been proposed for power balancing in natural gas burning large-bore engines [1], lean burn combustion in passenger cars [2], or stall control in aircraft engines. In the area of engine monitoring, combustion pressure, when detected in all cylinders, can provide the most deterministic information about engine performance and health [3]. In conjunction with other sensors cylinder pressure-based engine health monitoring systems can lead to increased engine reliability as well as reduced cost and frequency of preventive maintenance.

While the benefits of cylinder pressure information for engine monitoring or control have been known for decades, commercial implementations of practical systems have been hampered by one overriding factor: the lack of a cost-effective and reliable combustion pressure sensor. Conventional electronic pressure transducers, such as piezoelectric or piezoresistive, are not suited for continuous high temperature pressure measurements. Fundamentally, capacitance or strain gages used in pressure transducers exhibit large non-repeatable and unpredictable changes in gauge output at temperatures typically greater than 250°C or 125°C, respectively. These changes are caused by such effects as alloy segregation, phase changes, selective oxidation, and diffusion, and ultimately lead to premature failure of the gauge or lead wires.

In contrast to electronic devices, fiber-optic sensors are potentially very well suited for applications characterized by high temperatures and high levels of electromagnetic interference[4]. These benefits, combined with very small package sizes, make fiber optical sensors well suited for operation in automotive engine environment. In particular, these sensors can be combined with existing engine components, such as ignition spark plugs or fuel injectors; the ability to insert a pressure sensor into a combustion cylinder through an existing engine head opening offers significant cost advantage over techniques dependent on drilling a hole into an engine's cylinder head or other forms of engine modifications.

While special pressure measurement spark plugs have been used in engine research, they are not suitable for use in production engines. Measurement spark plugs typically have an off-axis, small diameter central electrode and compromise either spark plug performance or durability. In addition, piezoelectric sensors used with these spark plugs are very expensive and have a limited life time. A measurement spark plug suitable for engine control applications should preferably be derived from a production device for low cost and should have the same performance and durability characteristics of a conventional spark plug. In addition, for production engine applications, a spark plug-mounted pressure sensor should require no separate signal conditioner and a minimum number of cables and connectors. Finally, the sensor-spark plug module should be installed at minimum cost and allow low-cost maintenance.

2. SYSTEM DESCRIPTIONS

A measurement ignition system with embedded fiber optic combustion pressure sensor is schematically shown in **Fig. 1**. The system, termed the PSIcoil™, consists of four key components: (1) a miniature fiber optic pressure sensor extending from a spark plug boot, (2) a spark plug possessing a channel into which the sensor is inserted, (3) a high voltage boot/cable within which a fiber optic cable is embedded, and (4) an opto-electronic module integrated with an ignition coil, mounted either on or at spark plug or at the end of a high voltage cable.

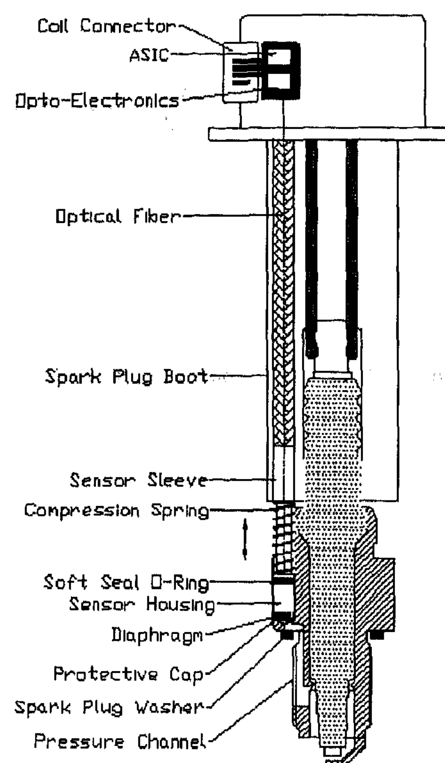

Fig. 1 PSIcoil™ schematic diagram

The fiber optic sensor is mounted at the end of a shaft extending from the spark plug boot. The sensor's diaphragm is protected by a metal cup which also provides an additional benefit of thermal shielding. As the spark plug connector latches onto the central electrode, the sensor is pushed into the measurement cavity and seals on the front of the protective cup. A spring, located between the spark plug boot and the shaft maintains a pressure tight seal. For added protection against pressure leaks an O-ring is mounted at the top of the shaft, away from high temperature area. The shaft section that is inserted into the spark plug is made of brass, or similar material with high thermal conductivity and good pressure sealing characteristics. Above the spark plug, the shaft is made of durable plastic so that the spark plug's electric field is not perturbed by the presence of any metal parts of the sensor.

The measurement spark plug is derived from a production-type device, as shown in **Fig. 1**, with an axially located central electrode. The spark plug key feature is a short, non-resonating passage connecting the inside spark plug area exposed to combustion pressure with the sensor located in the spark plug metal shell. The pressure passage consists of three sections: (1) a cylindrical hole parallel to spark plug axis extending to the bottom of the spark plug metal body, (2) a channel milled in the outside thread of the spark plug connected to the inside area by a transverse hole, and (3) a 1 mm diameter hole connecting the milled

channel to the sensor diaphragm. Note that by using the channel located in the spark plug thread the need to move the central electrode off axis, to create a pressure passage, is eliminated. The dimensions of the three sections of the pressure passage are optimized to minimize any distortions in dynamic pressure readings: (i) The total passage length between the spark plug top surface and the sensing diaphragm is kept to a minimum for minimum phase delays. (ii) The channel machined in the outside spark plug thread has a shape of letter V to eliminate any channel resonance. (iii) A hole connecting the outside and inside channels is optimized so combustion flame is quenched as it passes to the sensor chamber.

A number of options are available for this combustion pressure measurement ignition system. In one version, as schematically shown in **Fig. 1**, the sensor opto-electronics and Application Specific Integrated Circuit (ASIC) are mounted inside an ignition coil located on, or near, the spark plug. Through a channel formed in the measurement spark plug boot the sensor fiber optic strand enters the ignition coil package. There the strand is terminated with an opto-electronic module which in turn connects to the sensor's ASIC. The sensor is powered by the coil low-voltage supply cable and the combustion pressure output is available through an additional pin of the coil-on-plug electrical connector.

Alternatively, the fiber optical strand of the sensor can be broken into two sections, connected to each other via an optical connector. For ease of installation and low cost, the connector is combined with the coil electrical connector. Between the coil and Distributed Ignition System (DIS) the fiber optic strand is embedded right inside the high voltage cable, together with a carbon strand. Such an integration is only possible with a fiber optic cable, due to its non-electrical nature, so that neither the ignition field is perturbed nor the sensor cable is affected by the ignition system Electromagnetic Interference (EMI). Such a measurement ignition system is the most desirable for applications where an ignition coil may be exposed to temperatures over 125°C, such as for example in push rod engines.

Unlike in engine testing and R&D, a combustion pressure sensor intended for engine control applications does not need to be extremely accurate. The critical features are high reliability, low cost, and long life. Typically, no individual sensor calibration is needed in the interest to lower the total system cost. However, a high degree of linearity and low-hysteresis are required within a single combustion cycle so a normalization technique can be applied based on the ratio of cylinder pressure during compression and expansion stages of the cycle. Basic specifications for the PSIcoil sensor system are summarized in Table 1.

Pressure range:	0 to 1000 psi
Over-pressure range:	2x pressure range
Linearity & hysteresis:	+/-1.5%
Frequency response:	0.01 Hz to 15 kHz
Sensor housing continuous temperature:	-40 to 350 °C
Electronics and opto-electronics continuous temperature	-40 to 125 °C
Sensor Output:	0-5 V
Life time	200 Million cycles

3. PRESSURE SENSOR DESIGN

The fiber optic sensor described here consists of three basic components, a transducer, a fiber optic cable, and a "smart" connector/module located at the proximal end of the cable, as shown in **Fig. 2**

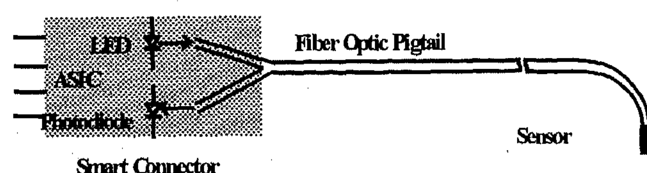

Figure 2. Sensor block diagram.

The "smart" connector consists of an opto-electronic module, containing a photodiode and a LED, and a dedicated ASIC. Two input electrical pins are for power supply and ground while two output pins are for sensor output and diagnostic voltages. The ASIC controls light intensity, amplifies and filters the photodiode signal, and provides the auto referencing function. The auto referencing function [4]-[5] regulates the sensor's input parameter, the LED light intensity, in response to any undesirable environmental conditions that may alter minimum detected light intensity. Based on the minimum detected pressure signal, the LED light intensity is adjusted in response to environmental conditions such that the minimum light intensity is always maintained at a constant level. This approach not only corrects for any possible offset drifts but sensor gain errors as well. In fiber optic sensors such errors may result from optical link transmission losses due to connectors' mechanical and thermal instabilities, fiber bending, or light source or detector temperature dependence. A side benefit of the auto-referencing technique, not available to other combustion pressure sensors, is the availability of sensor health monitoring output. By continuously monitoring the LED current level or its rate of change, one can identify potential sensor failure before it occurs. This ability is particularly important in control applications where sensor failure may cause malfunction or even failure of the controlled device.

The sensor head consists of a metal housing containing a sensing diaphragm laser welded to the sensor body, fiber

holding ferrule, and two fibers bonded inside the ferrule, as schematically shown in **Fig. 3**. Note that the dimensions are not show to scale.

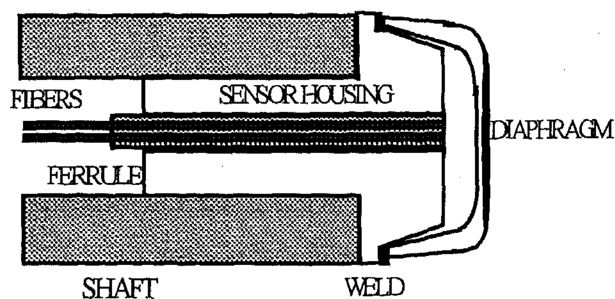

Figure 3. Sensor head construction.

The sensor response to pressure results from the displacement of a diaphragm that in turn results in changes in an optical signal collected by a receiving fiber. The light is emitted by a separate fiber. For a given diaphragm displacement, resulting from a pressure change, the sensor response can be adjusted by a suitable choice of optical fiber core diameters and numerical apertures, as well as relative position of the fibers in respect to the diaphragm. **Fig. 4** shows how the normalized amount of light collected by the receiving fiber changes as a function of the fiber to diaphragm distance.

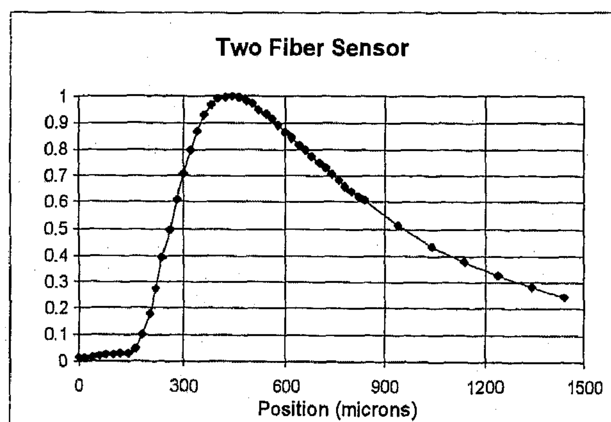

Figure 4. Normalized light deflection versus diaphragm fiber separation

Note that the response curve of **Fig. 4** is non-monotonic with a positive sensitivity (derivative of the curve) region for smaller fiber to diaphragm distances and a negative sensitivity region for larger separations. The positive response region is typically more sensitive to diaphragm displacement and is therefore preferred for pressure sensor applications. In a typical design the diaphragm is located approximately 200 microns away from the fiber tip when no pressure is applied. As this distance is optimized, the pressure response can be extremely linear, as shown in **Fig. 5**. The modulation parameter of **Fig. 5** is defined as a percentage of returned signal at full scale deflection to a signal at zero deflection.

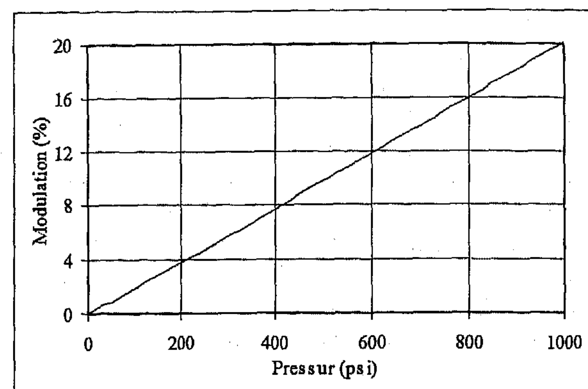

Figure 5. Calculated optical modulation versus applied pressure.

The primary design objective in designing the sensor diaphragm is to maximize its deflection while minimizing stress levels. Our proprietary hat-shaped diaphragm [6] made of Inconel offers an excellent high temperature strength, minimum stresses at nominal and over-pressure conditions, low creep, and good deflection characteristics. For a typical passenger car engine operation of 10 years, the sensor needs to meet the life-time requirement of approximately 200 million pressure cycles. Using an optimized diaphragm design the fatigue life time of 1 billion cycles is possible for the present sensor [4]. Other benefits of the present diaphragm construction include excellent linearity of pressure response and reduced sensitivity to direct flame effects. Finally, the diaphragm is welded to the sensor housing away from the flexing area improving long term weld stability and strength.

In annual production quantities of 1 Million the current sensor is expected to add between $7 and $10 to the cost of a conventional ignition coil. Unlike the competing electronic designs based on a piezoresistive diaphragm [7]-[8], our sensor has only a few components and its design lends itself to a low-cost manufacturing process. The ignition coil-integrated design of the fiber optic sensor package does not require a separate cable nor a connector, leading to minimum coil modifications. Finally, through the sensor mounting in a spark plug no addition installation costs are incurred associated with engine head modifications required for stand alone sensors.

4. LABORATORY AND ENGINE TEST RESULTS

Laboratory testing of the fiber optic sensor included linearity and hysteresis comparisons against commercially available piezoelectric sensors, temperature soaking and cycling, and sensitivity dependence on temperature. **Fig. 6** demonstrates a comparison of the typical room temperature dynamic pressure response, over 0 to 1000 psi pressure range, of OPTRAND's sensor and a reference piezoelectric transducer (PZT) (Kistler Model 6121).

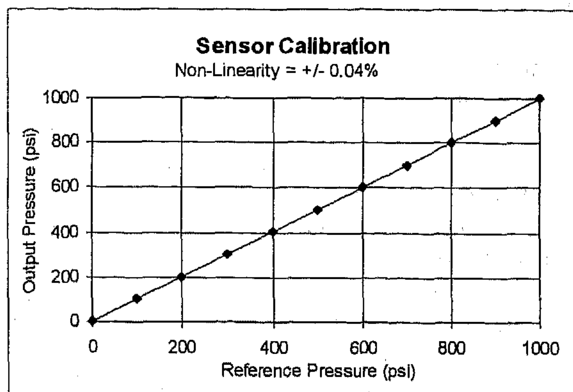

Figure 6. Dynamic pressure comparison between fiber optic and piezoelectric transducer at constant temperature

Note excellent non-linearity exceeding typical values of many laboratory devices. The signal to noise ratio (SNR) of approximately 2000 is comparable to that a reference transducer.

In a series of engine tests the performance of a spark plug-mounted fiber optic pressure sensor was compared to that of a piezoelectric reference transducer directly mounted in the engine head. For added accuracy the reference transducer was coated with a thin film layer of RTV and was installed behind a flame arresting hole previously identified as resulting in reducing thermal shock comparable to a water cooled sensor performance [9]. **Figs.** 7-9 demonstrate the results obtained on a single cylinder, gasoline-fueled motor generator set.

Fig. 7 shows the performance obtained with a sensor designed for nominal 1,000 psi pressure installed in OPTRAND's measurement spark plug, without a heat quenching feature in the spark plug. The left side vertical axis is for both optical and reference transducers while the right side axis shows the difference between the sensor readings. The measurement and reference traces are normalized so their peak to peak values are equalized.

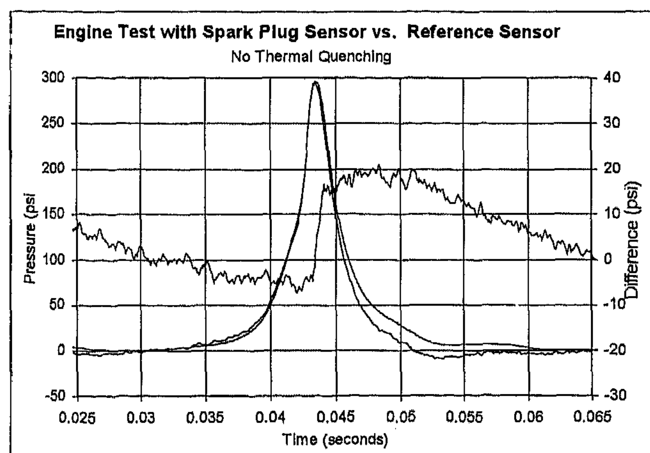

Figure 7. Engine test data for a spark plug-mounted sensor without heat shield

The maximum difference (error) between the sensors ranged from -7 psi to +20 psi. For a 1,000 psi sensor such an error corresponds to +2%, -0.7% full scale error, respectively. This error is due to the thermal shock effect [9] associated with intra-cycle changes in diaphragm temperature resulting from varying combustion gas temperature. Such an error is present in all types of diaphragm-based sensors including the widely used reference piezoelectric sensors. While the spark plug used in the present evaluation was equipped with a flame arresting hole connecting the sensor mounting cavity and the pressure channel, the hole alone does not provide the necessary cooling of combustion gasses before they impinge on the diaphragm.

To improve upon the thermal shock performance of the spark plug-mounted sensor, an additional heat quenching feature was incorporated in the spark plug design. This proprietary design reduces the direct effect of combustion gasses on the diaphragm without compromising the sensor frequency response. **Figs. 8-9** show the excellent performance of this new design spark plug sensor. A comparison of time-based response is shown in **Fig. 8** while **Fig. 9** illustrates a direct comparison between the two sensors demonstrating approximately +/-1.6% combined linearity-hysteresis performance of the enhanced spark-plug mounted fiber optic sensor.

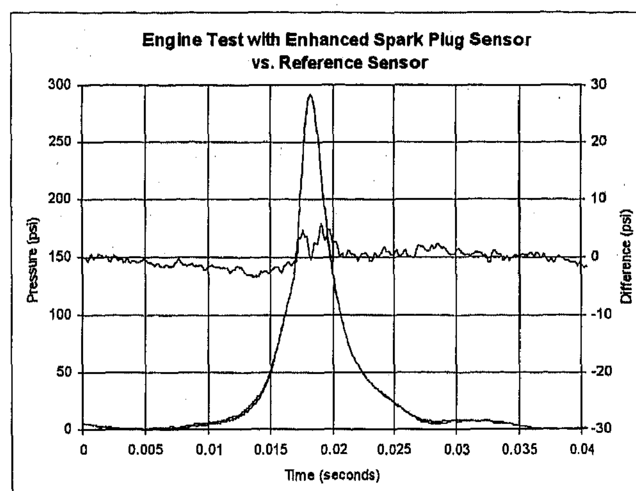

Figure 8. Engine test data for a spark plug-mounted sensor with heat shield

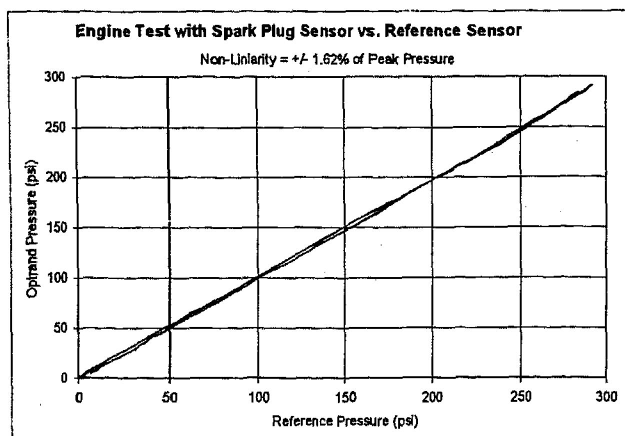

Figure 9. Linearity-hysteresis comparison between a spark plug-mounted fiber optic sensor and an engine head-mounted piezoelectric reference transducer

5. SUMMARY AND CONCLUSIONS

We have presented the design and performance of a fiber optic combustion pressure sensor integrated with an automotive ignition system. A miniature sensor is attached to a shaft extending from the spark plug. boot. The sensor is inserted into a modified spark plug during the process of boot pressing onto the spark plug connector. A smart auto-referencing technique compensates for sensor and fiber link environmental and temperature effects and guarantees drift-free operation. Using the optimized heat quenching design of the spark plug mounted sensor, the combined linearity and hysteresis of the present sensor stands at +/- 1.5%, demonstrating performance comparable to that of a laboratory grade piezoelectric transducers. With the targeted life-time of 200 Million pressure cycles and price between $7 and $10, the sensor meets the performance, durability, and cost requirements for production car applications.

Dynamic Film Measurements in Journal Bearings Using an Optical Sensor

Tory M. Jaloszynski

Michigan Technological Univ.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The primary goal of this research was to investigate the feasibility of measuring the oil film thickness in a journal bearing using an optical film thickness sensor earlier developed at Michigan Technological University. A bearing oil film thickness testing facility was designed to provide precise control of the sensor calibration and experimental measurements. The calibration of the sensor was achieved by the use of an in-bearing calibration setup that allowed manual changes of film thickness by moving the bearing sensor within the bearing. By varying the speed from 350 to 1100 RPM and the load from 0 to 55 kg in a journal bearing, the sensor was able to measure changes in oil film thickness from 0 to 25 μm. The trends caused by changing the load or speed were seen to be consistent with a mathematical model based on the two dimensional Reynolds equation for journal bearing design. The film thickness measurement technique developed was successful in evaluating the performance of a journal bearing under several operating conditions and should provide an excellent tool to further investigate bearing performance.

INTRODUCTION

The objectives of this research were the following:

1. Determine the feasibility of using the optical film sensor in the measurements of oil film thickness in a journal bearing.
2. Design a bearing oil film thickness test facility which can be used to perform in-bearing calibrations of the optical sensor.
3. Obtain accuracy and reproducibility in the calibration of the optical film thickness sensor in the testing facility.
4. Show dynamic film measurements obtained are consistent with expected bearing performance based on a mathematical model for speed and load effects.
5. Show transient response of the optical sensor during start-up.

These objectives were developed in response to the need for an unintrusive measurement system that allows the measurement of the actual oil film thickness. Accurate measurements of the oil film thickness in a journal bearing of an operating engine have been difficult to obtain because of the small, rapidly changing clearance seen in a journal bearing. Numerous different experimental techniques have been proposed to accomplish this objective, such as [1,2,3]. Many techniques have been developed that include the use of discrete probes or transducers located at various points around the circumference of the bearing. These probes have been designed to measure different physical quantities such as capacitance, magnetic fields, resistance, inductance, light waves, and eddy currents. The optical sensor for this research uses a single optical probe and reflected light to determine the changes in oil film thickness in a journal bearing.

The design of journal bearings is important to the development of rotating machinery such as compressors, pumps, turbines, internal combustion engines, motors, generators, etc. In its most basic form, a journal bearing consists of a rotatable shaft, called the journal, contained within a close-fitting cylindrical sleeve, called the bearing. The journal and bearing surfaces are separated by a film of lubricant that is supplied to the clearance space between the surfaces of the journal and bearing. The clearance is a critical factor in bearing design and has considerable effects on the assembly of the journal and bearing. The clearance provides space for the lubricant, allows for thermal expansion encountered in any harsh environments, and also provides tolerance for any shaft misalignment.

The internal combustion engine provides several excellent examples for uses of journal bearings. The journal bearings found on an engine's crankshaft main bearings, connecting rod bearings, and any accessory or balance shaft bearings provide sources of friction. The loads on these crankshaft journal bearings will be constantly changing, not only in magnitude, but also in direction. This is caused by the inertial loads of the piston/crank assembly and the pressures in the cylinder from combustion.

There is also considerable interest in reducing the fuel consumption in gasoline and diesel engines by using low viscosity lubricants [4]. As the viscosity is reduced, however, a point is eventually reached where metal-to-metal contact occurs in the bearing. When this occurs, an undesirable increase in friction

and wear is experienced. The use of low viscosity lubricants in bearings that were designed to run with higher viscosity oils can be catastrophic. Engine bearing performance can also be influenced by the passage of oil contaminants through the clearance of the journal bearing. The parameters that control how the bearing and the journal are separated could be clearly investigated using a controlled experimental system that provides accurate oil film thickness measurements.

In theory, the oil film thickness at a given set of conditions in a journal bearing could be compared with an extensive list of rheological properties for each oil. A statistical analysis of this information should be capable of identifying which known variables of oil dynamics have the greatest effect on the oil film thickness and whether any unknown variables are influencing the film thickness in a bearing. An accurate measurement system would allow analysis of current bearing design standards and indicate areas that need improvement.

BEARING MATHEMATICAL MODEL

Reynolds developed the theory of journal bearings based upon the concept of hydrodynamic equilibrium when the shaft is running at sufficient speed to support the shaft. Reynolds first suggested that if a lubricant is adhering to both the bearing and journal surfaces, so as to create a fluid pressure of sufficient intensity to support an external load, then the velocity, friction, and pressure distribution in the thickness of the lubricant film can be determined. These parameters can help to determine other unknown parameters required for complete journal bearing design. The hydrodynamic theory was based on the several simplifying assumptions. These assumptions are listed below.

1) Fluid film is thin enough to replace the curved partial bearings with flat bearings and the pressure variation over its thickness can be neglected.
2) Lubricants obey Newton's law of viscous fluid (Fluid is "Newtonian" or $\tau=\mu du/dy$).
3) Forces due to inertia and acceleration of lubricant are neglected ($F=ma=0$).
4) Lubricant is an incompressible fluid (flow in = flow out).
5) Viscosity of fluid is assumed to remain constant even though the inlet temperature and outlet temperature of lubricants are different (Average temperature value is used in any analysis or design).
6) The fluid experiences laminar flow with no slip at the boundaries.

With these simplifying assumptions, Reynolds began with the equations of equilibrium of forces on the fluid element shown in Figure 1. Using the above assumptions, the equilibrium of the forces shown on the differential element, and when end leakage fluid flow is included, the Reynolds equation for two dimensional flow can be developed, as shown in equation(1).

$$\frac{\partial}{\partial x}\left(\frac{h^3\partial P}{\mu\,\partial x}\right)-\frac{\partial}{\partial z}\left(\frac{h^3\partial P}{\mu\,\partial z}\right)=-6U\frac{dh}{dx} \quad \text{Eq (1)}$$

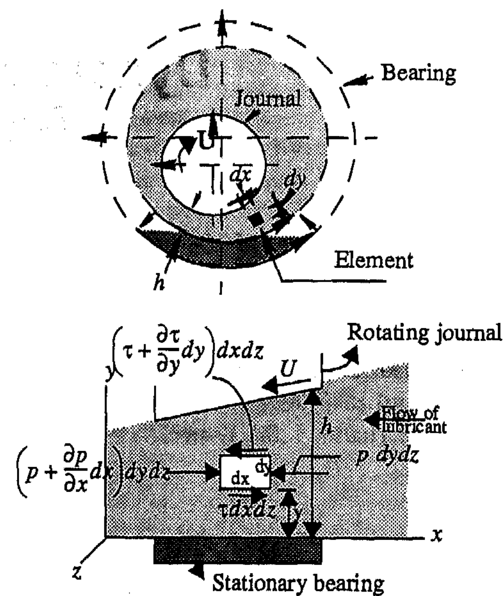

Figure 1. Shear element of oil in a journal bearing.

In Figure 1 and Equation (1), P represents the normal forces, due to pressure, acting upon the element. τ represents the shear forces, due to the viscosity, μ, and the velocity, U, and h is the thickness of the film. This differential equation has no analytical solution, therefore, the only solution that exists is a numerical solution. Raimondi and Boyd solved the Reynolds equation and presented their results in the form of several charts and graphs [5].

Dr. S. R. Bhonsle at Michigan Technological University has taken the graphical form presented by Raimondi and Boyd and digitized it in a numerical model. This model provides solutions for bearing geometries quickly and efficiently. This is a great improvement over the reading of the many charts and graphs presented by Raimondi and Boyd, which can be a tedious task and very susceptible to errors. Also, the design analysis is based on an average viscosity of the lubricant, which is based on the average temperature of the lubricant. At best, one only knows the inlet temperature of the lubricant. Therefore, an iterative process is required to arrive at the average temperature which can then be used to determine the viscosity of the lubricant used in the journal bearing. This, again, is time consuming and susceptible to errors. The output from the mathematical model can be seen in [6].

The experimental data obtained in this research was compared to the film thickness computed from the minimum oil film thickness and location of minimum oil film thickness from this mathematical model. Changes of the film thickness associated with changing the speed and load at which the bearing was operated were investigated in this research.

OPTICAL FILM SENSOR MEASUREMENT SYSTEM

The oil film thickness was measured in a journal bearing with an existing optical technique developed at Michigan Technological University under U.S. Patent Number 5,396,079. The

optical technique has been used for other studies, such as measuring the fuel film thickness in the intake port of an engine [7,8]. The film thickness sensor measures the depth of a fluid over a surface as shown in Figure 2.

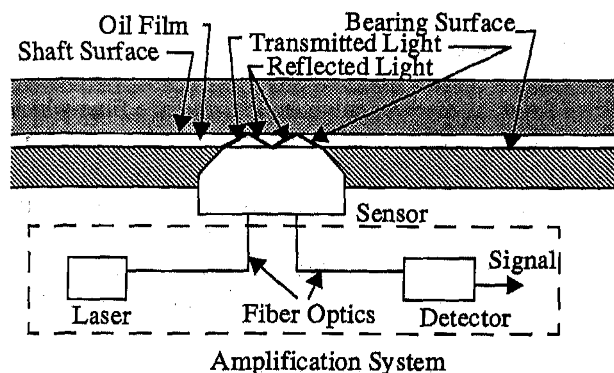

Figure 2. Overall film thickness measurement system.

The sensor is mounted flush to the bearing surface. The laser sends light to the sensor through fiber optics and forms a cone of light in the oil film. The light is reflected back to the sensor based upon the depth of the film. Fiber optics transmit the light to the detector which provides a signal based on the film thickness.

The operation of the sensor was developed using optical theory that states when a beam of light is sent from one medium to another, the degree of reflection, Θ, is determined by the angle of delivery, or angle of incidence, and the indices of refraction, n, of each medium. These angles can be determined by Snell's Law, as indicated by equation 2.

$$n_1 \sin\Theta_1 = n_2 \sin\Theta_2 \qquad \text{Eq (2)}$$

where subscript 1 denotes the characteristics of the medium in which the light is leaving and subscript 2 denotes the medium in which the light is entering. The path of a light ray according to this equation travelling from the sensor into the oil can be seen in Figure 3.

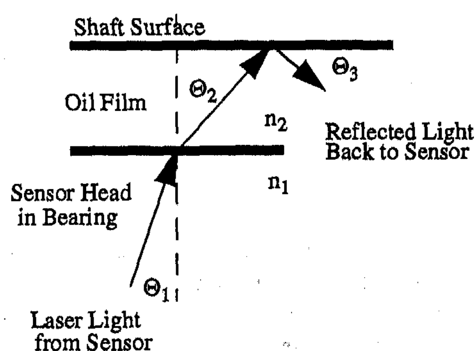

Figure 3. The effect of the different indices of refraction on a light ray traveling from the sensor into the oil film.

The angle Θ_1 is limited by a term called the critical angle. When Θ_1 is at the critical angle, the light cannot leave the sensor. The angle Θ_2 becomes 90° and results in no cone of light to be formed above the sensor. The critical angle for the sensor must not be reached to ensure proper operation of the measurement system.

Figure 4 illustrates the cylindrical optical film sensor. The optical sensor is manufactured with three main fiber optic bundles: an outer transmitter, an outer receiver and an inner receiver. The laser light enters the sensor from the transmitter bundle, placed around the perimeter of the sensor, and leaves through the outer transmitter section.

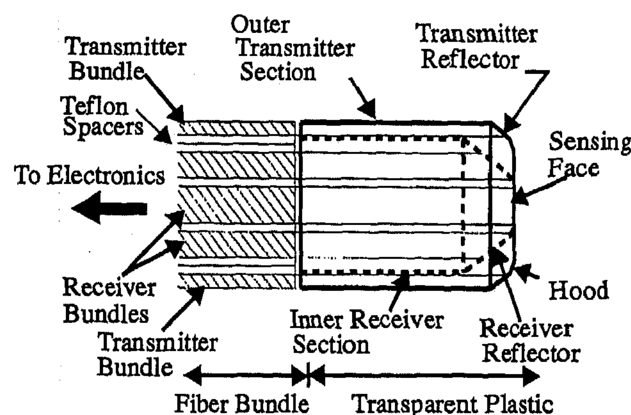

Figure 4. Sensor components and configuration.

The reflector surfaces are coated with a silvering chemical substance to enhance the reflection of the laser light and the other surfaces are painted black to reduce the reflection of stray light. The light, reflected from the cylindrical transmitter reflector, forms a cone of light in the oil film.

As the laser light enters the oil, a certain amount of its beam will be reflected back to the sensor depending upon the thickness of the oil film. The reflected light is gathered by the centrally located receiver section and sent to the detector. For zero film thickness, the voltage is also zero. As the depth increases, the amount of light returned to the receiver increases and the corresponding voltage increases.

INDEX OF REFRACTION MEASUREMENTS

The most important design variable was the angle of the transmitter reflector and the bending of the light leaving the plastic sensor head and entering the oil film. This angle was calculated from the index of refraction of oil, the plastic sensor, and the chosen maximum depth that the sensor can measure. Because there was no reference material available that gave the index of refraction for engine oils, measurements were taken to determine this parameter. Following the test standards developed according to ASTM D 1218-92 and D 1747, a Bausch&Laumb Abbe Refractometer was used to determine the index of refraction for several different weights of engine oils. Table 1 lists the indices of refraction for several different weights of engine oils and other liquids. The fluids where only one trial was given indicates a difficulty in measurement.

Table 1: Index of Refraction for Various Engine Oils

MEASUREMENT ELECTRICAL SYSTEM

Figure 5 shows the flow diagram of the light signal in the measurement system.

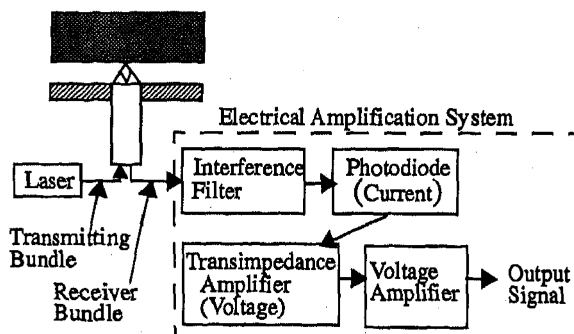

Figure 5. Diagram of film sensing signal.

A 3 milliwatt solid state diode red laser source is used to send the light signal, with a wavelength of 670 +/- 10 nanometers, from the amplification box to the journal bearing via a single plastic optical cable. This plastic cable was chosen in order to increase the light delivery efficiency and for its flexibility. For the wavelength of the laser, the cable has a loss of only 0.15 dB/meter [3]. This plastic cable is then connected to the glass fiber bundle which carries the light to the reflector surface of the sensor. Glass fibers were used in the region close to the engine because of the high temperatures that the sensor could encounter. The reflector surface sends the light at a specific angle to the sensing surface

The light from the receiver enters an interference filter which allows a very narrow bandwidth of wavelengths to continue. The bandwidth that the filter allows includes the wavelength of the laser light that was used. A filter was used to alleviate the possibility that light of other wavelengths would contaminate the measurements. The light exiting the filter directly enters the photodiode which transforms the light intensity to an electrical current. A phototransistor could also be used for this task since it provides a high level of internal gain.

However, the linear range of a phototransistor is smaller than that of a photodiode. The phototransistor also shows some sensitivity to temperature changes. Therefore, the diode was used with a higher powered, 3 milliwatt laser, to maintain a high enough output signal for the measurement range of interest. The transimpedance amplifier changes the current to a voltage signal. The interference filter, photodiode, and transimpedance amplifier were purchased as an integrated package to reduce losses between the filter and amplifier. It is also advantageous to include the transimpedance amplifier close to the diode since its output is on the order of milliamps. The final stage is a voltage-to-voltage amplifier which boosts the output level of the signal so that higher voltage readings can be acquired. A low pass filter is used after the signal is amplified to filter high frequency noise from the signal. The zero is adjusted using a voltage divider on the transimpedance amplifier when no light is entering the sensor. The gain is adjusted using the voltage amplifier with the sensor at a predetermined film thickness.

The entire package, laser and electrical circuit, was installed into one amplification box that was located near the engine. The zero and span functions were provided by the summing and gain amplifiers which could be adjusted through control knobs on the outside of the box. The output from this amplification box was sent to the Hi-Techniques IQ300 data acquisition system.

BEARING OIL FILM THICKNESS TESTING FACILITY

The testing facility for the bearing sensor required the incorporation of several key features that would allow the detailed experimentation of the journal bearing parameters. Of most interest in journal bearing research are the effects of speed, load, and viscosity of the oil. Figure 6 shows the overall setup of the bearing film thickness testing facility.

A 6KW Tecumseh horizontal shaft engine with a journal diameter of 30.15mm and a diametral clearance of 0.064mm was used for the experimental bearing. The clearance of the exper-

imental bearing was well within the designed maximum film thickness for the bearing sensor of 0.15mm. The most notable features of the test facility are the loading setup, A, and the in-bearing calibration setup, G. These features will be explained in full detail later in this section.

Other features of the bearing oil film thickness testing facility include an encoder, oil pump, oil flow meter, thermocouples, contoured sensor head, and placement of the electric motor. The Disc Instruments incremental shaft encoder, B, was included in the facility in order to increase the accuracy of the shaft rotational speed. The encoder output 360 pulses per revolution and also one top dead center pulse. The time between top dead center pulses was used to calculate the rotational speed. An electronic speed controller was used to maintain constant rotational speed.

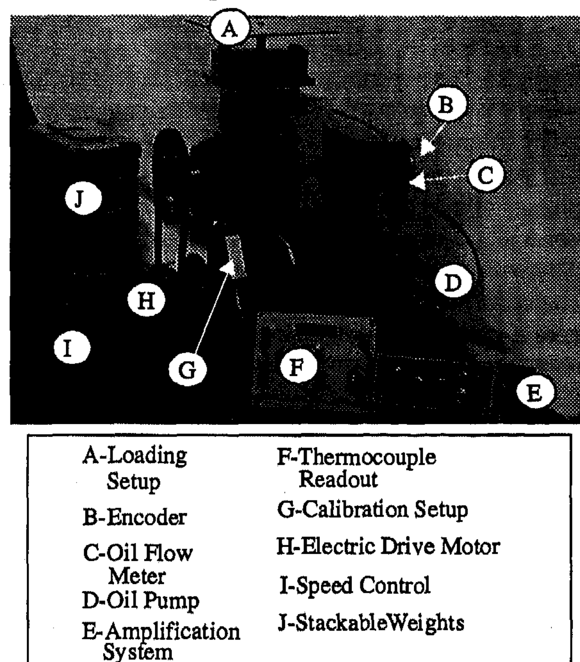

Figure 6. Overall view of the bearing film thickness testing facility.

A shaft of comparable diameter was machined to replace the crankshaft in order to allow a load to be applied. Since the original engine used a splash-type lubrication system that was obtained by the spinning of the crankshaft and dipping the connecting rod down into the oil, a different lubricating system needed to be added. The variable speed oil pump, D, was included to continuously supply the engine bearing with a controlled amount of oil. In conjunction with the oil flow meter the amount of oil fed to the bearing was precisely controlled.

A test stand was also constructed to locate the electric motor in relation to the engine. The electric motor, H, was placed below the engine in order to transmit the belt tension in the vertical direction. This would generally act as a weight applied to the shaft instead of pulling the shaft in a different direction. E-type thermocouples were also included in both the inlet of the oil pump and the outlet of the bearing in order to monitor the temperature of the oil during experimentation.

Since the calibration of the optical sensor proved to be difficult to obtain outside of the bearing, a simple device that would allow for calibration of the sensor directly in the bearing was designed and incorporated on the bearing oil film thickness testing facility. It was desired to calibrate the sensor directly in the bearing because it was necessary to maintain an oil film above the sensor at all times and, at the smaller film thicknesses, squeeze the oil film out from between the shaft and sensor. This new design was also beneficial because a calibration could be performed and then run directly without having to mount the sensor. This design would allow the sensor to be continuously calibrated and also be removed if necessary for inspection. This new calibration setup can be seen in Figure 7.

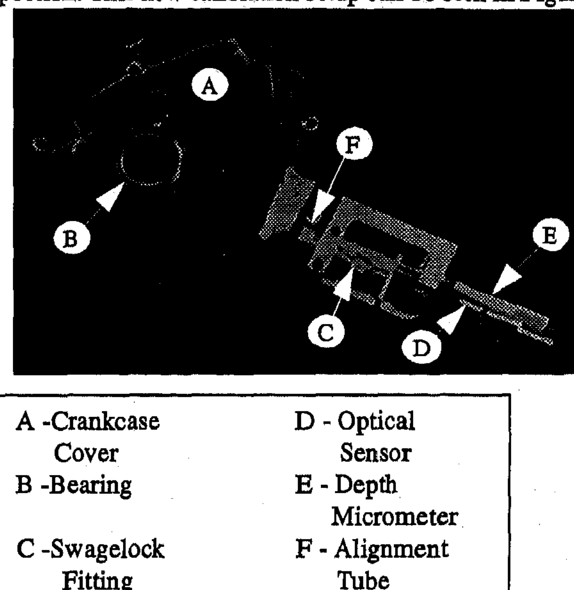

Figure 7. New in-bearing calibration setup.

From Figure 7, the bearing sensor, cast in a piece of tubing, mounts into an alignment tube that guides the movement of the sensor in and out from the bearing. A Swagelock fitting with nylon ferrules was incorporated around the bearing sensor to provide an oil pressure seal. When the Swagelock fitting was loosened, the tubing was allowed to move in or out and induce a film change directly in the bearing. A depth micrometer was used to measure this depth change. The Swagelock fitting was then tightened to provide a sufficient seal for the oil pressure to develop normally within the bearing.

From Figure 8, it can be seen that the bearing sensor was cast into a length of stainless steel tubing and the end ground to match the contour of the bearing surface. The sensor face was contoured so that the oil dynamics within the bearing would be minimally disturbed by any type of profile change.
The only effect may come from the differences in materials.

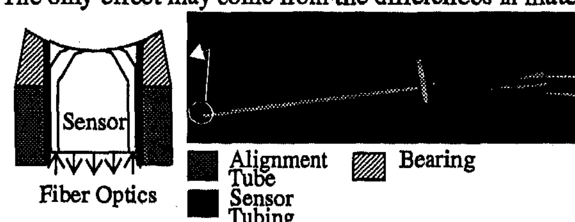

Figure 8. Final sensor mounted in tubing.

The bearing sensor installed in the bearing can be seen in Figure 9.

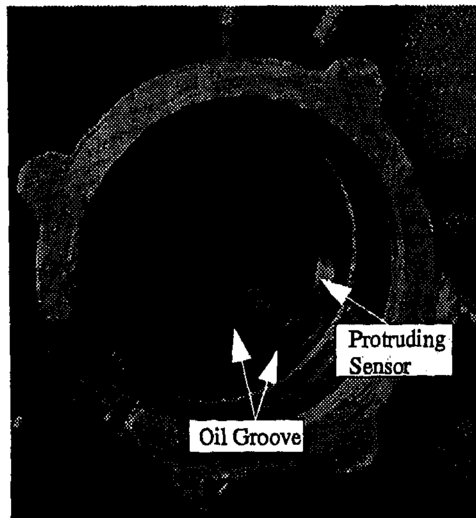

Figure 9. Bearing sensor protruding into bearing.

Another feature of the bearing film thickness testing facility was a loading setup used to load the shaft. The shaft was connected to a connecting rod and attached to another rod and plate that was used to load the shaft. An adjustable block was incorporated in the design and allowed the angle of the load to be applied at various angle from 30° counterclockwise to 30° clockwise from vertical. On top of the loading plate, weights of 9kg increments were stacked to apply a load to the shaft. This setup allowed the flexibility to apply the load while the shaft was running and also when the shaft was at rest.

CALIBRATION OF BEARING SENSOR

A calibration of the bearing sensor was performed using the in-bearing calibration setup. The engine was assembled and the shaft was pulled tight to the bearing, and held away from the sensor. The calibration was performed with the shaft not rotating and the bearing filled with oil. This calibration curve can be seen in Figure 11.

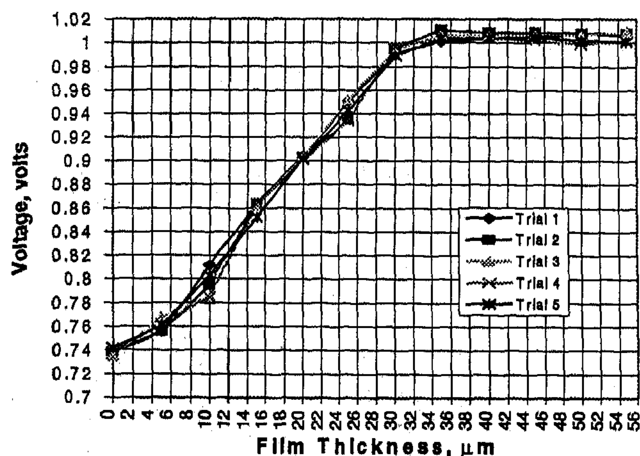

Figure 11. Calibration curve for bearing sensor.

Figure 11 shows that as the sensor moved closer to the journal, causing the film thickness to decrease, the voltage decreased. The calibration for the bearing sensor was performed five times under the same conditions. For each trial, the zero and gain of the amplifier were set when the sensor was 55µm away from the zero film condition. The overall change in voltage can be adjusted using the gain of the amplifier. Adjusting the gain, however, does not change the shape of the calibration curve.

The small variation that was seen in this calibration curve can be explained by the amplification system and calibration setup that was used. The amplifier used for calibration did have a small amount of drift. The flange on the tubing of the sensor did flex, so it was important to recheck the depth of the sensor in the bearing to obtain an accurate measure of the film thickness.

EXPERIMENTAL TESTING

STEADY STATE CONSTANT SPEED

Vertical Loads - The experimental portion of this research was to prove that the sensor was seeing trends similar to the trends predicted by the mathematical model. The first experiment performed was accomplished for a constant rotational speed and applying various loads to the shaft. For this experiment the sensor was locked into the flush position using the Swagelock fitting with Teflon ferrules. This experiment was done at constant speeds of 600 RPM and 1000 RPM for bearing loads ranging from 0 to 55 kg. The results from this experiment compared to the mathematical model for the same speeds can be seen in Figure 12.

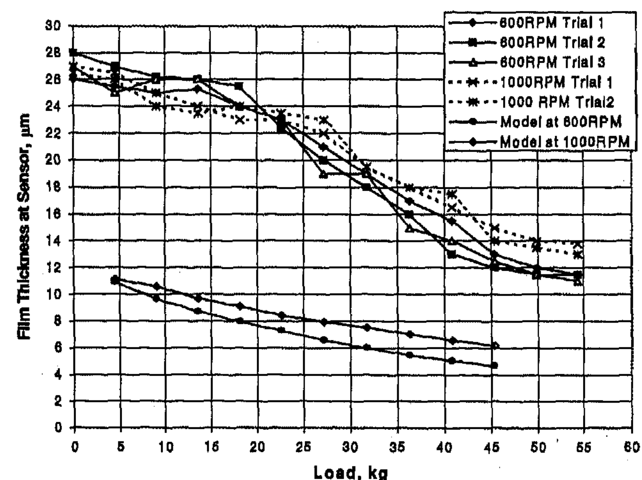

Figure 12. Experimental vs. model film thickness as a function of load.

Figure 12, shows that the general trend of increasing the load decreases the film thickness. This decreasing trend is consistent with the mathematical model. Figure 12 also shows that at the high load condition the film thickness for the 600 RPM condition is lower than the 1000 RPM condition. This trend is also consistent with the mathematical model. The large difference in magnitude between the experimental data and the mathematical model will be explained in the Differences Between Mathematical Model and Experimental Testing section.

Angled Loads - The same experiment was performed for the load applied at an angle of 30° directed toward the sensor at speeds of 600 RPM and 1000 RPM, which should cause the film thickness to decrease. The results from this experiment can be seen in Figure 13.

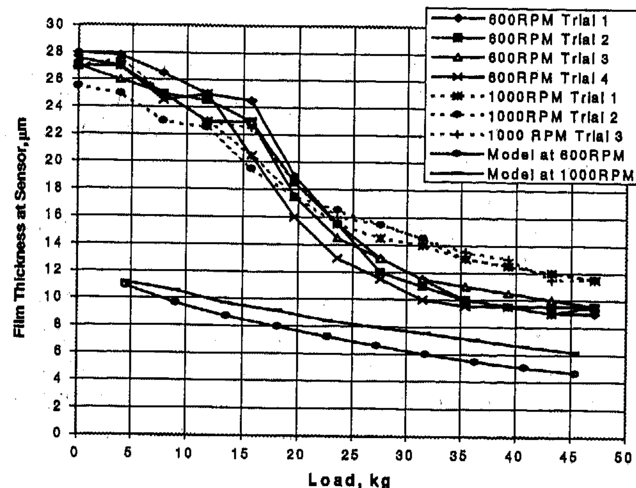

Figure 13. Experimental data for load at 30° angle vs. model data for vertical load.

Figure 13 once again shows the agreement between the decreasing trend of film thickness as a function of load at constant speeds between the experimental data and mathematical model. Another important result that can be seen from this figure is that at the higher loads, the difference between 600 RPM and 1000 RPM is more pronounced. The film thickness for the 600 RPM case was smaller than the 1000 RPM case. This was again consistent with the mathematical model predictions. Also, the film thicknesses at larger loads were less than the vertically applied load condition.

Another experiment was performed to test the effect of speed on the oil film thickness. By maintaining a constant load and increasing the rotational speed, similar trends should be achieved. This experiment was run for load cases of 18, 27, 36, and 45 kg of bearing load for a speed range of 375 RPM to 925 RPM.

STEADY STATE CONSTANT LOAD

Figure 14 illustrates the oil film thickness based on speed at constant loads. As the speed increased for all the load cases, the film thickness also increased. Also as the load decreased, the magnitude of the oil film thickness increased. The experimental data trend for each load case compares well with the predicted mathematical model trend. Once again, there is a large difference in the magnitude of the oil film thickness between the experimental data and the mathematical model.

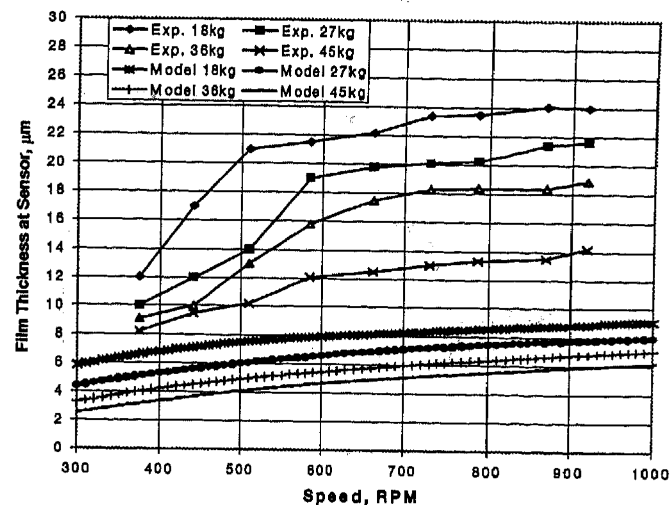

Figure 14. Film thickness at sensor as a function of speed vs. mathematical model.

Even though the trends compared well with the mathematical model, there were differences between the overall change in oil film thickness. A comparison between the change in oil film thickness for the vertical load case and speed case can be seen in Table 2 and 3.

Table 2: Change in Film Thickness for a Change in Load from 18 to 45 Kg for Constant Speeds of 600 and 1000 RPM

	Oil Film Thickness, µm	
Speed,RPM	Experimental	Model
600 RPM	12.5µm	3.5µm
1000 RPM	9µm	3.5µm

Table 3: Change in Film Thickness for a Change in Speed from 375 to 925 RPM for Constant Loads of 18 and 45 Kg

	Oil Film Thickness, µm	
Load, Kg	Experimental	Model
18 Kg	12µm	3µm
45 Kg	6µm	3µm

DYNAMIC TESTING

No Load Condition - The goal of this research was also to show the transient response during the start-up of the journal. Figure 15 shows the start-up of the bearing with no load to 260 RPM. As the speed is increased, the film thickness rises to an operating value.

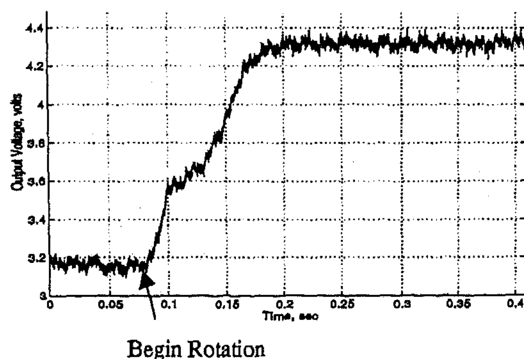

Figure 15. Start-up of bearing to 260 RPM with no load.

Loaded Condition - The effect of load on start-up was next investigated. This is shown in Figure 16.

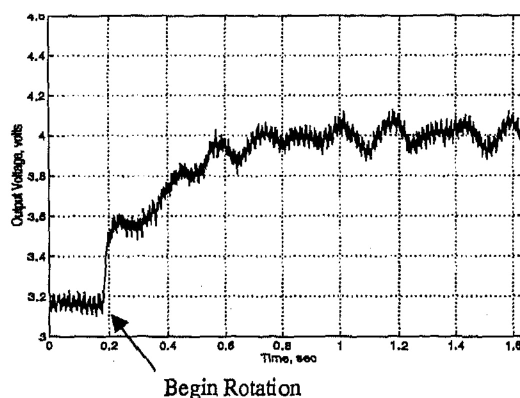

Figure 16. Start-up of bearing to 260 RPM with 36 kg bearing load.

From Figure 16, it can be seen that the start-up has a similar trend, but does not reach a constant value. The sensor seems to see the journal oscillating within the bearing. The origin of the oscillation was not investigated. Also, this average value is smaller and takes longer to reach than the no load condition. The lower voltage is a result of the load causing the film thickness to be reduced and therefore the voltage to decrease.

DIFFERENCES BETWEEN MATHEMATICAL MODEL AND EXPERIMENTAL TESTING

Several important reasons could explain the differences in the changes of thickness. The most important reasons for the differences are attributed to the assumptions used in the mathematical model. The first difference between the mathematical model and experimental conditions is the centrally located oil groove in the bearing. This oil groove can be seen in Figure 9. Oil grooving in a journal bearing provides two purposes: (1) to establish and maintain an efficient film of lubricant between the bearing moving surfaces; and (2) to provide adequate bearing cooling. The oil groove alters the pressure distribution within the bearing and significantly influences the bearing performance. The mathematical model provides conditions with no oil grooving and assumes a symmetric pressure profile across the width of the bearing. The central groove would seem to reduce the oil film thickness by altering the pressure distribution into two smaller regions across the width of the bearing.

However, an oil groove also permits more oil to pass through the bearing, thus keeping it cooler. Cooler oil temperatures result in higher viscosities. This aspect is the second major difference between the experimental data and the model. The thermocouples placed in the inlet and outlet positions of the bearing were used to substantiate the temperature of the oil. The mathematical model predicted a temperature change of 7.22°C, while the actual temperature change that was seen in the experiments was 2.78°C. When the shaft was running at 1000 RPM under a bearing load of 55 kg, the model overpredicted an increase in the outlet temperature. The resulting viscosity increase of 12.8 μreyn would tend to increase the oil film thickness.

A third influence that needs to be considered when comparing the model to the experimental data is the method of supplying oil to the bearing. The mathematical model assumes that the oil is supplied to the bearing at atmospheric pressure. Since the original engine supplies the bearings using a splash fed system, the film thickness could be influenced by supplying the oil with an oil pump. The splash fed system originally used the connecting rod to scoop oil from the crankcase and splash oil into the feeder holes of the bearing. For the oil pump system, hoses were set into the holes to feed the bearings. Even though there was no sealed system, a small increase could be attributed to the oil pressure supplied to the bearing by the oil pump.

The observed differences may also be attributed to a few more of the general assumptions used in the model. Three differences - that the oil is not fully incompressible, that the viscosity of the lubricant is not constant over the dimensions of the bearing, and that the fluid is not Newtonian - may have significant effects on the performance of the bearing. Newtonian fluids are defined as those oils for which the shear stress is directly proportional to the shear rate and for which the viscosity is only a function of temperature, pressure, and oil composition. The oil used in this research was Unocal 76 Guardol SAE 20W-20 API Service CD/SG and may contain several additives that alters the oil from being a Newtonian fluid.

ACCURACY OF FILM THICKNESS MEASUREMENTS

The accuracy with which the optical sensor can measure the oil film thickness in a journal bearing depends on the accuracy of the calibration. For the bearing film thickness testing facility, the metric depth micrometer used in the in-bearing calibration setup has an accuracy of 1μm. A statistical analysis of the calibration curve, Figure 11, shows that the observed output voltage at specified film thicknesses, on average, has a standard deviation of 0.004515 volts.

SUMMARY AND CONCLUSIONS

The following conclusions can be made regarding the evaluation of using the optical film thickness sensing system in a journal bearing application:

1) The film thickness sensing system is capable of measuring the dynamic changes of oil film thickness in a journal bearing.
2) Experimental data received from the bearing film thickness sensor is consistent with the mathematical model, which states that increasing the load decreases the oil film thickness and increasing the rotational speed increases the oil film thickness.
3) The bearing oil film thickness testing facility provided a satisfactory means to control load, speed, and oil flow.
4) The in-bearing calibration setup and technique resulted in a reproducible calibration of the bearing sensor.
5) The bearing sensor performs well, even though difficulties existed in sensor construction.

ABSTRACT

The Quality-Level-Temperature-Sensor (QLT-Sensor) provides the dielectric number, level and temperature of fluids used in passenger car engines e.g. engine oils. The dielectric number can be used to indicate changes in oil-quality. Level detection can be used to determine oil consumption, minimum oil level or critical overfilling. The oil-temperature can be used in combination with the dielectric number for precisely predicting the oil drain time. The design-principles and functions, including compensation of aging and temperature effects are described. It is shown, what engine constructors and developers must consider when regarding mechanical and electrical interfaces.

INTRODUCTION

In general measuring oil quality alteration requires a large laboratory in the background, since numerous and not always the same parameters determine the oil's useful life. Essential parameters are e.g.: viscosity, additive concentration, contents of soot etc. Degradation of engine oil performance is a multidimensional problem and cannot be monitored sufficiently solely by one factor.

Today maintenance intervals of vehicles are generally set by a fixed mileage or time span due to the lack of available tools for determining exact performance degradation of various vehicle components. Normally the main maintenance determining factor is the engine oil. Its degradation is a function of how the engine is operated. Hence monitoring this operation would result in a flexible servicing system [1].

In search of a solution a practical approach was chosen: finding and measuring one parameter which showed a good correlation to oil degradation, especially to the condition of additives. In the laboratory numerous tests were conducted, which resulted in finding sufficient correlation between changes in the oil's dielectric number and its aging. This is nothing new [2] but up today no adequate methods had been available capable for doing this on-vehicle. When fresh oil is toped up or water condenses, the dielectric number is influenced. It is obvious, that such effects must be taken into account. Hence considering parameter changes in dielectric number and oil level effects in combination with a few engine parameters , oil drain period can be more precisely predicted.

Prototypes based on a capacitance measuring system are running successfully since 1993 in passenger car engines. In 1994 industrialization of the sensor started and volume production has commenced in August 1996.

FUNCTION OF THE SENSOR

The sensor cell consists of two cylindrical capacitors. One is totally immersed in oil. The capacitance depends on the dielectric number of the oil. The second capacitor is in a position, that the oil levels between the expected maximum and minimum levels can be measured. Its capacitance depends on the dielectric number of the oil and on the level in the sump. Figure 1 shows a schematic cross section of the sensor.

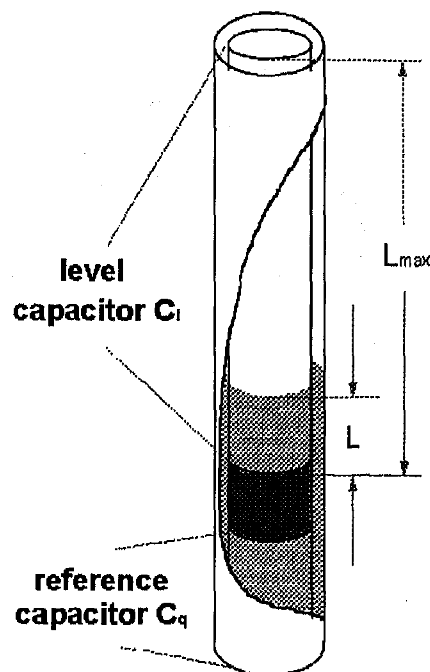

Figure 1: Schematic cross section of the sensor

The relative dielectric number of the oil is given through equation 1:

$$\varepsilon_r = \frac{C_q(oil)}{Const._1} \quad (1)$$

The oil level is given through equation 2 (derivation of the formula see APPENDIX):

$$L = \frac{L_{max} \times (C_l - Const._2)}{(\varepsilon_r - 1) \times Const._2} \quad (2)$$

Capacitance and resistance of a temperature sensitive device are measured by an electronic circuit, which converts the data into pulse width modulated signals. The signals are sent on a single signal line within a 300 millisecond time slot (100 milliseconds for each signal). After a pause of 1 second the next measuring cycle starts. The electronic circuit (Figure 2) is state of the art for resistance and capacitance sensitive circuits. It is composed of very precise reference devices like resistors and capacitors with lowest temperature coefficients, thus minimizing any temperature drift of the sensor. In a separate operation cycle the conductivity of the oil is measured. In the next cycle the capacitance are measured and the leakage current due to the conductivity of the oil is compensated through programmable current sources.

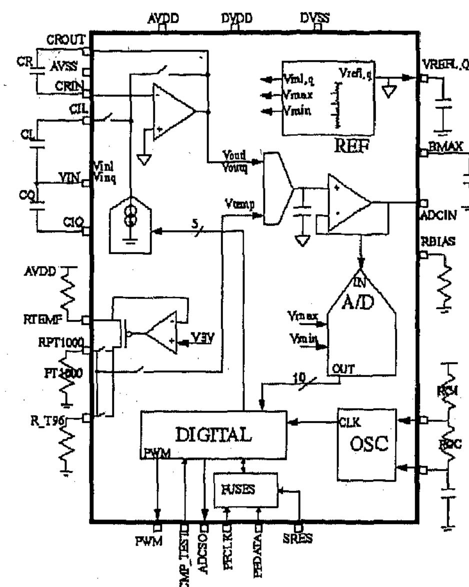

Figure 2: Block diagram of sensor control circuit

Thus a multifunctional sensor, measuring oil temperature and capacitance is realized. Dielectric number and oil level can directly be calculated with these results.

DESIGN OF THE SENSOR

The sensor has 4 major elements: a sensor cell comprising cylindrical capacitors and temperature sensor, a mechanical adapter for fixing the cell to the oil pan, a feed through including sealing elements, and an electronic housing with integrated connector.

The sensor cell consists of stainless steel tubes and spacer elements made of polyphenylene-sulfide resin. Oil tightness is realized by seal-rings made of synthetic rubbers. The tubes are connected to a printed circuit board in the electronic housing by shielded cables with crimped spring contacts. The temperature sensitive device is integrated in one of the spacer elements, forming good thermal contact to the oil. The housing of the sensor cell is made of plastic and has a well situated inlet hole for the oil, an opening for ventilation and the fixture to the oil pan. A seal-ring is designed into the sensor cell to prevent leakage through the oil pan. Of course all materials have a high temperature and chemical resistance, so that temperatures of 160°C and fluids like fuel, detergents and so on have no effects and influence on function and reliability of the components.

In addition the plastic parts, especially the part with the fixture to the oil pan were dimensioned in such a way that all expected thermal, mechanical

and chemical stress leads to no degradation of function.

The special choice of materials, as well as the parameters for molding have been chosen in accordance with FEM-simulations and verified through tests with a shaker in a climate chamber at high temperatures.

Of special interest was the material of the printed circuit board and the electronic devices, forming the electronic circuit. Well suited are epoxy-circuit boards made of FR4-05 material and passive elements like resistors and capacitors which are qualified for up to 150°C. The active part of the circuit is an application specific silicon chip (ASIC), designed in C-MOS technology. This technology has been tested over 6000h at 125°C and over 1000 h at 140°C with no failure.

Today interconnection technology is the determining factor for reliability. Only certified technologies like SMD-technology for the printed circuit board and crimping for the wiring have been chosen. The connectors are joined to the printed circuit board by pressing the contacts into the board forming a very tight reliable contact.

MODULARITY OF THE SENSOR

Various solutions for the sensor's mounting within passenger car engine's oil pans have been realized. For example, if there is not much space inside the oil pan, but enough space between oil pan and road surface, mounting from the bottom side can be recommended. Normally mounting from the bottom side solution is standard but requires a design-in time point at an early stage in the project. A mounting solution from the engine's upper side is also available, having advantages for designs with low road surface clearances. However complex the construction situation might be, there is always a way to get the sensor in the right position for sensing QLT (quality, level, temperature) since the modules as described above can be combined in various ways. As an example 3 construction types for different mounting situations are shown in the following figures (Figure 3, Figure 4, Figure 5):

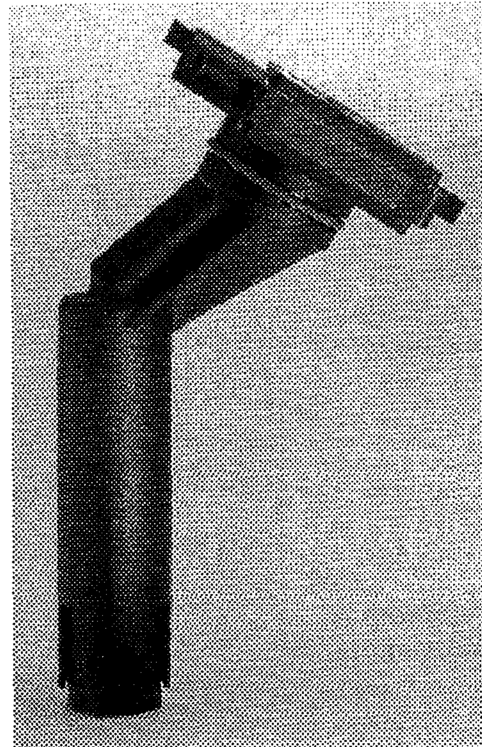

Figure 3: Sensor for mounting from the top side

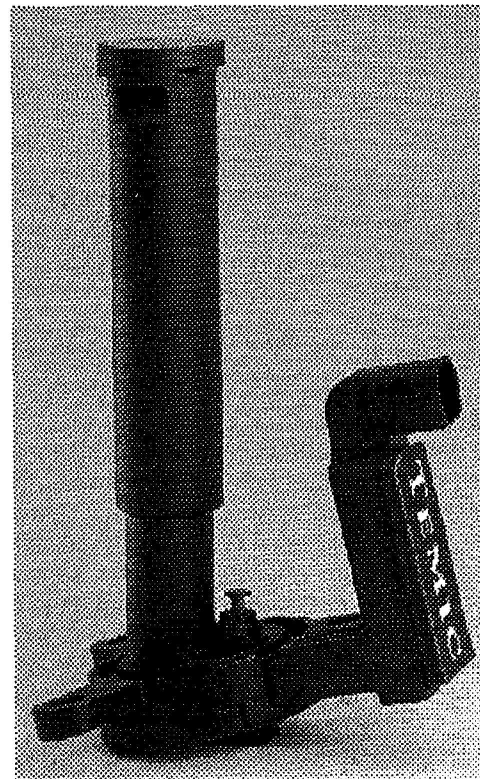

Figure 4: Sensor for mounting from the bottom side

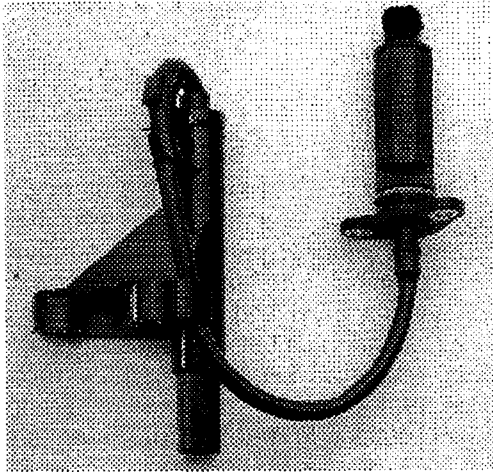

Figure 5: Separate sensor cell and an electronic housing connected through a flexible cable

MEASUREMENT RANGES

The sensor measures oil temperatures in the range of -40°C up to +160°C with an accuracy of ± 2°C. Dielectric numbers from $\varepsilon_r = 1$ up to $\varepsilon_r = 6$ are measured with an accuracy of ± 0.1. The range of the level measurement depends on the mechanical design. Ranges from 48mm up to 125mm are possible with an accuracy of about 3.8%, including the error contribution of all the signal conditioning circuits like sensor electronics, processing unit and display driving units.

MECHANICAL INTERFACE

The mechanical interface is of high interest for the engine developer. The fixture of the sensor must be able to fulfill all the high requirements of exact fitting, because the measured level also depends on the tolerances of the oil pan's fixture points . No part of the sensor should get into the critical range of moving parts inside or outside of the engine.

The mounting of the sensor has to be compatible with automation. Two assembly methods are validated: automated screwing and a pick-place and clamp-method. Design and development of these interfaces were realized according to simultaneous engineering principles.

ELECTRICAL INTERFACE

The electronic engineers have 3 major tasks to achieve: to reach the specified accuracy, to match the sensor's output with the calculating unit's input and to fulfill electromagnetic compatibility (EMC). The first two tasks are normally easy to do. To take precautions against influences like conducted distortions on the power and signal lines or electromagnetic radiation is a difficult and very complex task, especially when a capacitance measuring sensor is involved. Laboratory testing on samples is the first step to prove whether the sensor design meets the requirements. But this does not guarantee, that in the car the sensor and all other components will work well, when radiated with high electromagnetic fields. Due to special EMC-design electromagnetic interference testing was successful up to fields of 200 V/m.

TEST RESULTS

Temperature measurement with short response times and transmission of the data to the engine management unit supports functions for reducing emissions/exhaust fumes, reduced fuel consumption or fine tuning of additional mechanical functions.

The oil level in a passenger car engine is a function of engine speed, various vehicle movements and diverse oil properties. Figure 6 shows the oil level in a V6-engine as a function of engine speed. Figure 7 shows the influence of car steering.

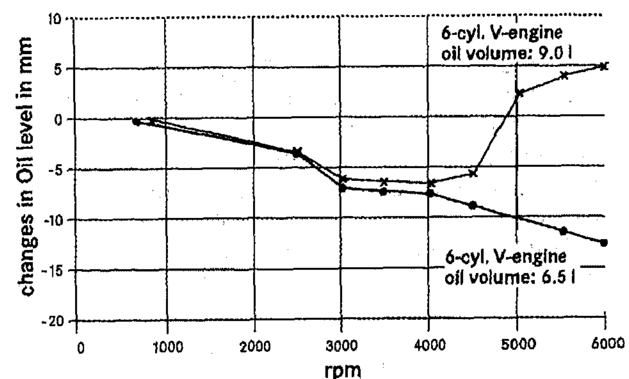

Figure 6: Oil level vs. revolutions per minute

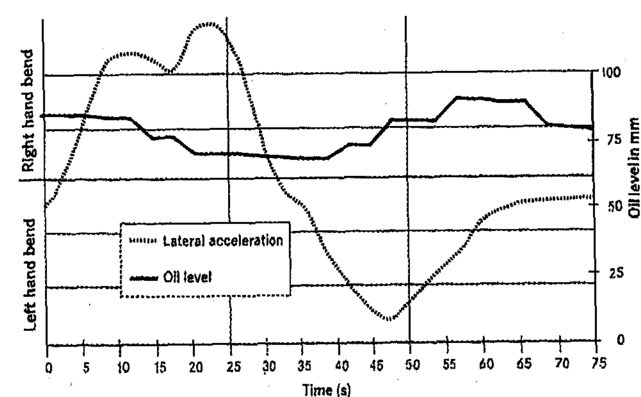

Figure 7: Oil level alteration when curving

Especially developed Algorithms can eliminate such influences. For example forming averages over a time interval or over a driving distance can eliminate influences arriving from steering or acceleration (Figure 8). Systematic effects (like engine speed) can be compensated and for extreme situations (like foaming oil, high acceleration or a high steering angle) values can be discarded. Thus the oil volume can be calculated with an accuracy of ± 1,6% taking all this measures into account.

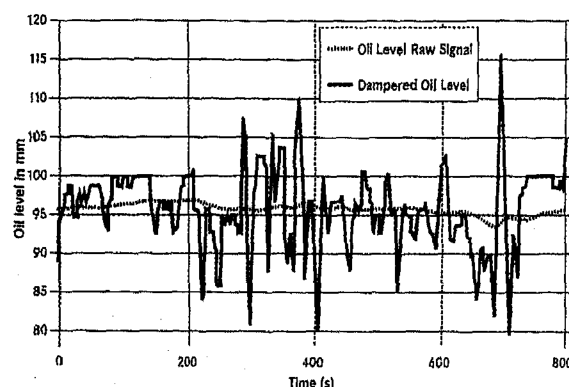

Figure 8: Data from sensor, mean value and oil level

Figure 9 shows the change of the dielectric number for several oils of different initial qualities and different driving conditions. The change depends on the quality of the oil and on the special driving conditions. It is not possible to determine oil quality only by evaluation of the dielectric number. In combination with further engine parameters customized oil drain periods can be achieved in a much more precise way.

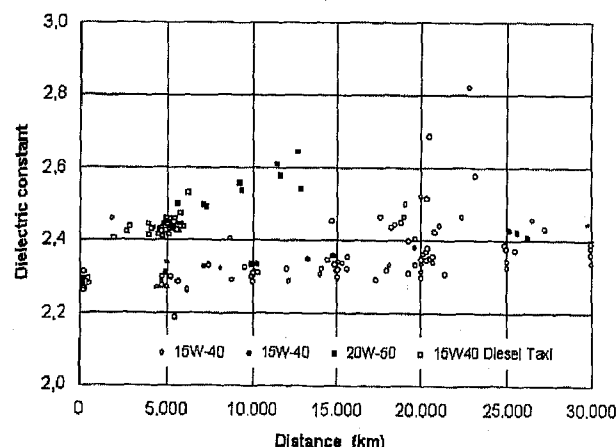

Figure 9: Change of dielectric number for several oils

It is important to know, that the oil temperature has great effects on the dielectric number. One possibility to overcome these difficulties is the evaluation of the dielectric number, measured always at the same temperature, e.g. at 80°. There are situations which lead to an increase of the dielectric number, e.g. short distance driving. The intrusion of water and fuel due to blow-by in the engine can be simulated with the so called hot and cold idling test shown in Figure 10 [3].

Fuel and water in the engine oil results in an increase of volume and therefore a higher level-signal. Driving a longer period under normal engine operating conditions with oil temperature exceeding 90°C evaporates water and fuel, so that the original level and dielectric number is reached (Figure 10). It is evident, that such situations can be recognized. Evaluation of the sensor data and other operation parameters enables to find the true interpretation of the state of the engine oil.

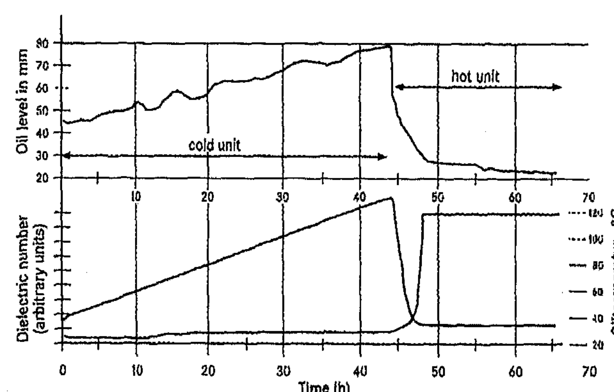

Figure 10: Hot and cold idling test

CONCLUSION

The QLT-sensor is the first system that can measure engine oil parameters on-line. Apart from oil level and temperature oil quality via detection of the dielectric number is achieved for the first time by a direct measuring instrument. Oil consumption and oil drain time can be calculated with sufficient precision contributing in saving natural resources due to less fresh and used oil. An important parameter for precise managing of other functions within the engine is oil temperature. As a result fuel consumption and exhaust emissions can be optimized.

ABSTRACT

The recent progress of electronic control systems in vehicles is remarkable as evidenced by the development of electronic fuel injection systems,(EFI), automatic transmission control systems, and anti-lock brake systems,(ABS). The number of actuators for the systems has been increasing.

Consequently, a need has been identified for a reduction in volume and number of the system actuators for control purposes. A composite magnetic material has been developed with the aim of miniaturizing magnetic solenoid valves for actuator applications. A composite magnetic material is such that both ferromagnetic and paramagnetic sections coexist within a single material, and can contribute to optimization of the magnetic circuit of a solenoid valve.

This paper describes the development of a composite magnetic material, and its resultant characteristics. The chemical composition of the material, essentially 18% Chromium - 8% Nickel stainless steel, required to improve both ferromagnetic and paramagnetic properties and the process of producing composite magnetic properties are reported in detail.

This composite magnetic material exhibited superior properties, having a magnetic flux density B40 (Induction at H of 4000A/m) of 0.8 Tesla in the ferromagnetic section, and relative permeability μ r of 1.01 in the paramagnetic section. The application of this material to a magnetic solenoid valve for ABS could reduce by approximately 20% volume.

INTRODUCTION

Magnetic solenoid valves shown in Fig.1 are usually constructed from coil, moving core, stator core, and valve components. The function of the valve is to control the flow of a liquid or gas by moving a core using a magnetic force. In order to seal the liquid or gas, a metal component called a sleeve is used. This component is generally paramagnetic to maximize magnetic flux transfer from the moving core to the stator core.

If this component is constructed from a ferromagnetic section and a paramagnetic section as shown in Fig.2, magnetic efficiency can be improved, and the volume of the valve can be reduced. This may be accomplished by joining ferromagnetic and paramagnetic sections by welding; however, this method is costly, and presents difficulties in terms of sealing.

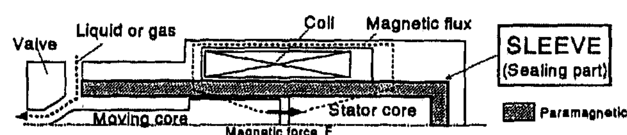

Figure 1. Typical magnetic solenoid valve

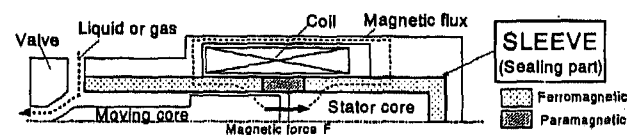

Figure 2. Efficient magnetic solenoid valve

A material has been investigated which may be either ferromagnetic or paramagnetic through the use of simple processing, and which may have both ferromagnetic and paramagnetic sections in coexistence. This material has been designated a composite magnetic material.

CONCEPT OF THE COMPOSITE MAGNETIC MATERIAL

It has been well known that austenitic stainless steels (e.g. AISI type 304) are composed of austenite after solid solution treatment, and that these materials exhibit paramagnetic properties. Furthermore, the austenite phase may be transformed to martensite through cold working, so called deformation-induced martensite, and the resultant martensite phase is ferromagnetic. Therefore, when a part of this martensite is made transform to austenite by heat treatment, a composite magnetic material is obtained as shown in Fig.3.

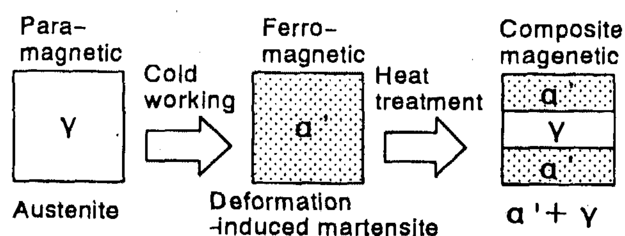

Figure 3. Schematic production process of composite magnetic material

Unfortunately, the amount of deformation-induced martensite formed upon cold working is small in typical austenitic stainless steels, such as AISI type 304, and these steels have insufficient ferromagnetic properties, a low magnetic flux density and a low maximum permeability. The development of a composite magnetic material was based upon the optimization of 18Cr 8Ni austenitic stainless steel with improved magnetic properties.

EFFECT OF CHEMICAL COMPOSITION ON MAGNETIC PROPERTIES

The effect of chemical composition on magnetic properties was investigated using various 18-8 stainless steels as detailed in Table 1.

Magnetic flux density, B40 (Induction at H=4000 A/m), for test samples after 70% cold reduction is shown in Fig.4 as a function of (Ni). Relative permeability after solid solution treatment is shown as a function of (Ni) in Fig.5. (Ni) is Hirayama's Ni equivalent [1,2] and defined as follows:

$$(Ni) = [Ni] + 0.65[Cr] + 0.98[Mo] + 1.05[Mn] + 0.35[Si] + 12.6[C] \qquad (1)$$

where [Ni], [Cr], etc. are elemental concentrations in wt% of the steel of interest. It has been known that (Ni) has a close relation to the volume fraction of deformation-induced martensite or athermal martensite.

The magnetic flux density following cold rolling increases with the reduction of (Ni) as seen in Fig.4. Additionally, the relative permeability following annealing decreases with increasing (Ni) as seen in Fig.5. Using these two factors, a chemical composition which optimizes magnetic properties may be arrived at. Magnetic flux density indicates that (Ni) should be held below 21.5 wt%. Relative permeability data indicates that optimum performance is obtained with (Ni) above 20.5 wt%.

Md AND Ms TEMPERATURES

The application of the composite magnetic material to automotive magnetic solenoid valve

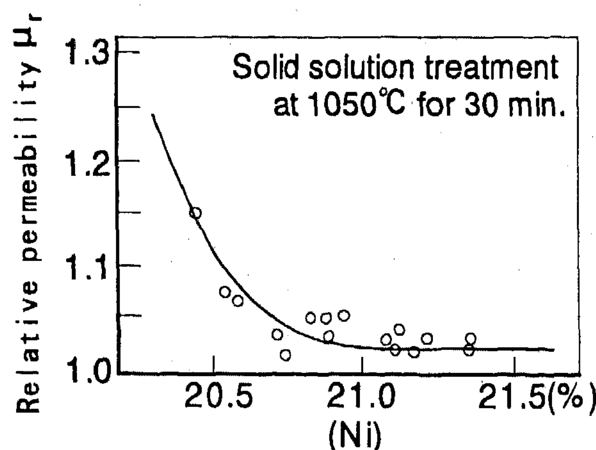

Figure 5. Variation of relative permeability μ r as a function of Hirayama's equivalent (Ni)

actuator sleeves further requires an investigation of the Md and Ms temperatures of the alloy. This is necessitated by the relationship of the Md temperature to ferromagnetism, and the Ms temperature to paramagnetism. Chemical compositions of the steels which were examined are given in Table 2.

Md TEMPERATURE - The Md temperature is defined as the temperature above which austenite will not transform to deformation-induced martensite upon mechanical working[3]. The current application dictates that the material temperature during cold deformation should be kept below the Md temperature so as to enhance the ferromagnetic properties of the material, thus promoting magnetic flux density and maximum permeability.

The martensite content variation as a function of temperature at 30% true strain is illustrated in Fig.6. Deformation-induced martensite fraction decreases rapidly with increasing temperature. The Md temperature can be estimated from Fig.6 by observing the temperature at which the volume fraction of martensite approached zero.

The variation of Md temperature with (Ni) is shown in Fig.7. As can be seen, the Md temperature is approximately 80℃, and is a very weak function to (Ni). This data indicates that working temperature is a critical property for ferromagnetic property development, and is a critical parameter for process control.

Ms TEMPERATURE - Paramagnetic austenite transforms to athermal martensite below the Ms temperature, and the magnetic property becomes ferromagnetic. The Ms temperature of the composite magnetic material should be lower than the expected operating range of the component to inhibit this transformation. If not, the relative permeability of the paramagnetic section would increase, and the advantages gained with respect to magnetic flux transfer between the moving core and the stator core would be lost.

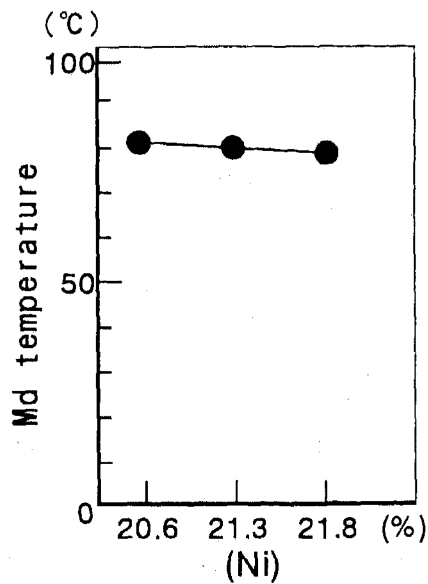

Figure 7. Variation of Md temperature as a function of Hirayama's Ni equivalent (Ni)

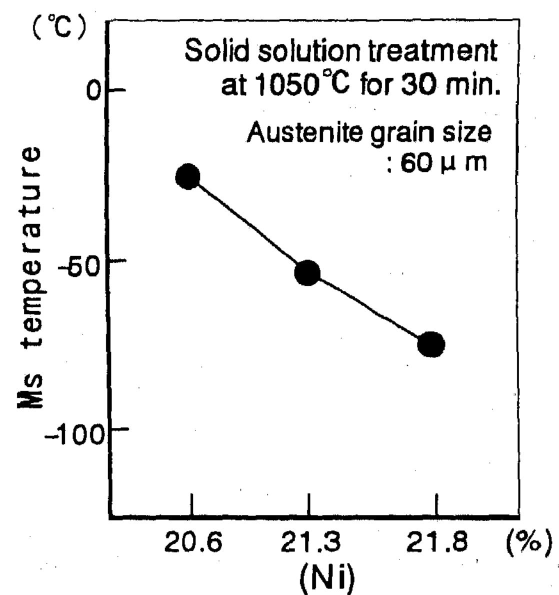

Figure 8. Variation of Ms temperature as a function of Hirayama's equivalent (Ni)

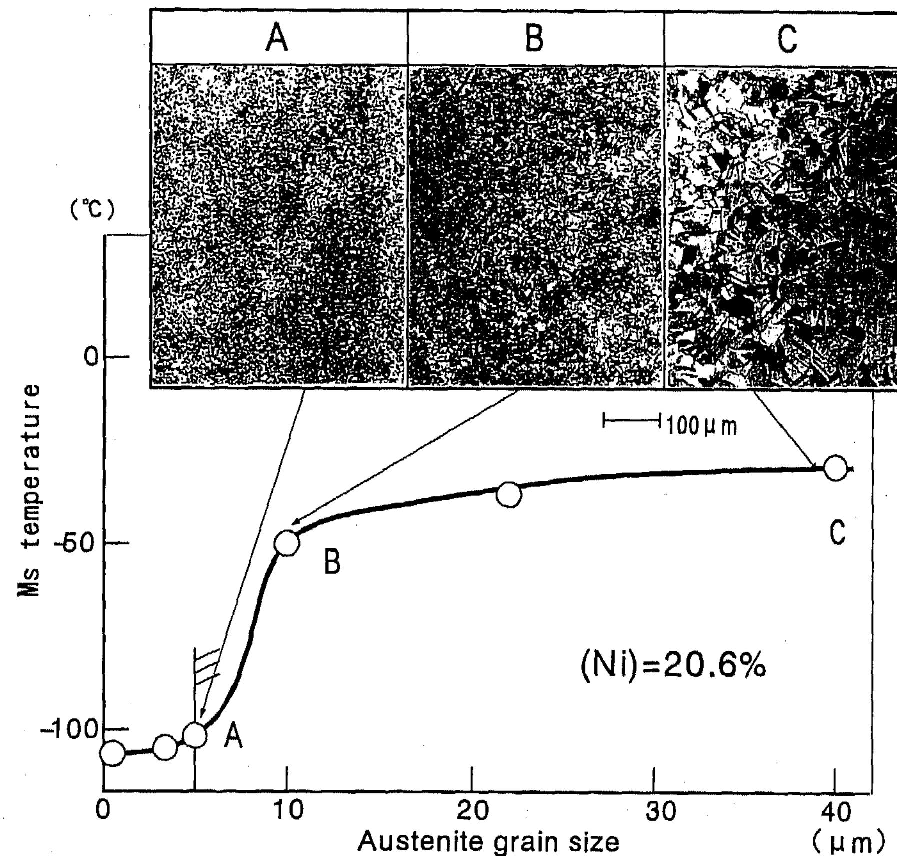

Figure 9. Effect of austenite grain size on Ms temperature

The variation of the Ms temperature with (Ni) for the materials in Table 2 is illustrated in Fig.8. The Ms temperature was measured with the differential scanning calorimeter. Ms temperature is found to decrease as the (Ni) is increased. At a (Ni) of 20.6%, the Ms temperature is found to be -28℃. As the actuator operating temperature may be below -28℃, the Ms temperature must be decreased further than is possible from strictly chemistry control.

There have been numerous studies of the Ms temperature in various steels throughout the literature[4-6], mainly conducted in Fe-Ni and Fe-Ni-C systems. Several studies have been conducted using Fe-Ni-Cr alloys, such as AISI type 304. Previous studies of Fe-Ni and Fe-Ni-C systems had concluded that the austenitic grain size had an effect on the Ms temperature of these steels [7], but that this grain size effect was small in comparison when Fe-Ni-Cr system was considered.

Based on these results, the effect of grain size on the Ms temperature of Fe-Ni-Cr steels was investigated further. The steel considered for this portion of the evaluation had a (Ni) of 20.6%. Austenitic grain size was varied through control of the austenitizing temperature of the alloy.

Fig.9 illustrates the Ms temperature as a function of austenite grain size. The Ms temperature is found to rapidly decrease with decreasing austenitic grain size when the austenite grain size is below about 10 μ m. This effect is enhanced by controlling the austenitic grain size below 5 μ m, for maximum Ms reduction.

APPLICATION TO ABS MAGNETIC SOLENOID VALVES

The composite magnetic material discussed above has been suggested for application in an ABS magnetic solenoid valve. A schematic of this type of valve is given in Fig.10. The composite magnetic materials described in Table 2 were tested for performance in the sleeve component of the valve. A production process for the manufacture of the composite magnetic sleeve is illustrated in Fig.11.

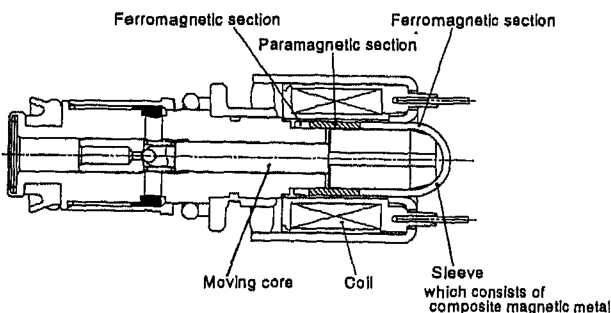

Figure 10. Schematic view of ABS magnetic solenoid valve

The sleeve was formed of the composite magnetic material, having an initial structure consisting of paramagnetic austenite. The working temperature was maintained below the 80℃ Md temperature established earlier. Mechanical working under these conditions induces a certain portion of the austenite to transform to ferromagnetic martensite as detailed previously. Subsequently, a section of the sleeve was induction heated into the austenite range to form the paramagnetic region of the sleeve. Induction heating parameters such as frequency, voltage, current, and time were adjusted to yield an austenitic grain size of less than 5 μ m, and thus obtain maximum Ms reduction.

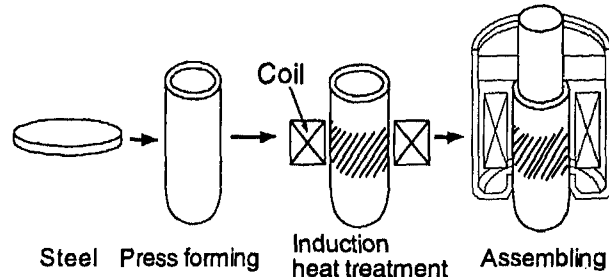

Figure 11. Schematic production process of sleeve of ABS magnetic solenoid valve

Table 3. Magnetic properties and Ms temperature of composite magnetic sleeves

(Ni)	B40(T)	μ r	Ms(℃)
20.6	0.38	1.007	-110
21.3	0.60	1.012	-105
21.8	0.80	1.020	-90
Desired value for sleeve of ABS valve	≧0.3	≦1.2	<-40

·B40 of ferromagnetic section Is measured after press forming

· μ r and Ms of paramagnetic section are measured after induction heat treatment

Table 4. Comparison of ABS magnetic solenoid valve performance

	Sleeve material	
	Composite magnetic material	AISI type 304
Outer diameter of ABS magnetic solenoid valve (mm)	ϕ 19	ϕ 24
Coil ampere turns (A·turns)	320	452
Magnetic force (N)	30	30

·Composite magnetic material has (Ni) of 21.3%

The resultant magnetic properties of the both ferromagnetic and paramagnetic sections of the composite magnetic material are given in Table 3. The resultant Ms temperature of the paramagnetic section is also given. The sleeve was found to have a

magnetic flux density, B40, of 0.38 - 0.80 T, a relative permeability, μ r, of 1.007 - 1.020, and an Ms temperature of -90 to -105℃. These properties satisfied required values.

A comparison of the ABS magnetic solenoid valve with a composite magnetic sleeve and with a sleeve of AISI type 304 is given in Table 4. Application of the composite magnetic material to the sleeve allows a 20% reduction in outer diameter as compared to the AISI type 304 sleeve. ABS valves using the composite magnetic material have been successfully used in field service since 1996.

CONCLUSION

A composite magnetic material having both ferromagnetic and paramagnetic sections has been developed from an austenitic stainless steel.

Results of this development can be summarized as follows:

(1) The coexistence of ferromagnetic and paramagnetic regions within the material may be accomplished by holding the Hirayama's Ni equivalent (Ni) within the range of 20.5 to 21.5%.
(2) Ms temperature of the alloy was substantially reduced through the control of the austenitic grain size.
(3) Application of the composite magnetic material to the sleeve of the ABS magnetic solenoid valve allowed reduction of the valve outer diameter of approximately 20%.
(4) Typical properties of the sleeve component were found to meet product expectations as follows: magnetic flux density, B40, 0.38 - 0.80 T, relative permeability, μ r, of 1.007 - 1.020, and Ms temperature of -90 to -105℃.

Complex Shape Headlamps: Eight Years of Experience

Eric Blusseau and Laurent Mottet
Valeo - Lighting Systems

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Until the late 1980s, the technology used in automotive lighting was relatively limited. Designers had little styling freedom as the main prerequisite of car makers was to reduce the size and increase the performance of lighting systems. VALEO invented SC (complex surface) technology to improve luminous efficiency. The first cars equipped with SC were the EAGLE PREMIER in the United States the CITROEN XM in Europe.

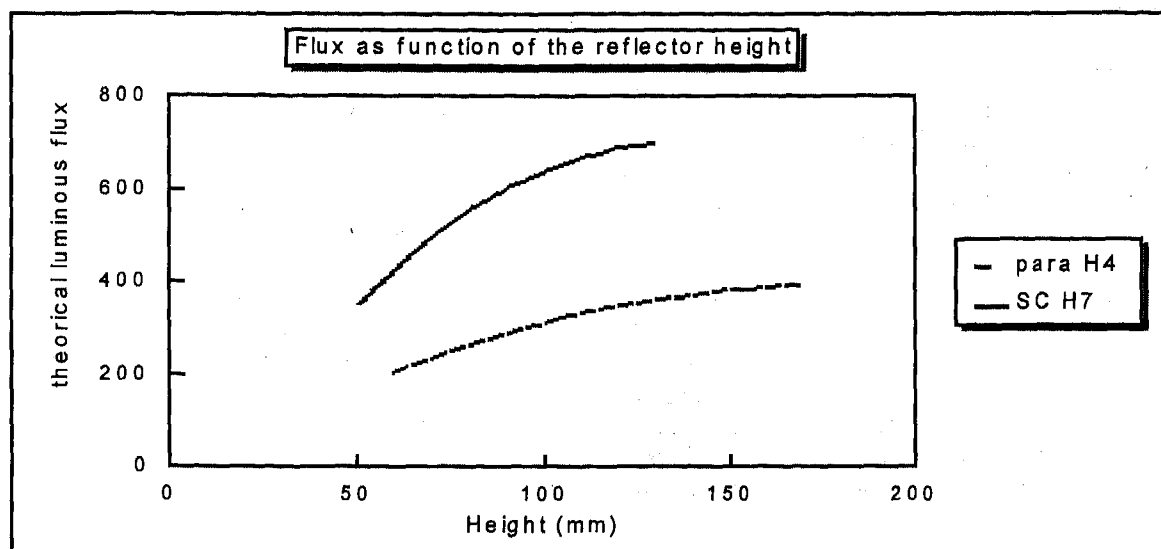
SC2 followed. SC2 incorporates reflector technology that controls both the vertical and horizontal deviation of the light and increases styling freedom especially for fog lamps.

The latest in the line of high performance lamps, SC3, was developed to optimize beam patterns in order to meet statutory requirements whatever bulb is used. Because SC3 uses a clear lens with an optical reflector, styling can be much more original and the angle of the lens can be increased to 60°. This technology is currently being made available to all VALEO customers worldwide in the form of SC3 clear lens high performance headlamps.

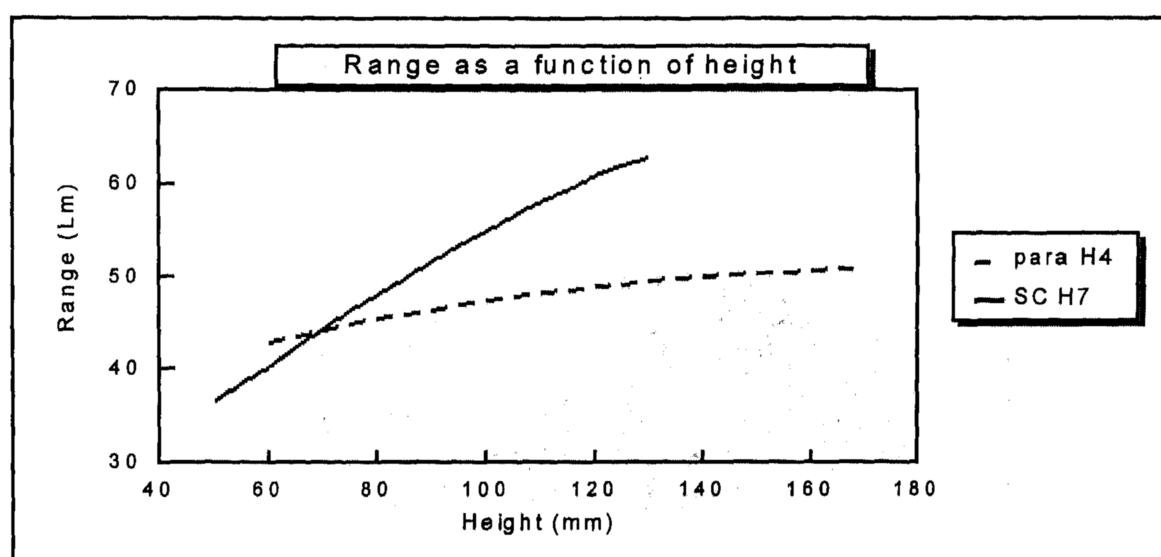
The photometrical performance of these new technologies requires higher precision and quality in the shape of the reflector. This is achieved by new processes developed with computer-assisted design and digitally controlled tools associated with dependable quality assurance facilities.

Since the beginning of the 1990s the higher performance and styling advantages of SC headlamps have resulted in their being used in more than 30% of new programs worldwide. VALEO's continuous growth is based on technological leadership in product innovation and manufacturing processes. The high performance of SC and HID lamps with clear lenses and automatic dynamic leveling systems form an integral part of VALEO's technological development.

INTRODUCTION



THE NECESSITY FOR COMPLEX SURFACES - Automobile lighting technology developed only slowly until the mid 1980s. Until that time the basic operating principle of headlamps had remained essentially the same. A parabolic reflector placed behind a filament directed the light ahead while a lens in front spread the light horizontally.



EUROPE - All over the world, regulations require vehicles to be equipped with a low beam. In Europe, in order to avoid glare, this low beam is characterized by an asymmetrical cutoff line which differentiates the illuminated area (below the HH line) from the darker area above.

European technology is based on the utilization of a light shield located below the light source. This light shield, associated with the filament, generates a cut-down beam. This technology has been proven on millions of vehicles. Nevertheless, automobile designers motivated by the need to improve aerodynamics demanded headlamps which were increasingly narrow. This powerful trend was incompatible with photometric performance which in addition was required to respond to the increased performance of the vehicles themselves. To meet these two contradictory demands, it was vital to find new solutions.

90's style: Low profiled headlamps

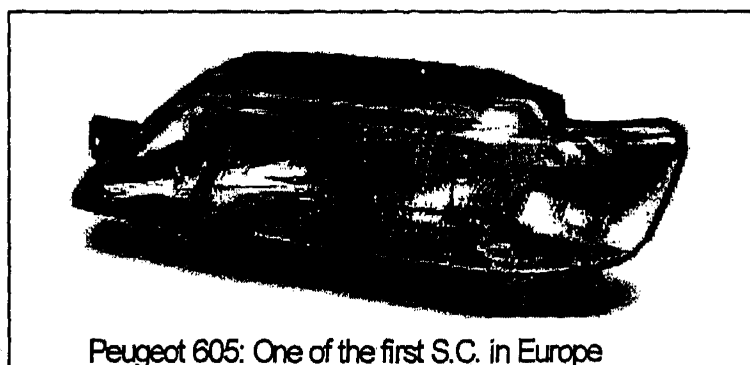
USA - US headlamps in 1985 utilized transversal filaments. This technique very rapidly reached its natural limits. The use of transverse light sources is not the best way to control luminous flux. Transverse light sources also require relatively high reflectors with a long focal distance if they are to provide satisfactory illumination. In the mid 1980s, axial filament bulbs appeared. These were more efficient in terms of illuminance, but their application to low beams required highly prismatic lenses which were difficult to produce. This handicap could be overcome by choosing reflectors with a long focal distance but at the cost of a significant drop in flux, which also limited styling possibilities (see SAE presentation 1987).

The demand for new solutions was therefore urgent both in the US and in Europe. Traditional technology could not meet that demand.

SC1: THE REVOLUTION

THE INVENTION OF COMPLEX SURFACES - The problem was clear, but the solution had yet to be found. As it happened, the identification of the problem coincided with the massive expansion of computer assisted design and optical simulation in photometric laboratories.

The idea was to "align the highest points of reflected images". The search for a mathematical definition of the surfaces took 2 years and resulted in an initial series of patents in 1982. The potential of this new concept of surface, which disassociated the horizontal and vertical focus lines from the reflecting surface while maintaining continuity, was considerable. The problem was solved in a manner which was both elegant and efficient. For a given dimension, the product is considered to be 50% more effective than a traditional headlamp. This means that for a given performance, the height of the headlamp can be divided by 2. Any combination of these two extremes is of course possible.



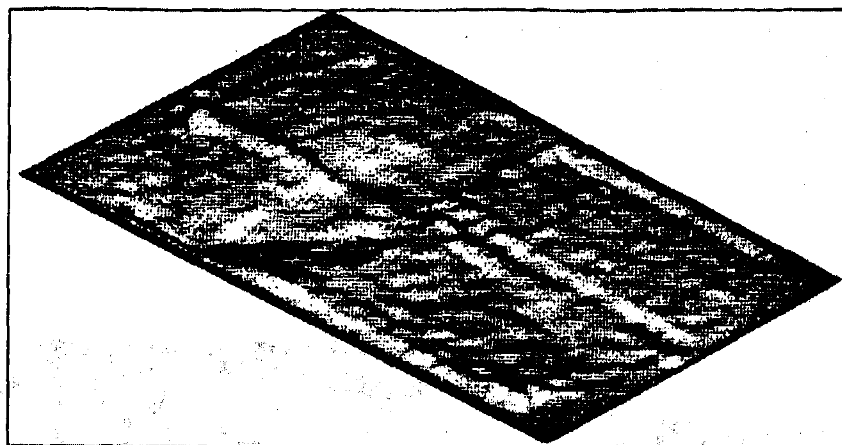
The immediate applications of this surface concept are immense.

- improvement of fog lights by simplifying distribution lenses,
- definition of a European low beam illuminance shape,
- definition of a US low beam illuminance shape with the possibility of optimizing the image position.

THEORY INTO PRACTICE - Once the concept had been discovered and developed, it had to be put into practice. A large number of mock-ups and prototypes were produced in order to improve control of light distribution. Lens trials were carried out. The impact of dispersion of filament positioning was measured.

The concept was presented to manufacturers all over the world. They immediately saw the importance of the contribution this technology could make and were able to see to what extent it fulfilled to their demands as regards both styling and performance.

The first orders were filled for the EAGLE PREMIER in the US, the CITROEN XM and PEUGEOT 605 in Europe.



Peugeot 605: One of the first S.C. in Europe

INDUSTRIALIZATION

The next difficulty was the mass production of these headlamps, which were precision optical instruments. The utilization of CAD/CAM in the machining of these complex surfaces became common. Digital control was indispensable in the production of the machine tools.

Newer, more dimensionally stable materials with improved resistance to operational temperature requirements were developed for the reflectors.

Research was carried out particularly on thermo-hardened materials with excellent heat-resistance characteristics. In fact, the reduction in the size of headlamps resulted in an increase of some 50°C in the temperatures inside the headlamp. Composite materials with precisely adjusted expansion coefficients were perfected. The parameters of injection presses became increasingly sophisticated in order to be able to obtain optimum mold performances for reflector injection.

Visualization of the difference between the reflector and the theoretical shape

The use of industrial robots in varnishing processes also improved the surface treatment of the reflectors.

At the same time, new tools had to be developed to check the surfaces in order to be able to assure the optical quality of these products. Plungers had to be accurate to within 5 microns and the surface of the reflectors to within 1/100 mm.

THE LIMITS

The complex surface technique has enabled the efficiency of low beam lamps to be increased to a significant degree both in the US and in Europe. It has opened up new fields of possibilities in terms of styling particularly by allowing smaller headlamp reflectors while maintaining or even improving optical performance. Today around the world, 30% of the new automobile models presented by manufacturers are fitted with complex surface headlamps (i.e. non-parabolic surfaces). Nevertheless, with ever bolder and more original styling trends, it has proved necessary to advance even further. And to meet new demands.

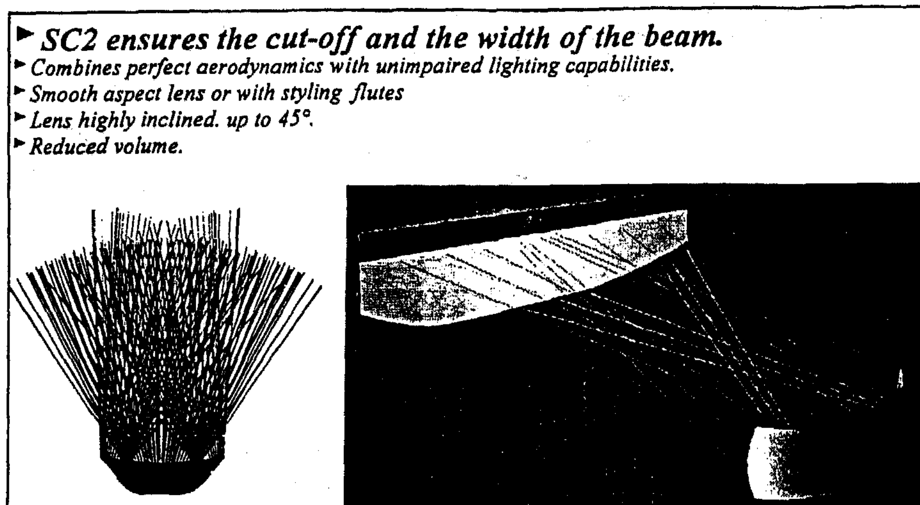
The initial limits were revealed by shaped fog lights. In fact, the combination of light deviation ribbing with a lens inclined at more than 30° posed a problem. However, complex surfaces, confronted with this new challenge, would provide the solution.

SC2: ANOTHER STEP FORWARD

Complex surfaces didn't allow the production of a high performance beam with very inclined glass with optics. The overall beam suffered unacceptable deviations.

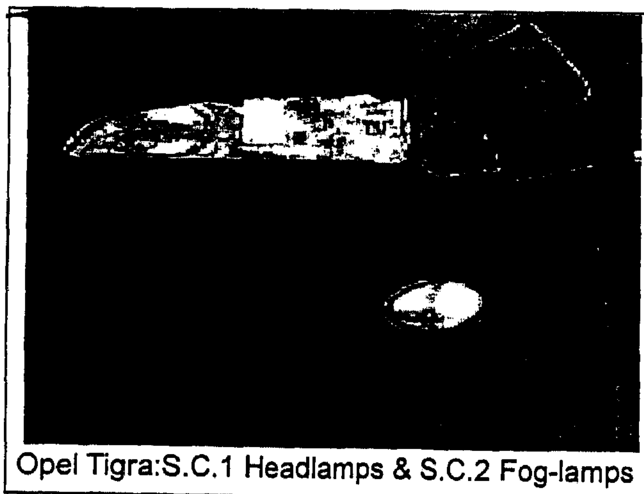
THE PRINCIPLE - The idea consisted in seeing that there were only two possible solutions to the dilemma that though inclined ribbing was unsatisfactory, inclined headlamps were required by the manufacturer,:

1) either incorporate a second lens, with the inner lens handling the distribution of the light, while the smooth outer lens ensures continuity of line and closure.



2) have the light distributed as much as possible by the reflector, with the external lens only slightly ribbed or completely smooth.

The first alternative was rejected by engineers because the double lens caused problems of temperature, volume, appearance and cost.



The second path was therefore the one that was explored.

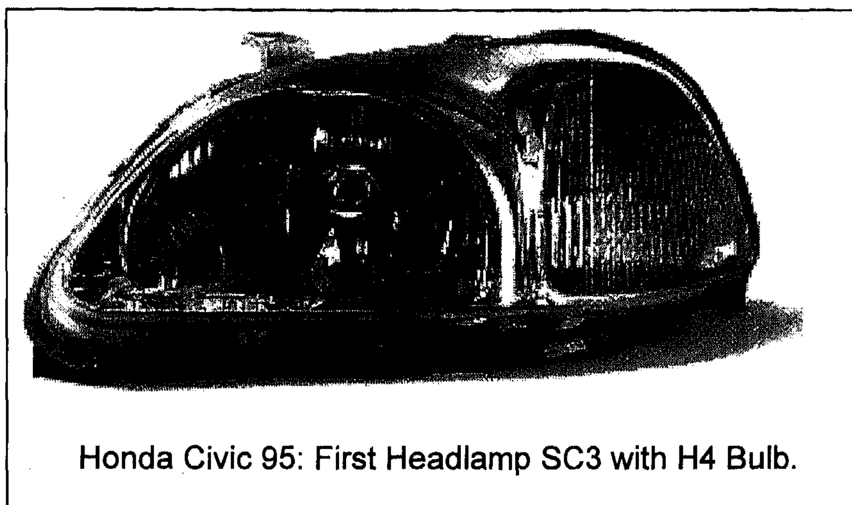
It took more than two years of research to find the technical solution. The work concentrated on the optimization of the shape of the reflector in order to ensure the desired distribution of the light. After numerous trials, SC2 was presented in 1991, and promptly won the 1st prize of INNOVATION for automobile equipment in Paris 1991. This was not without reason, as the product's multiple functions were interesting from numerous points of view. It ensured the lateral distribution of light for the vehicle and took account of the external environment of the vehicle to preclude any unlit areas.

The design took account of the interior structure of the headlamp in order to avoid interference between the reflected light and the bulb or any headlamp cache. Thermal constraints were overcome by optimizing parallel light levels in one lens.

APPLICATIONS - This principle was widely employed in fog lights. The combination of an SC2 surface with a smooth lens enabled a range of variously shaped standard reflectors (round, rectangular) which could then be installed in different vehicle configurations. These products have been fitted to various European and American model ranges (Renault, Ford, Saab, Mercedes, G.M., etc.). Standardization of the mirrors and the simplicity of the lens have led to a reduction in R&D costs as well as in production costs.

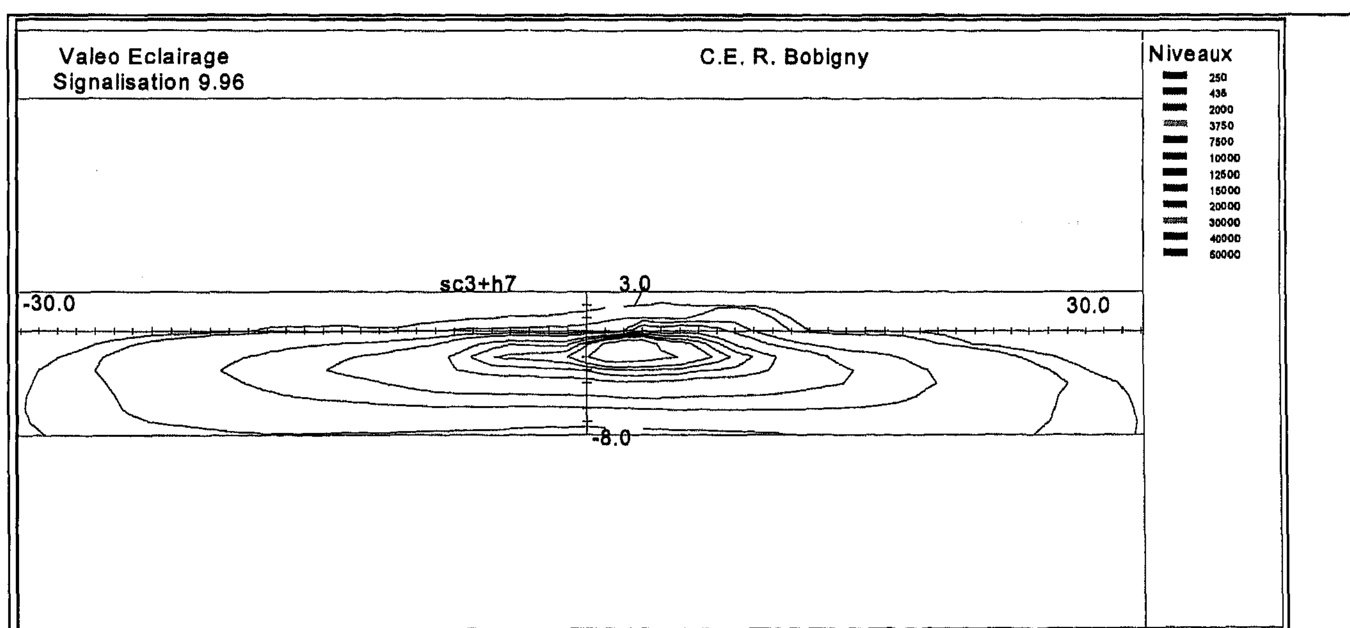
Opel Tigra:S.C.1 Headlamps & S.C.2 Fog-lamps

SC3: EXTENDING THE CONCEPT



Styling demands were increasingly exacting. As regards main headlamps, the increasingly pressing need for originality expressed by the inclination of the lens prompted VALEO engineers to go even further in their research into optical surfaces.

The aim was to optimize portions of locally modified SC2 surfaces, sometimes by tilting them, or by adding optics to the standard surfaces.



Research into optical surfaces was carried on for 2 more years. The complex surface concept was refined and adapted to all types of bulbs (9005/9006, 9007, HB2) and for European and US beams. In Europe, 6 different types of surface were defined.

This new concept of complex surfaces brought about breakthroughs in styling. In fact, the clear lens associated to a faceted reflecting surface gives a deep, shimmering (glistening) appearance to the headlamp. The shininess of the aluminum and the surface facets give the lamp a jewel-like quality. The optically neutral clear lens can be inclined at more than 60° and even be curved in without impairing the beam. Yet this freedom of styling is not achieved at the expense of the efficiency of the headlamp, and SC3 performance is at least equivalent to an SC1 surface of the same dimensions. This new generation of complex surfaces has required developments in industrial tools. The quality criteria for surface states have been pushed back and requirements in terms of the appearance of headlamps are increasingly draconian. Dust-free production lines have had to be created.

APPLICATIONS - SC3 headlamps were first released in Europe and Japan in 1995. In Europe, the Renault Safrane and in the U.S., the 1997 Saturn Coupé were fitted with this new technology, which is assured a promising future.

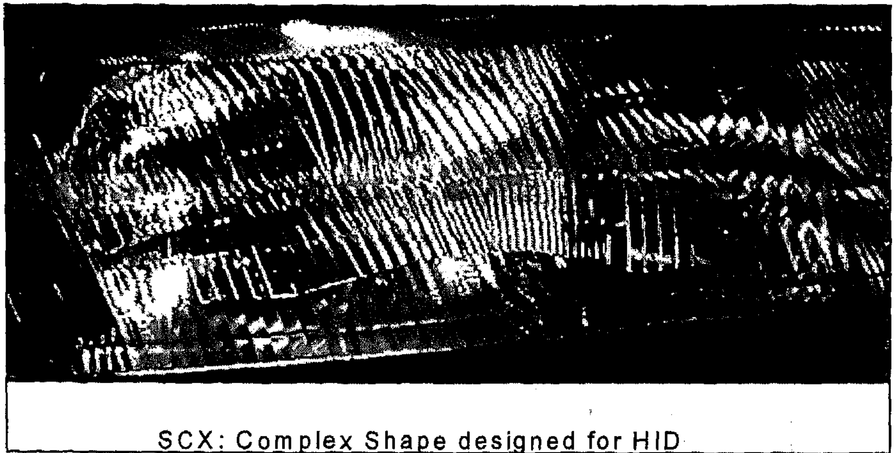
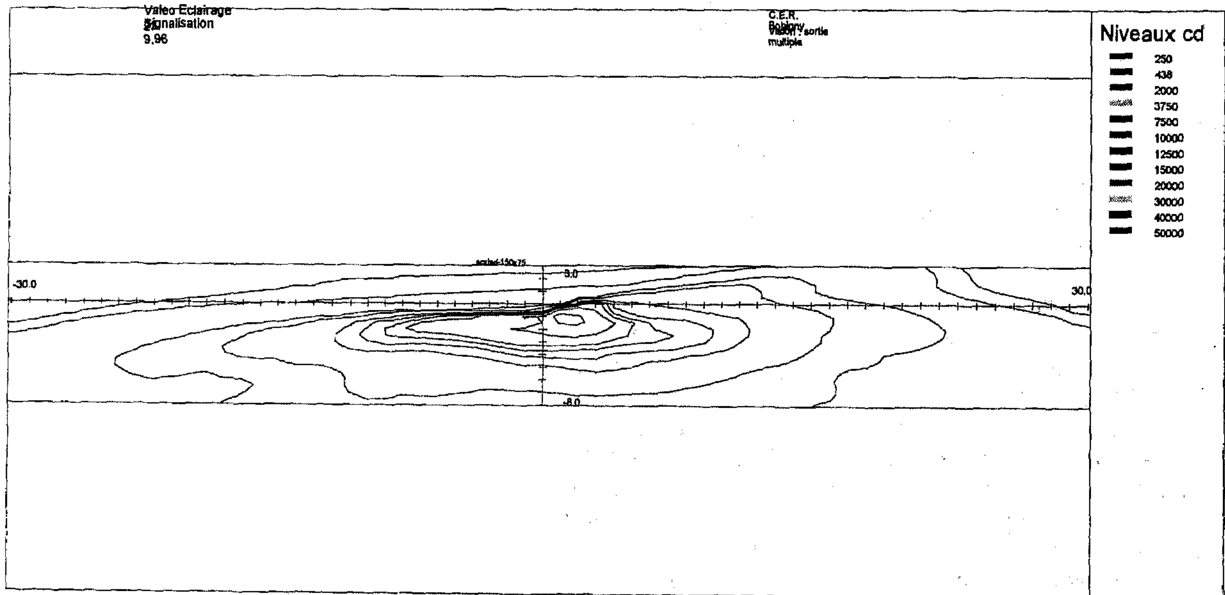
HOW ABOUT TOMORROW?

Complex surfaces have brought about a revolution in automobile lighting techniques. At this time, parabolic technologies still represent 70% of all new vehicles manufactured. By 2000 this proportion will have fallen to 50%. Of the remainder, SC1 lamps will account for 35% and SC3 lamps 22%.



Experience and success prompted further research in this area. Development work is currently being concentrated in two main areas:

1) In order to anticipate and contribute to the ongoing global harmonization of photometric regulations, Valeo has created a new SC concept which will enable the principle of "design to cost" to be applied to our complex surfaces worldwide. For example, it is already possible to use the same tool cavity for the U.S., Europe, and Japan. Only the plunger is still specific depending on the sense of the traffic (left or right-hand drive). Over 50% of tooling costs can thus be saved.



2) The emergence of H.I.D. represents a new opportunity for the SC concept to demonstrate its potential for development. This super-powerful lamp, with indistinct lighting contours, makes the computation of optical surfaces much more difficult. Even so, the complex surface concept has been adapted to meet the challenge. SCX (lens with optics) and SC3X (smooth lens), are complex surface products undergoing validation and are already being proposed to manufacturers around the world for their new headlamps. Yet another step in the reduction of dimensions, with a consequent improvement in performance that will be of benefit to all.

CONCLUSION

Today's situation as well as future trends both in Europe and in the U.S.A confirm the success of the concept of complex surface, whatever their evolution. They fulfill the designers aspirations while optimizing the lighting efficacy and downsizing, without sacrificing the cost. In a rare example, progress in technology made it possible to make happen in the real world the most daring styling demands.

Design Strategy for Free-Form Reflector Head Lamp Using High Intensity Discharge Light Source

Ben Wang, Douglas Kreysar, and Jianzhong Jiao
North American Lighting Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A design strategy for implementing High Intensity Discharge (HID) light sources in low beam head lamps with Free-Form Reflectors (FFRs) is presented. A theoretical analysis of a light source image formed by each portion of a reflector is presented as well as a strategy for using those images to create a head lamp beam pattern. Simulation results are shown for a head lamp design using this strategy.

INTRODUCTION

Styling and performance requirements have directed the automotive industry towards head lamps with clear lenses and free-form reflectors (FFRs)[1,2]. Further increases in head lamp performance demands have led to much interest in high intensity discharge (HID) light sources[3,4]. In order to marry the two technologies into one product, several technical problems must be overcome. Two of the most difficult issues in designing a FFR low beam headlamp with an HID source are A) the control of glare light and B) the control of excess amounts of foreground light. These difficulties stem from the extended discharge area of the HID source (4.4 mm x 4.4 mm x 7.1 mm ellipse, see Fig. 1) compared to a typical tungsten halogen (TH) bulb (5.2 mm x 1.2 mm cylinder). The extended discharge area translates into a large effective light source size, which causes a large angular spread of light from a point on the reflector surface. This large angular spread can lead to excess amounts of glare light or foreground light.

The angular spread of light (i.e., image size) from a point on the reflector depends on the size of the light source and its distance to the point on reflector. In order to decrease the image size produced from a point on the reflector, the distance between the light source and the point on the reflector should be increased. This paper presents a theoretical analysis of the image size formed by a free-form reflector and a method of categorizing these images whereby the reflector is divided into "zones" based on the image size formed by different areas of the reflector. Furthermore, this paper discuss how the difficulties of the HID light source are overcome by using different zones of the reflector for different areas of the beam pattern.

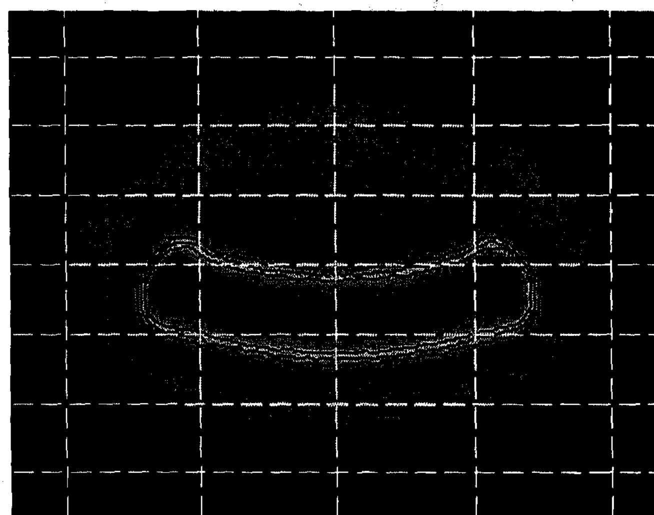

Fig. 1 Image of D2S HID Light Source

THEORETICAL ANALYSIS OF THE IMAGE SIZE FORMED BY DIFFERENT PORTIONS OF A FREE-FORM REFLECTOR

A reflector can be considered an imaging device. If only specular reflector is assumed, images of a light source

(filament or arc) are formed by each point on the reflector. When the light source geometry and location are defined, the image varies with respect to the points on the reflector. In geometrical optics, the relationship between object, image and reflecting surface can be described using vector notations.

Let $\mathbf{a}_i$ be the direction of incident light from a light source to a surface, $\mathbf{a}_r$ be the direction of reflected light, and $\mathbf{n}$ be the normal to the surface at the point of incidence. The vectors $\mathbf{a}_i$, $\mathbf{a}_r$, and $\mathbf{n}$ are unit vectors, and p is the point of incidence on the reflector surface (see Fig. 2). For specular reflections, Snell's Law[5] states that

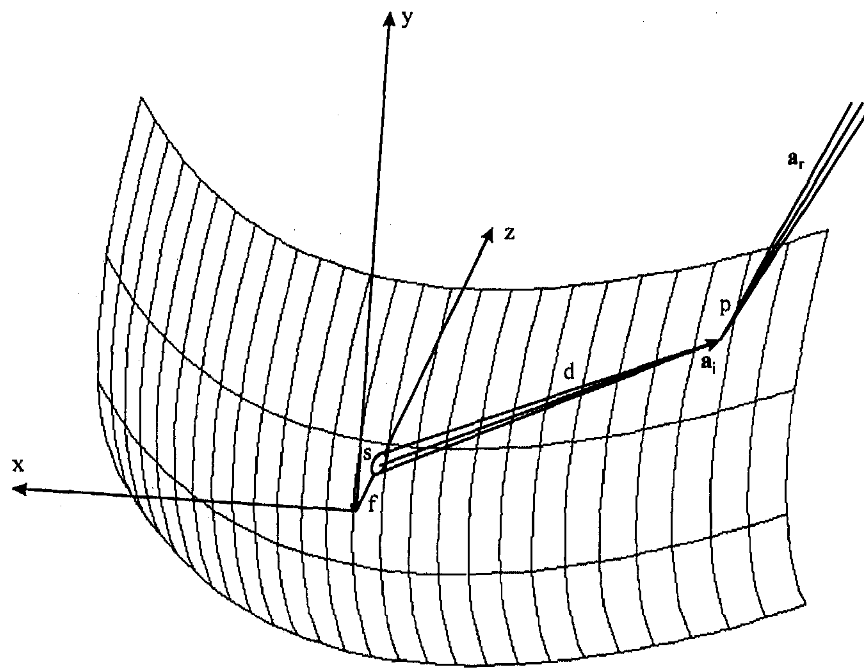

Fig. 2 Diagram of Light Rays from Source to Reflector to Screen

$$-\mathbf{a}_i \cdot \mathbf{n} = \mathbf{a}_r \cdot \mathbf{n} \qquad (1)$$

where the vectors $\mathbf{a}_i$, $\mathbf{a}_r$, and $\mathbf{n}$ are coplanar, which means that $\mathbf{a}_i$, $\mathbf{a}_r$, and $\mathbf{n}$ are linearly dependent:

$$-\mathbf{a}_i + \mathbf{a}_r = r\mathbf{n} \qquad (2)$$

where r is a coefficient.

For a given reflector, if the center of the light source is located at point (0, 0, f) and extends from $-l_x$ to l_x, $-l_y$ to l_y, and $-l_z$ to l_z, then (Δl_x, Δl_y, $f+\Delta l_z$) can represent an arbitrary point of the light source. The value for the incident vector from an arbitrary point of the light source to an arbitrary point on the reflector, p, can written

$$\mathbf{a}_i = \left(\frac{p_x - \Delta l_x}{d}, \frac{p_y - \Delta l_y}{d}, \frac{p_z - f - \Delta l_z}{d} \right) \qquad (3)$$

where

$$d = [(p_x - \Delta l_x)^2 + (p_y - \Delta l_y)^2 + (p_z - f - \Delta l_z)^2]^{1/2} \qquad (4)$$

At the center of the light source,

$$\mathbf{a}_i = \left(\frac{p_x}{d}, \frac{p_y}{d}, \frac{p_z - f}{d} \right) \qquad (5)$$

For simplicity, the reflector is approximated as a parabola with the center of filament on at the focal point (i.e., the light is reflected straight ahead from the reflector surface), so that $\mathbf{a}_r$ = (0, 0, 1). That is approximately the case for the high intensity area of a low beam head lamp centered at 2R 1.5D, which is near the areas of greatest concern for both excess glare light and excess foreground light (see next section). The normal of the reflector surface is thus

$$r\mathbf{n} = -\mathbf{a}_i + \mathbf{a}_r = \left(\frac{-p_x}{d}, \frac{-p_y}{d}, \frac{d - p_z + f}{d} \right), \qquad (6)$$

Solving for $\mathbf{n}$ and normalizing, we obtain for a parabolic surface:

$$\mathbf{n} = \left(\frac{-p_x}{[p_x^2 + p_y^2 + (d - p_z + f)^2]^{1/2}}, \frac{-p_y}{[p_x^2 + p_y^2 + (d - p_z + f)^2]^{1/2}}, \frac{d - p_z + f}{[p_x^2 + p_y^2 + (d - p_z + f)^2]^{1/2}} \right). \quad (7)$$

The direction of reflection for any point of light source is

$$\mathbf{a}_r = \mathbf{a}_i - 2\,\mathbf{n}\,(\mathbf{a}_i \cdot \mathbf{n}) = (\,I - 2E\,)\,\mathbf{a}_i, \quad (8)$$

where

$$I = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad (9)$$

and

$$E = \begin{pmatrix} n_x^2 & n_x n_y & n_x n_z \\ n_y n_x & n_y^2 & n_y n_z \\ n_z n_x & n_z n_y & n_z^2 \end{pmatrix} \quad (10)$$

Finally,

$$(a_{r_x}, a_{r_y}, a_{r_z})^T = \begin{pmatrix} -2n_x^2+1 & -2n_x n_y & -2n_x n_z \\ -2n_y n_x & -2n_y^2+1 & -2n_y n_z \\ -2n_z n_x & -2n_z n_y & -2n_z^2+1 \end{pmatrix} (a_{i_x}, a_{i_y}, a_{i_z}). \quad (11)$$

Equation (11) determines the vector of the reflecting rays from any point on the reflector, (p_x, p_y, p_z), given the incident ray vector, $\mathbf{a}_i$. For any point of the light source, the incident ray vector, $\mathbf{a}_i$, can be calculated by using equation (3). Thus given an arbitrary point on the reflector and an arbitrary origination point in the light source, we have a method to calculate $\mathbf{a}_r$. By calculating $\mathbf{a}_r$ for light source points at a specific reflector point we can calculate an image size (in degrees) for that specific reflector point. The image size of the HID light source for a FFR using a 24 mm "focal distance" has been calculated. The results are shown in Fig. 3.

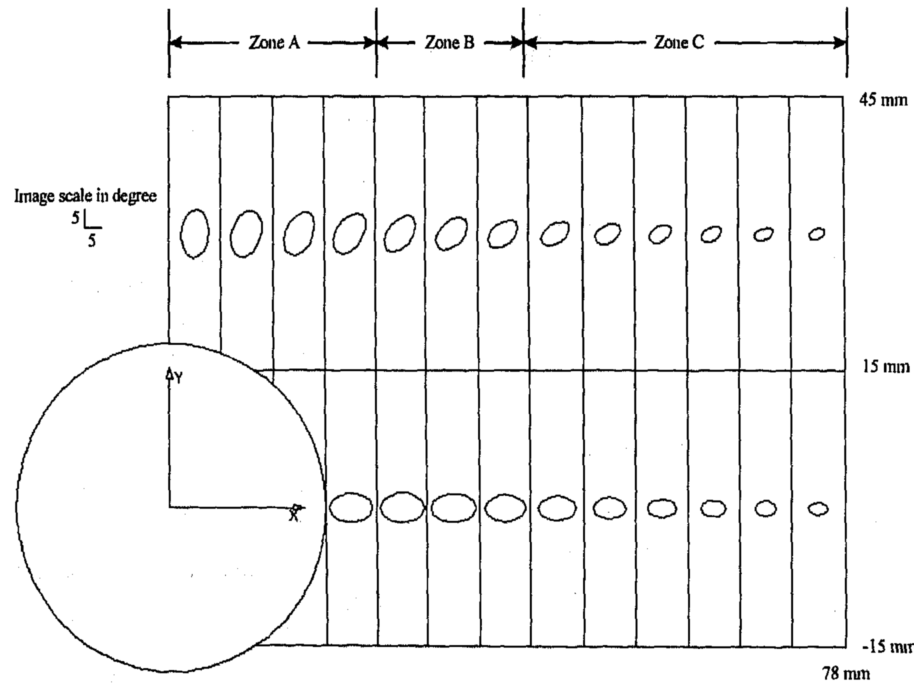

Fig. 3 Image Size of HID Light Source for Points of a Reflector

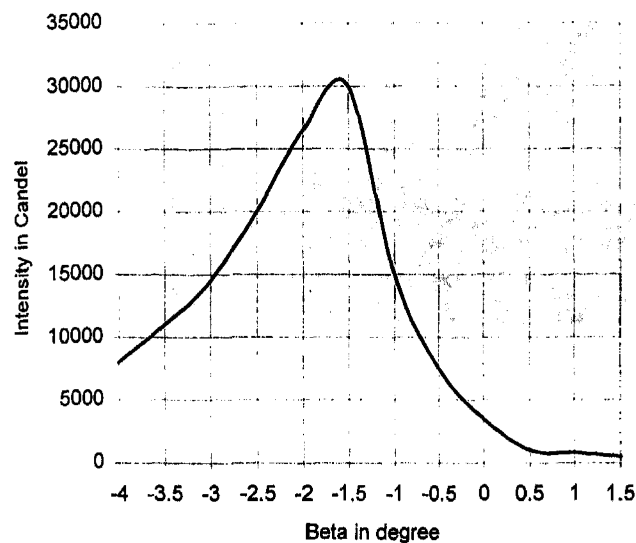

Fig. 4 Intensity Distribution Curve for a Vertical Section at the high intensity Area of an SAE Low Beam

INTENSITY DISTRIBUTION CURVE OF THE HIGH INTENSITY AREA

Based on SAE[6] and FMVSS108[7] photometry requirements for the low beam head lamp, an intensity distribution curve of a vertical section through the high intensity area (i.e., 4D to 1.5 U at 2R) can be devised (Fig. 4). To construct the high intensity area of the beam pattern using a FFR with an HID D2S source, the image size must match the intensity distribution curve. The intensity distribution for a given area of a beam pattern is a superposition of all the images produced by the reflector and projected to the area. Therefore all the images superimposed on that area must be restricted in their size, or else the intensity distribution shown in Fig. 4 can not be achieved.

ZONAL DIVISION OF THE FFR SURFACE

The design strategy used here to divide the reflector surface into three zones based on local angular spread (Fig. 3). The lumen collection at each area of the reflector are calculated and shown in Fig. 5. In order to achieve a high performance beam pattern, Zone A is used for horizontal light spread since it has the largest image size. Zone B has intermediate image sizes and is used for smoothing the beam pattern. Zone C has the smallest image sizes and is used for the high intensity area. The beam pattern simulation results from the FFR are shown in Fig. 6.

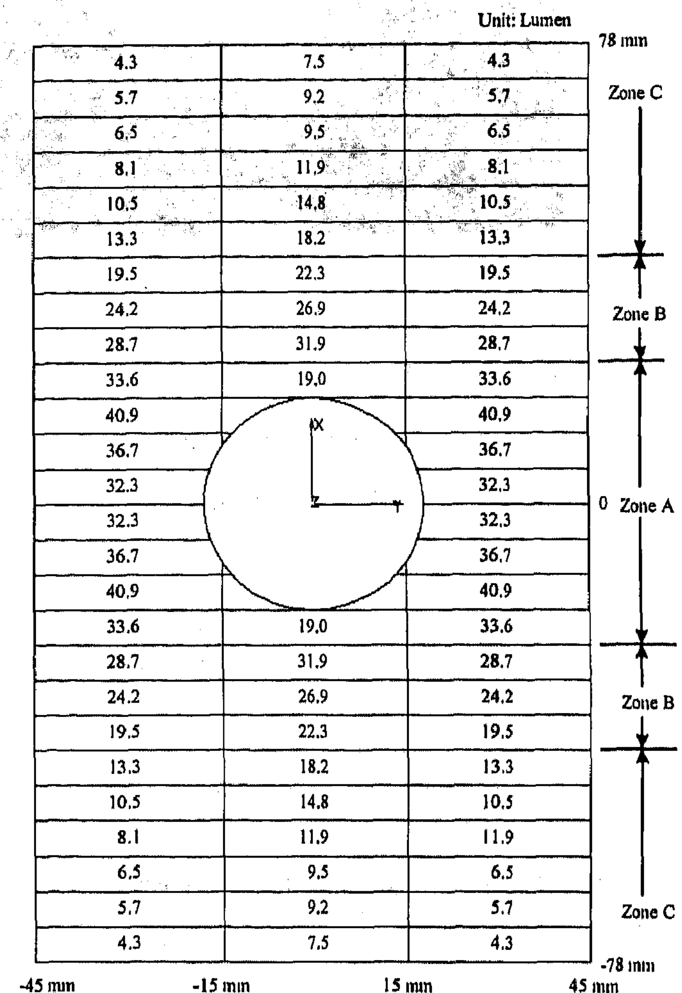

Fig. 5 Light Collected from an HID Source at Each Area of the Reflector (Focal distance = 24 mm)

CONCLUSION

The design difficulties for a FFR using an HID source have been discussed, and solutions have been proposed. The strategy used here allows a high degree of freedom to manipulate the reflector surface so that light can be collected and projected to a desired beam pattern. More importantly, the relationship between the source (object), the spread (image) and the reflector surface has been mathematically defined. This mathematical definition can be used to develop computer-aided engineering (CAE) programs to precisely design FFRs with an HID source and conduct accurate simulations which in turn can to help further reduce the optical design lead-time in product development.

Styling and Reflector Design - New Reflector Shapes for Low Beam, High Beam and Foglamps

Doris Boebel
Robert Bosch GmbH

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

For the automotive industry, the styling of a car is an important feature. Since the appearance of a car is strongly characterized by the headlamp, stylistic aspects have an increasing influence on the development of headlamps. At the same time, the trend goes toward reducing the constructional volume available to the headlamp and also integrating other functions such as foglamps. To fulfill all these requirements, new reflector shapes had to be created.

In this paper, different reflector concepts for low beam, high beam and foglamps are presented. They will be discussed under consideration of stylistic aspects (e.g. space for the required bulb shield, semi-clear outer lens) and technical aspects (e.g. thermal stress of plastic lenses).

INTRODUCTION

Modern headlamps are playing an important role as stylistic elements of cars. Simultaneously, a high quality light pattern is very important for the safety and comfort of drivers. Because of this situation, the challenge for the headlamp manufacturer is to develop attractive headlamps from the stylistic point of view and to improve the quality of light patterns.

Free-form reflectors have the potential to fulfill these requirements [1,2]. The geometry of a free-form reflector shape can not be described in a simple mathematical way like a parabola or an ellipse. But parts of the reflector behave like these conventional geometries. In the horizontal cross section the basic concepts for the calculation of a free-form reflector shape can be described as continuous transitions of parabolic, hyperbolic and elliptical areas. In the vertical cross section they are nearly parabolic. To connect the horizontal and the vertical concept to a complete reflector shape and to achieve the required light pattern, a program is necessary which allows the local variation and optimization of all reflector areas. Our optical design program CAL (Computer Aided Lighting) [1,3] is a tool for the calculation of such reflector shapes. The calculation can be done fully automatically, semi-automatically or manually by the optical engineer. With CAL it is also possible to calculate the light distribution in the plane of the outer lens. This is important for the design of headlamps that incorporate plastic lenses.

In the following sections reflector shapes for low beam, high beam and foglamps are presented. Some technical and stylistic aspects are discussed and specific examples are shown.

REFLECTOR SHAPES FOR LOW BEAM

There are trends in the USA and in Europe which require new reflector shapes for low beam applications. In the USA, visually aimable headlamps will be introduced in the near future. In Europe, car designers are asking more and more often for headlamps with clear outer lenses. Both leads to a demand for low beam reflectors which produce high quality light distributions with cutoff lines.

Reflectors with smooth surfaces are a good choice to achieve the required quality of light patterns. Faceted reflectors have the disadvantage that the steps between the individual segments can cause stray light. Especially the horizontal steps are critical in view of keeping glare values low and maintaining a good contrast at the cutoff line.

In principle, two different reflector concepts are applied to create reflector shapes for low beam light patterns: the diverging (Fig.1) and the converging

reflector concept (Fig.2). In both concepts the light from the outer part of the reflector is directed nearly parallel to the optical axis (parabolic behavior). This light is used to form the center of the light distribution with the highest illuminance. The light from the central part of the reflector is used to form the horizontal spread of the light distribution. In this point the two concepts differ.

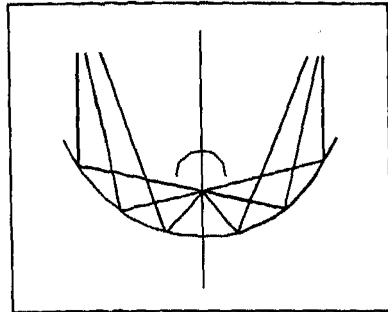

Fig. 1: Diverging reflector concept for low beam (horizontal cross section).

The horizontal cross section of the diverging concept (Fig.1) shows that the rays from the central part of the reflector are forming the horizontal spread of the light distribution without crossing the optical axis (hyperbolic behavior). This feature is important if a bulb shield is required as styling element or to block the direct light of the bulb. Furthermore, the diverging reflector concept is a good choice if the depth of the reflector is limited by the dimensions of the headlamp. The hyperbolic characteristic in the central part leads to flat reflector shapes in comparison to converging-concept reflectors. The light distribution of an SAE application using the diverging reflector concept is shown in Fig. 2.

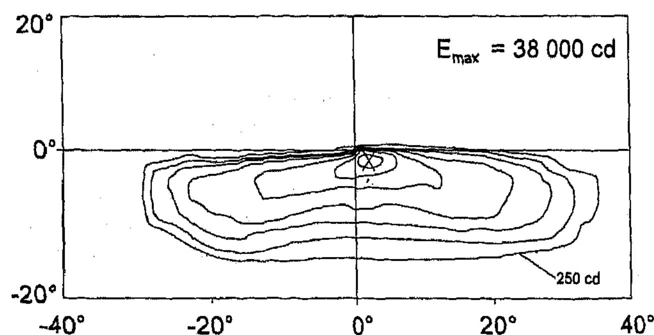

Fig. 2: Light pattern of an SAE low beam, diverging reflector concept. HB4 bulb. Rectangular reflector 160 mm wide, 100 mm high.

In the converging reflector concept shown in Fig.3, the rays from the central part of the reflector are crossing the axis to form the horizontal spread of the light distribution (elliptical behavior).

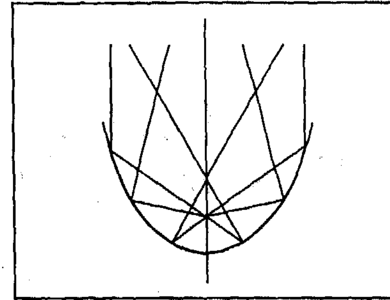

Fig. 3: Converging reflector concept for low beam (horizontal cross section).

The converging reflector concept is a good choice for small reflectors. Typically, they have a small focal length. Therefore a high amount of the luminous flux of the bulb can be used for the light distribution. But the depth of converging concept reflectors is higher than that of reflectors of comparable width calculated with the diverging concept. Fig. 4 shows the light distribution of an ECE low beam, calculated with the converging concept.

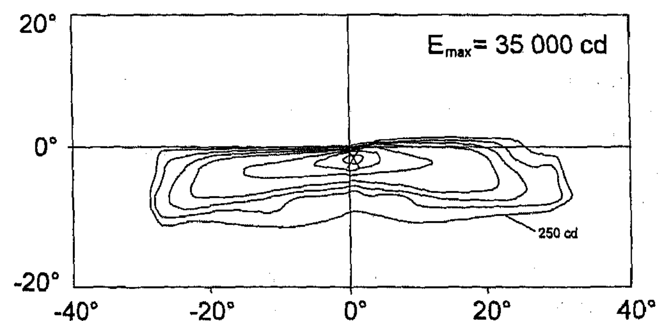

Fig. 4: Light pattern of an ECE low beam, converging reflector concept. H7 bulb. Rectangular reflector 110 mm wide, 100 mm high.

REFLECTOR SHAPES FOR HIGH BEAM

In view of customer's demand for clear outer lenses for the entire headlamp, new high beam reflector shapes have to be designed as well. On the other hand there are customer design requests for semi-clear outer lenses for high beam, in most cases combined with projector-type units for low beam. In this case the optical engineer has to develop a reflector shape which forms the light distribution together with optical profiles in the lens, but all profiles with the same scattering angle.

The concepts applied to the calculation of high beam reflectors are in principle the same as those for the calculation low beam reflectors. They differ in the central part of the reflector. Due to the smaller horizontal spread of high-beam light distributions, rays reflected in the central part of the reflector have smaller angles to the

axis than in low beam reflectors. The horizontal cross sections of a diverging and a converging reflector concept are shown in Fig. 5.

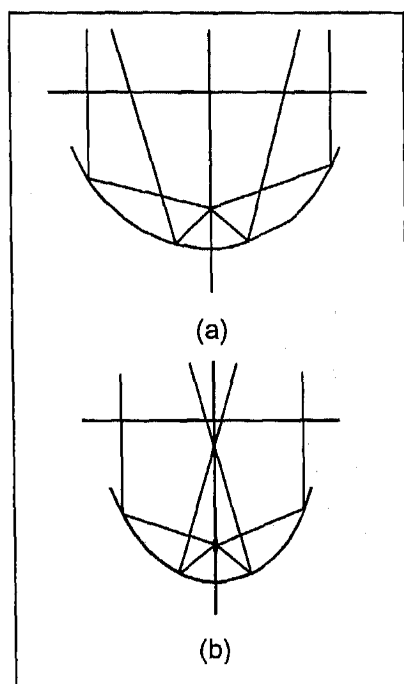

Fig. 5: Diverging (a) and converging (b) reflector concepts for high beam applications (horizontal cross sections).

The sections in Fig.5 show outer lenses in front of the reflector. For two specific examples, the light distributions in the outer lens plane are shown in Fig.6.

The distance between the filament and the lens is 100 mm in both cases. The rays of the central part of the reflector have an angle of about 15 degrees with respect to the axis. In this special case, the diverging reflector concept generates two hot spots on the left and the right side respectively, whereas the converging reflector concept generates a single hot spot in the middle of the lens plane. The maximum illuminance of the spot in the middle (Fig.6a) is about 1.5 times higher than that of the spots on the sides (Fig.6b).

For headlamps that incorporate plastic lenses, the thermal stress of the outer lens is sometimes critical. The light distribution in the plane of the outer lens has a major influence on the temperature in the lens. Therefore it is important to choose the reflector concept not merely in accordance with the space for a bulb shield or the total luminous flux. The light distribution in the plane of the lens has to be taken into consideration as well.

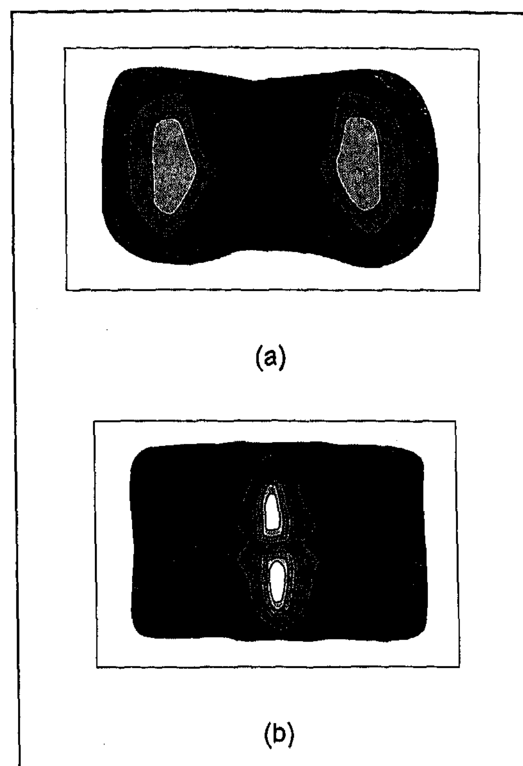

Fig. 6: Light distributions in the plane of the outer lens.

The following example shows a high beam reflector with a semi-clear outer lens. The reflector is calculated with the converging concept. The horizontal cross section in Fig.7 shows that the angles of the rays in the central part of the reflector are smaller than those in reflector shapes for clear outer lenses (Fig.5).

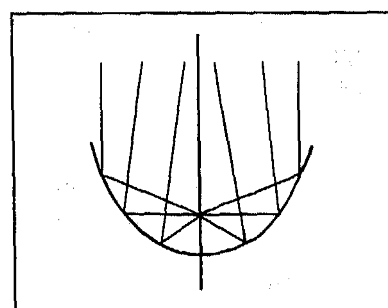

Fig. 7: High beam reflector concept for semi-clear outer lens (horizontal cross section).

The pre-scattered light distribution formed by the reflector (a) and the final light distribution completed by the outer lens (b) are shown in Fig.8.

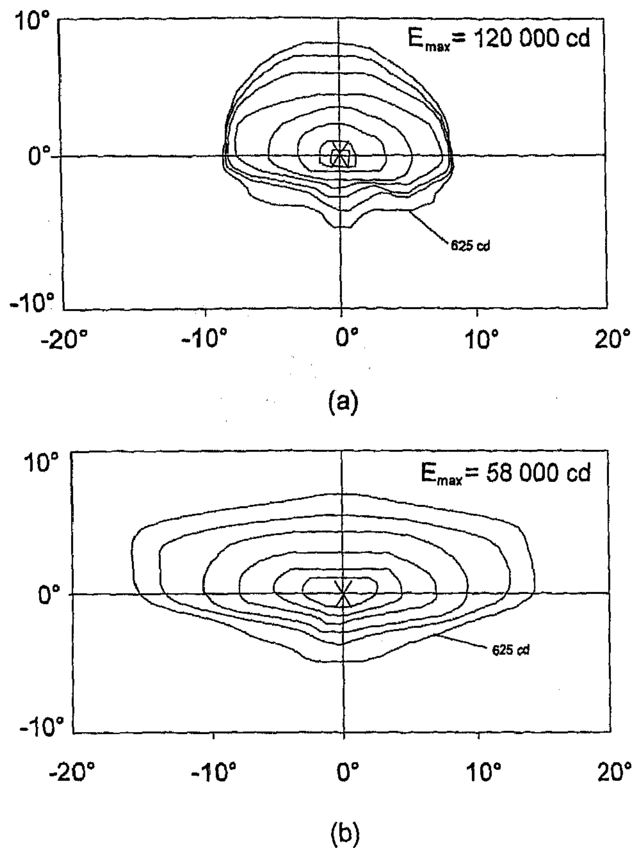

Fig. 8: Pre-scattered light distribution (a) and final light distribution (b) completed by the outer lens.

REFLECTOR SHAPES FOR FOGLAMPS

The trend towards clear or semi-clear outer lenses is the same for foglamps. From the technical point of view, this trend is helpful. The aerodynamic shape required of modern cars also influences the contour of the headlamp outer lens. The resulting high inclination angles make it difficult to form the light pattern with optical profiles in the lens. This is especially true in the case of foglamps, where a very wide spread is required for the light pattern.

For the calculation of reflector shapes for foglamps, a converging reflector concept similar to the one shown in Fig.3 is applied in most cases. Since most foglamps are quite small, it is important to utilize as much of the available luminous flux as possible for the final light pattern.

The first example is a foglamp with a semi-clear outer lens. For this application a H1 bulb is used. A bulb shield is necessary to block the direct light of the bulb and to prevent stray light from those parts of the reflector, which are not designed to contribute to the light pattern. The size of this bulb shield is determined by the available space in the center of the reflector. Here, the available space is very limited because the central rays cross immediatelly in front of the bulb. Hence the bulb shield has to be small and conical in shape. In this case, it is no styling element of the headlamp. The completed light pattern formed by reflector and lens is shown in Fig.9.

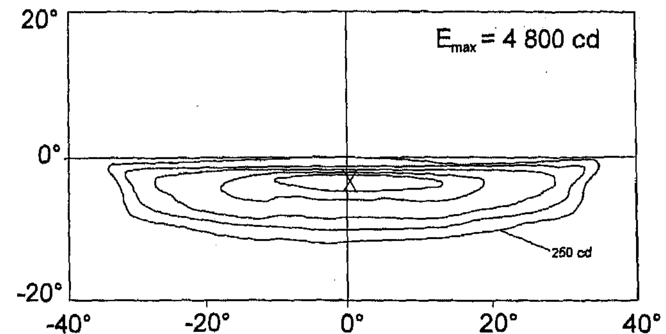

Fig. 9: Light pattern of a fogbeam with a semi-clear outer lens, converging reflector concept. H1 bulb. Reflector 90 mm wide, 70 mm high.

The second example is a foglamp with a clear outer lens. In this case, the light source is a H3 bulb with a transverse filament. For the same reasons as in the example before, a small conical bulbshield is used.

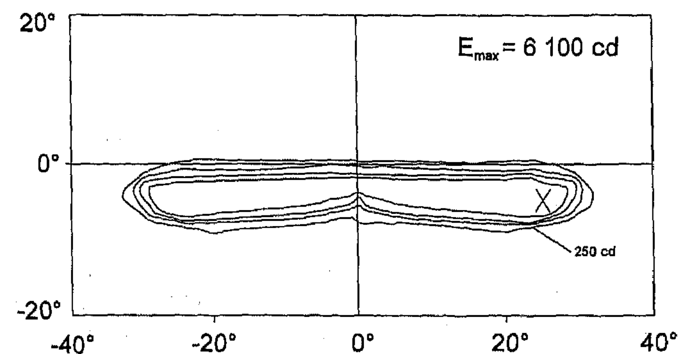

Fig. 10: Light pattern of a fogbeam with a clear outer lens, converging reflector concept. H3 bulb. Round reflector, diameter 85 mm.

Other light sources with transverse or axial filaments are also suitable for foglamps. For each application with a different light source or a different size of the reflector a new reflector shape has to be calculated to achieve a high quality light pattern.

CONCLUSION

For every headlamp, it has to be determined if the stylistic and technical requirements can be fulfilled simultaneously. A selection of typical reflector characteristics has been presented, together with appropriate choices in reflector design. These examples do not offer complete, ready-to-use solutions. The best reflector concept has to be chosen for each headlamp project individually.

Headlamp Design Variations Using HID in Projector Type Headlamps

Heike Eichler
Robert Bosch GmbH

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

For some years now the new HID technology has been used for headlamp systems to improve safety and comfort during night time driving. A new generation of projector type headlamps starts series production in 1997. The characteristics of the HID bulb and the specific requirements of the light distribution make it necessary to calculate special optical systems to control the high amount of light. There are different possible design strategies. On one hand, it is possible to improve the light pattern, e.g. increase the luminous flux and the range. On the other hand it is possible to build a system with extremely small dimensions. Such a system ensures an excellent light quality even in smallest headlamps and gives way to new styling possibilities. To match such different targets, some parameters of the reflector and the lens have to be optimized. Some examples of projection headlamps which are designed for different applications will be discussed.

INTRODUCTION

In 1991 Bosch introduced the first headlamp with a High Intensity Discharge bulb (Litronic) to the market, it was a projector type headlamp (1). Since then, a lot of test drivings have been done, and the Litronic system which is also known as Xenon Light has been improved continuously (2). The number of cars equipped with a HID lamp has grown. Nowadays nearly all major car manufacturers have already introduced the HID headlamp to the market or are preparing series production. With the validation of the homologations for gas discharge bulbs and headlamps using HID, the floor is open for the development of a new generation of optical systems which give a higher amount of light on the street and a higher range. The high luminous flux of the HID lamp can be used more efficiently. The optics are also developed in a more global way, to give way to harmonization efforts of the SAE and ECE light pattern. According to the customers' wishes, one of the most important aspects is to make the system smaller so that less space is needed and a maximum styling freedom is achieved.

LIGHT PATTERN - ASPECTS TO IMPROVE

The high light output of the HID lamp opens a wide range of completely new possibilities for the light pattern design. However, due to the high luminances that can be achieved with the HID lamp, the light pattern has to be shaped very carefully and in a rather controlled fashion. The advantages in comfort and safety should be given in all driving situations, even under adverse road or weather conditions. A characteristic feature of the light pattern is the strong asymmetry between the right and the left side of the road. The hot spot on the right side of the street has a high luminance and thus results in excellent range. Early recognition of street direction and possible obstacles enables the driver to choose the appropriate cruise speed. Since the superposition of the two light patterns for both vehicle headlamps can lead to zones of high illumination, the 15-degree slope is cut off above the horizontal line. Thus, glare for the oncoming traffic is controlled efficiently.

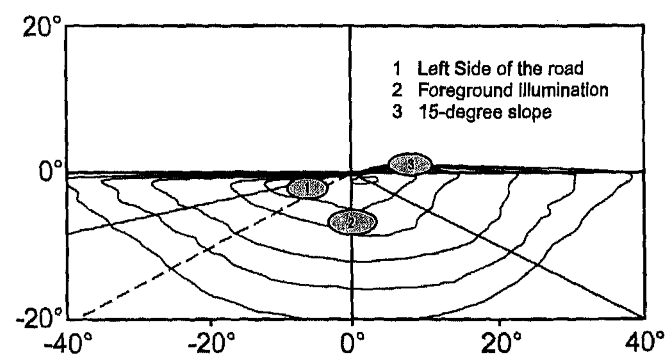

Fig. 1: Zones in the light pattern which need special control.

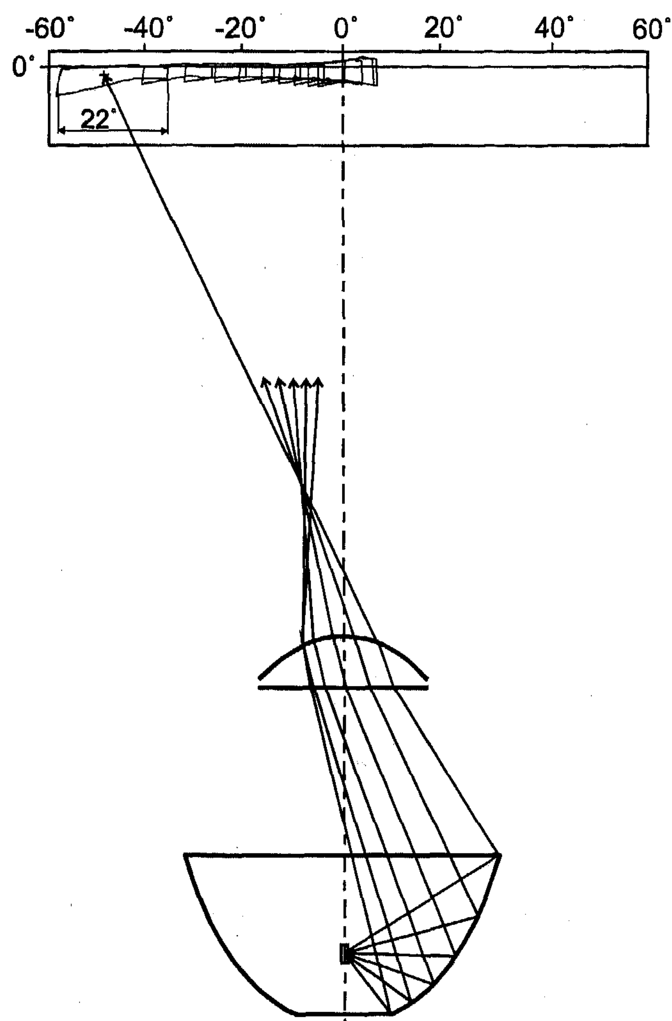
The illumination of the left side of the street is always a compromise between range and glare. A high amount of

lateral dispersion can reach 60 degrees. This is realized by the Compact PES System which has an excellent lateral dispersion.



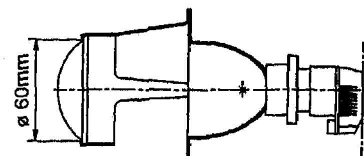


Fig. 3 shows how the high lateral dispersion of the Compact PES is achieved.

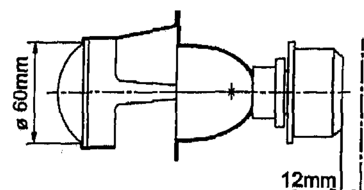

NEW PROJECTOR TYPE SYSTEMS

There are two new PES systems developed by Bosch. The comparison of these systems to the current series PES system is shown in Fig. 4. The overall length as well as the volume has been reduced by using smaller focal lengths. These systems can be used more flexibly and in headlamps with small dimensions. This might become an important point for lighting systems of the future because of better aerodynamics, packaging advantages and design freedom.

Current PES

New PES
- improved range
- lower foreground illumination

Compact Litronic PES

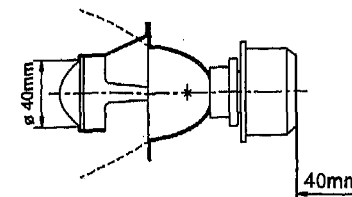

Fig. 4: Litronic PES low beam.

PES WITH LENS DIAMETER 60MM - The light pattern has been improved. As shown in the isocandela light pattern, the maximum luminous intensity has been increased from 30000cd to 40000 cd which leads to improved range. Because the cut-off line is built by a diaphragm the glare can be precisely controlled. The foreground illumination has been reduced further, so that the ratio between hot spot and foreground becomes more comfortable for driving. The lateral dispersion and the luminous flux remain roughly the same. The isocandela light pattern and the bird's-eye view are shown in Fig. 5 and Fig. 6.

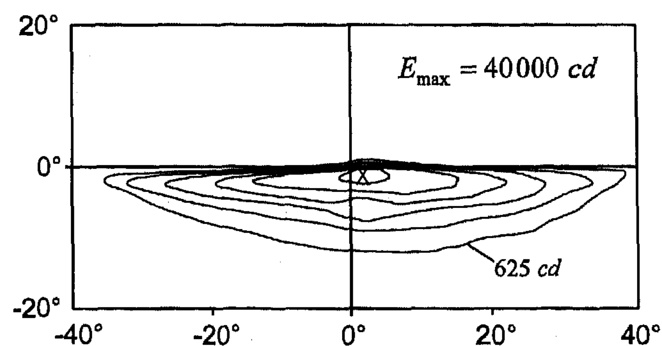

Fig. 5: SAE isocandela light pattern of new PES lens diameter 60mm.

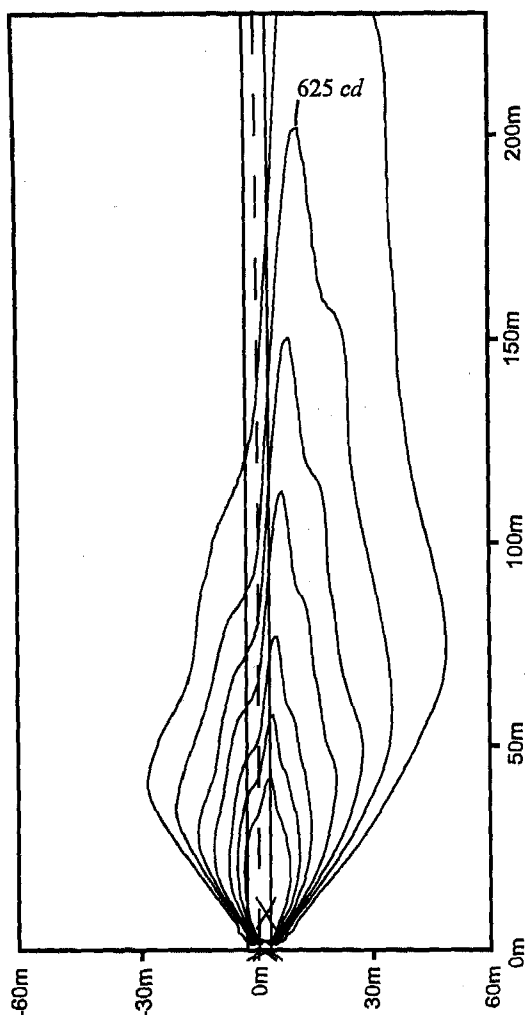

Fig. 6: Bird's-eye view of SAE light pattern lens diameter 60mm.

COMPACT PES - LENS DIAMETER 40MM - A completely different design strategy is necessary when minimizing a Litronic PES system down to the smallest possible dimensions. If done sucessfully, the light output is nearly equal to that of the PES system with 60mm diameter lens, in quality as well as in luminous flux. The isocandela light pattern and the bird's-eye view are shown in **Fig.** 7 and Fig. 8.

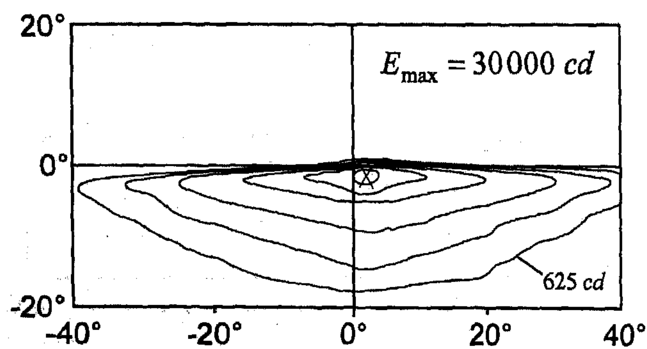

Fig. 7: SAE isocandela light pattern of Compact PES.

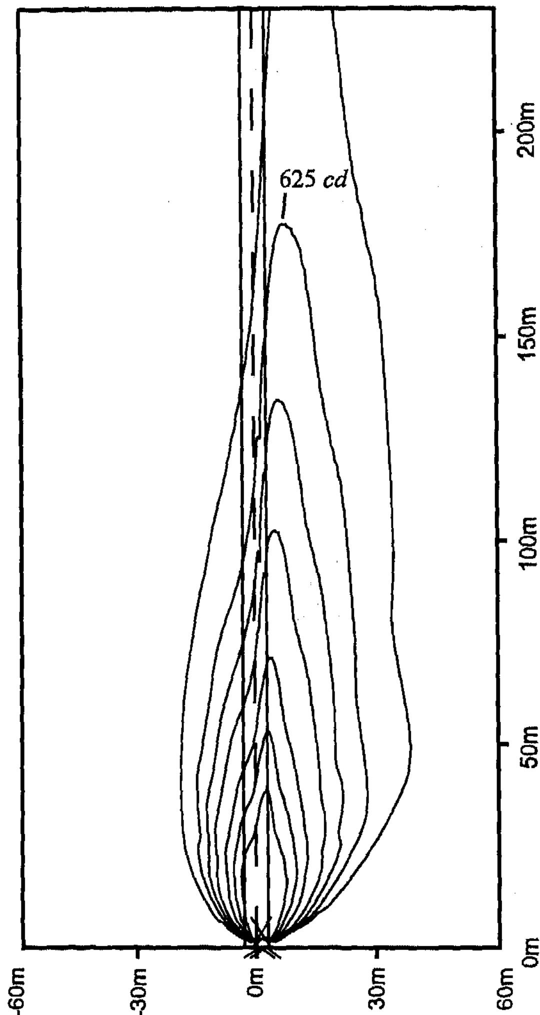

Fig. 8: Bird's-eye view of SAE light pattern Compact PES with 40mm lens diameter.

The light pattern shows a maximum of 30000 cd and a moderate foreground illumination. The system accomodates even in the most restrictive space requirements.

SIZE OF SIGNAL IMAGE - Especially with the HID lamp, the signal image of the headlamp should have a minimum illuminated size. Several investigations in recent years have proven that small illuminated surfaces lead to an increase of discomfort glare. This effect, which was investigated and confirmed also for Litronic applications (6), can easily be avoided by enlarging the signal image. There are several possibilities of creating an illuminated area around the lens, one of them being the implementation of an additonal ring-shaped reflector (7). With the Compact PES which uses only a 40mm diameter lens, enlarging the signal image becomes even more important than with a 60mm diameter lens. By using a signal image closer in size to that of conventional reflector-type headlamps, the discomfort glare can be reduced drastically. The design possibilities of the illuminated surface are virtually unlimited.

CONCLUSION

More light from even smaller and more compact headlamps is a trend in modern vehicle lighting. Better aerodynamics, packaging advantages and more design freedom are requested. The new generation of projector type headlamps offers a convincing solution. The compact PES system reduces the overall length by 25% compared to the current series system. Luminous flux and range are essentially the same. The lens diameter is 40mm instead of 60mm, and the headlamp volume has been cut in half. This Compact PES sets new standards and facilitates introduction of Litronic technology to the compact and subcompact class. With the new 60mm compact PES. the overall length is reduced by 10%. Nevertheless, the range and the light distribution is improved.

Headlighting - Toward a Model of Customer Pleasing Beam Patterns

Stephen M. O'Day, Christopher H. Stone, Daniel D. Jack, and Vivek D. Bhise
Ford Motor Co.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The headlamp beam pattern development process contains both subjective and objective evaluations. The subjective evaluation, communication between the customer and the engineer, was developed in previous work [1][2]. This paper presents exploratory models used in the identification of objective photometric variables of a beam pattern that relate to the subjective impression of the beam pattern. Additional research will allow use of the photometric variables and their selected ranges for designing and evaluating beam patterns to achieve improved customer pleasing beam pattern driving experiences.

BACKGROUND

For many years engineers have recognized two important conditions for the meaningful evaluation of the products they produce: 1) the evaluation should be done by the intended customer and 2) the evaluation should be conducted in the environment in which the product is intended to be used. In the past many headlamp beam pattern designers have experimented with different ways of satisfying both of these conditions. Such differences in practice have lead to considerable variations in the visual quality of beam patterns. The semantic differential approach to headlamp beam pattern evaluation [1][2] satisfied both of the above stated conditions and was the first step in the process of improving the quality of beam patterns based on customer input. Our previous work has shown the value of acquiring customer input during the headlamp design process. The information gained from the customer can positively influence headlamp beam pattern design and result in a higher quality beam pattern as measured by customer satisfaction. This paper reports on the next steps taken toward the development of a model for customer pleasing beam patterns. These steps involved the analysis of the photometric characteristics of the beam patterns and relating them to the previously acquired customer subjective evaluations of the headlight beam patterns.

ANALYZING THE BEAM PATTERN

The analysis of the physical aspects of headlamp beam patterns started with photometric measurement of each headlamp system using a goniometer (see Figure 1). Twelve beam patterns representing a wide cross-section of currently available headlamp technologies including conventional, complex reflectors with smooth form back cans, complex reflectors with faceted back cans and projectors were measured.

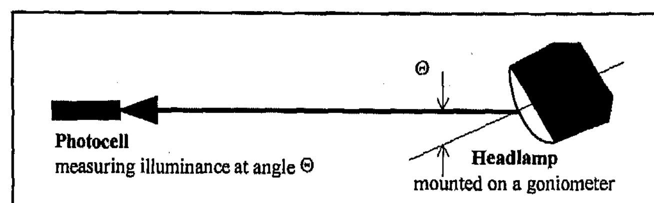

Figure 1 - Photometric measurement of a headlamp

Each headlamp was measured on the goniometer over a horizontal range from 40° left to 40° right at .25° intervals and over a vertical range of 4° up to 15° down at .25° intervals. Photometric data from the right and left headlamps was input into a computer program that combined them to form a complete beam pattern. The program then "projected" the beam pattern (i.e. illumination) by interpolating the beam pattern data onto the road surface at every 0.1° as it would appear from the view point of the driver. Road reflectance was calculated according to research by Bhise et al. [3]. Multiplying the computed reflectance coefficients by incident illumination provided pavement luminance values. These luminance values are here referred to as brightness. The 0.1° grid of brightness values thus provided a more complete reconstruction of each beam pattern. A brightness, iso-foot-Lambert(fL), contour plot of one of these computer reconstructed beam patterns is shown in Figure 2.

The plot is presented in polar coordinates with respect to the driver's eye position. The negative numbers on the vertical axis refer to what the driver would see looking DOWN from the horizon that many degrees. On the

horizontal axis the negative numbers refer to what the driver would see looking LEFT and the positive numbers correspond to what the driver would see looking RIGHT. Five milli-foot-Lamberts (mfL) was selected as the lowest brightness level for plotting. Each succeeding contour represents a brightness level at least 50% higher than the previous contour. The assumption was that a 50% increase, or decrease, in road brightness will be perceptually noticeable to the human eye. Thus these polar contour plots should closely represent the discernible levels of brightness on the road surface as perceived by the driver.

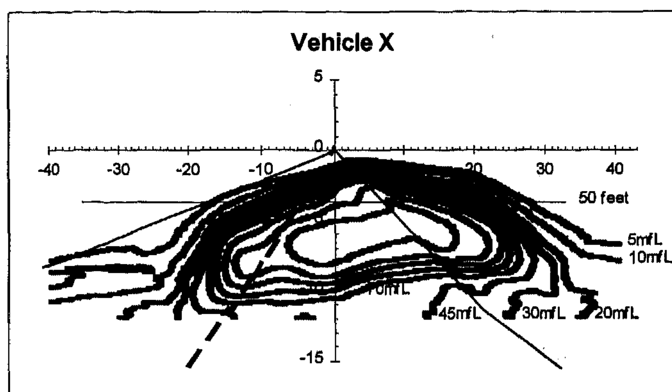

Figure 2 - Brightness (iso-fL) contour plot of Vehicle X's beam pattern

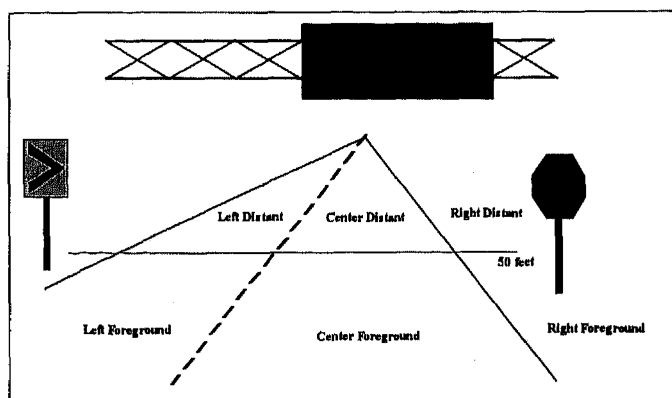

Figure 3 - Road scene showing the location of the six zones.

PHYSICAL CHARACTERISTICS

Based on a previously reported factor analysis of subjective data [1][2] it was determined that four beam pattern factors were considered important to the customers: uniformity, aim, power and comfort. The goal was to find physical measures within the photometry data that would characterize these factors. Though not present in the factor analysis it was decided that another factor, beam shape, should be included to arrive at a more complete analysis of a beam pattern. Each of these factors, derived from customer input, describes a distinctly different aspect of a beam pattern. Note that they may not be mutually exclusive of one another.

The physical measures described below were thought to have a high probability of being important in quantifying each factor before the analysis and model building process began. However, many of these measures were not included in the models due to criteria that will be described later.

BEAM PATTERN UNIFORMITY - Uniformity is perhaps best quantified by a measure of the changes or gradients in brightness of a beam pattern. Vertical gradients (along the direction of travel) and horizontal gradients (perpendicular to the direction of travel) were measured for each beam pattern. Maximum and average gradients as well as maximum and average second order gradients occurring in each zone (see Figure 3) of the beam pattern were also considered.

Each of these simple gradient measures could have a problem characterizing uniformity for both bright and dim beam patterns. A bright beam pattern, for example an HID lamp, would always have higher gradients compared to a conventional lamp regardless of uniformity. To address this potential problem a relative difference in brightness and a second order difference in brightness was calculated for each beam pattern. These measures were calculated as a sum total of all the relative differences for various areas on the road surface:

Relative Difference in Brightness =

$$\sum_{\substack{i=vertical\\angle}} \sum_{\substack{j=horizontal\\angle}} \frac{(b_{i,j+1} - b_{i,j})}{b_{i,j}} \qquad (1)$$

2nd Order Difference in Brightness =

$$\sum_{\substack{i=vertical\\angle}} \sum_{\substack{j=horizontal\\angle}} \left[\frac{(b_{i,j} - b_{i,j-1})}{b_{i,j-1}} - \frac{(b_{i,j+1} - b_{i,j})}{b_{i,j}} \right] \qquad (2)$$

where $b_{i,j}$ is the brightness on the road surface at angles i and j (incremented at every 0.1 degrees) relative to the driver's eye position.

BEAM PATTERN AIM. Many measures used in the study were affected by aim. The most direct measure of aim was the center of mass of the beam pattern. This was defined as the point on the road surface that had the same amount of light around it in any direction. The center of mass was calculated by weighting each illuminated point on the road surface according to the amount of light it received. The vertical and horizontal average then gives the polar coordinates that describes the center of mass of the total beam pattern.

$$\text{Center of Mass}_{\text{thorizontal}} = \frac{\sum_{\substack{i=vertical\\angles}} \sum_{\substack{j=horizontal\\angles}} j * b_{i,j}}{\sum_{\substack{i=vertical\\angles}} \sum_{\substack{j=horizontal\\angles}} b_{i,j}} \qquad (3)$$

$$\text{Center of Mass}_{vertical} = \frac{\sum_{\substack{j=horizontal\\angles}} \sum_{\substack{i=vertical\\angles}} i * b_{i,j}}{\sum_{\substack{j=horizontal\\angles}} \sum_{\substack{i=vertical\\angles}} b_{i,j}} \quad (4)$$

where $b_{i,j}$ is the brightness at angles i and j on the road surface relative to the driver's eye position.

BEAM PATTERN POWER. The power of the beam pattern referred to the amount of light the headlamps put on the road surface. It was measured four ways. One measure was the amount of brightness generated within the 6 zones on the road surface (see Figure 3), as well as, the total amount of brightness within the photometry space. Various brightness ratios were also calculated, including the ratio of foreground brightness to distant zone brightness and the ratio of brightness in the center distant zone to total beam pattern brightness.

A second measure was the calculation of areas bounded by various brightness contour levels projected on the road surface. The power of a beam pattern was assumed to be proportional to the area of a beam pattern at a given brightness level.

The third measure of power was the calculated perimeter of the brightness contours. It was thought that the power of a beam pattern would be proportional to the perimeter of any given iso-footLambert contour.

Lastly, a calculation of the horizontal and vertical dimensions (overall width and height) of the brightness contours was used as a measure of power.

BEAM PATTERN SHAPE Quantifying the shape of a beam pattern was accomplished by borrowing some measures used in the growing field of computer character recognition. These measures included: circularity, ellipsity and convexity. In addition to these measures the area on the road surface covered by the beam pattern and the width of the beam pattern at 6 degrees down (as viewed from the driver's eye) were also included.

Circularity measures how circular a given contour is by looking at the perimeter and the area enclosed by a given contour. A circle has the following properties:

$$\text{Area: } A = \pi R^2 \quad (5)$$

$$\text{Perimeter: } P = 2\pi R \quad (6)$$

where R is the radius of the circle.

From this it can be seen that the ratio P^2/A is always 4π for a circle. The circularity for an iso- footLambert contour is defined as $C = P^2/(4\pi A)$. Therefore, a circle would have a circularity measure of 1.0. Since a circle encloses the greatest area with the smallest perimeter, any other shape would have a circularity greater than 1.0. For instance, a square would have a $C \approx 1.2$ and a triangle would have a $C \approx 1.44$.

Since the shape of a beam pattern is usually elliptical, a measure of ellipsity was employed. An ellipse has the following properties:

$$\text{Area: } A = \pi ab$$

$$\text{Perimeter: } P = 2\pi\sqrt{\frac{a^2+b^2}{2}} \quad (8)$$

where a and b are the lengths of the semiaxies.

Thus, the ratio

$$\frac{P^2}{A} = \frac{2\pi(a^2+b^2)}{ab} \quad (9)$$

for an ellipse. The ellipsity measure, E, was defined as:

$$E = \frac{abP^2}{2\pi A(a^2+b^2)} \quad (10)$$

This measure will equal 1.0 for an ellipse (as well as a circle), but for a square $E \approx 1.27$ and for a triangle $E \approx 1.84$.

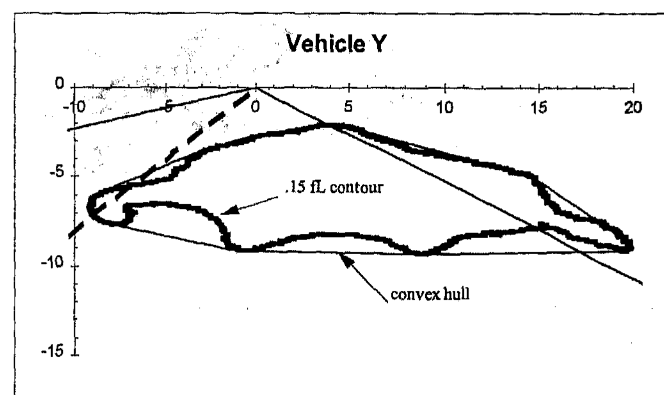

Figure 4 - Convex hull circumscribing the .15 fL contour.

To quantify the bumpiness of a beam pattern a measure of convexity was employed. This measure is a ratio of the perimeter of an iso-footLambert contour to the perimeter of it's convex hull. A convex hull is a shape with no indentations. Figure 4 shows the .15 fL contour of a beam pattern and the convex hull that circumscribes it. The convexity measure was intended to quantify the jaggedness and bumpiness of the beam pattern. A cursory examination of some of the beam pattern shapes suggested that a smooth convex shape may be more pleasing to the customer than a rough or non-convex shape.

TOWARD A MODEL

A preliminary model of customer pleasing beam patterns can be summarized as follows:

Subjective Experience of a Pleasing beam pattern =
f (Physical Characteristics of the beam pattern)

This equation states that the customer's subjective experience of a pleasing headlight beam pattern is equal to some function of the measurable physical (ie. photometric) characteristics of the beam pattern. Measures of the subjective experience of a pleasing headlight beam pattern have been previously acquired and summarized using semantic differentials. Physical measures of the evaluated beam patterns (mentioned above) have been identified and calculated. The only piece of

the model left to determine was the function that relates the subjective measure(s) to the physical characteristic(s).

The identification of the functional relationship was explored in the following manner. Physical photometric measures were calculated for 12 beam patterns. These 12 beam patterns represented a cross-section of lamp technologies and exhibited a wide range in their subjective evaluation scores. Five of the beam patterns were subjectively judged in field evaluations to be pleasing, five were judged to be unpleasant and two were judged to be not especially pleasing but not unpleasant.

Choosing this mix of beam patterns was an acknowledgment that beam pattern design is in essence a "turnip" (see figure 5). There are a few ways to make a good beam pattern and a few ways to make a bad beam pattern, but there are many ways to make a mediocre beam pattern. A quick examination of the beam patterns on the road today show this to be the case. This over abundance of mediocrity could confound attempts to find a functional relationship between subjective and physical measures. Therefore, the 12 beam patterns were specifically chosen to balance the good and the bad and minimize the confusion in between.

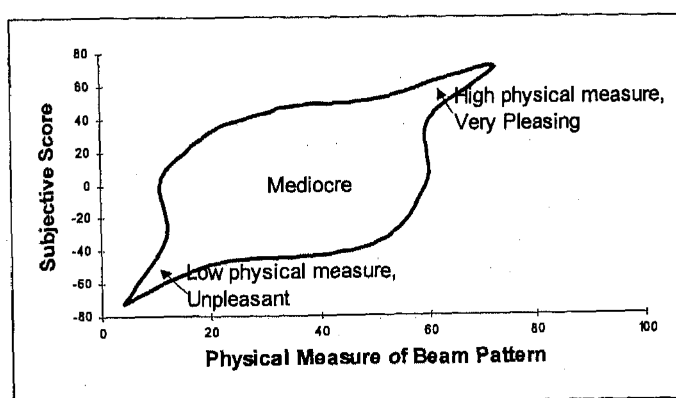

Figure 5 - The Bulge of Mediocrity in headlamp design

On the subjective side of the equation each beam pattern was evaluated by at least 5 to as many as a hundred subjects during a series of dynamic night drives. The evaluations consisted of a set of 25 word pairs related to an aspect of the beam pattern (this process is detailed by Jack et al. [1]). Subject responses were obtained using a five point scale. For example with the word pair "Uniform-Spotty", the subject could respond in one of the following ways: very uniform, somewhat uniform, neither uniform nor spotty, somewhat spotty, very spotty. The subject's response was encoded as a number from +2 to -2. These responses were then averaged over all subjects for each of the 12 beam patterns. Some of these subjective word pair averages were combined to form a summary score for each of the five factors: uniformity, aim, power, shape, comfort. The composition of the subjective score for each factor is shown in Table 1. Each factor's constituent word pair averages were added together and scaled to arrive at the summary score. These summary subjective factor scores were then correlated with the physical measures.

The physical measures mentioned above were calculated for each beam pattern and along with their subjective scores were subjected to a stepwise regression analysis [5]. The results of these analyses served as a starting point to identify the functional relationships between the subjective impressions and the measured physical attributes of the beam patterns. To complete each regression model physical measures were added to or subtracted from those identified by the step-wise regression analysis based on the following criteria:

1. Each model should be composed of physical measures that in some rational way make sense with respect to the subjective measure it is attempting to describe.

2. Each model should be as simple as possible with little or no redundancy.

Table 1 -Composition of the subjective summary factor scores

UNIFORMITY =	Uniform-Spotty score + Smooth-Choppy score + Blended-Streaky score + Unified-Divided score + Balanced-Uneven score + Uniform-Streaky score.
AIM =	Balanced-Uneven score + Elongated-Truncated score + Long-Short score + Aimed-Misaimed score + Right-Left score.
POWER =	Sufficient-Insufficient score + Long-Short score + Strong-Weak score.
SHAPE =	Spacious-Defined score + Long-Short score + Elongated-Truncated score.
COMFORT =	Comfortable-Uncomfortable score + Sufficient-Insufficient score + Secure-Insecure score + Pleasant-Unpleasant score.

The results of this step-wise regression process are shown in Table 2 along with the correlation coefficients and R^2 values between the physical measures and the 5 subjective factors. The correlation between the subjective factors and the corresponding regression models are also shown in Table 2 and are marked with an asterisk. These individual regression models for each factor can be restated as follows:

Subjective UNIFORMITY = $a_u(\Delta_2) + b_u(\Delta_{max}) + c_u$
Subjective AIM = $a_a(M_h) + b_a(M_v) + c_a(W_6) + d_a(C_{30}) + e_a$
Subjective POWER = $a_p(B_{cd:t}) + b_p(W_6) + c_p(P_{30}) + d_p(HV_{20}) + e_p$
Subjective SHAPE = $a_s(W_6) + b_s(R_{70}) + c_s$
Subjective COMFORT = $a_c(B_{cd:t}) + b_c(\Delta_{max}) + c_c(HV_{20}) + d_c$

where

Δ_2 = the sum of the second order difference in brightness
Δ_{max} = the maximum difference in brightness
M_h = the horizontal center of mass
M_v = the vertical center of mass
W_6 = the width of the beam pattern at 6 degrees down.
C_{30} = the convexity of the 30 mfL line.
R_{70} = the circularity of the 70 mfL line.
P_{30} = the perimeter of the 30 mfL line.

$B_{cd:t}$ = the ratio of the center distant brightness to the total brightness of the beam pattern.

HV_{20} = the horizontal * vertical dimensions of the 20 mfL line.

and a, b, c, d, e are regression coefficients.

Table 2 - Model factors/physical characteristics and statistics

UNIFORMITY	Correlation	R^2 Value
sum 2nd order Difference in Brightness	-0.802	0.643
Max Difference in Brightness	-0.557	0.310
UNIFORM regression model *	**0.825**	**0.681**
AIM		
Horizontal Center of Mass	0.118	0.014
Vertical Center of Mass	-0.499	0.249
Width of the beam pattern at 6 degrees down	0.659	0.434
Convexity of the 30 mfL line	0.755	.570
AIM regression model *	**0.943**	**0.888**
POWER		
ratio of brightness in the Center Distant zone to Total brightness	-0.406	0.165
Width of the beam pattern at 6 degrees down	0.672	0.452
Perimeter of the 30 mfL line	0.109	0.012
Horizontal * Vertical dimensions of the 20 mfL line	0.661	0.437
POWER regression model *	**0.921**	**0.849**
SHAPE		
Width of the beam pattern at 6 degrees down	0.655	0.429
Circularity of the 70 mfL line	-0.196	0.038
SHAPE regression model *	**0.776**	**0.602**
COMFORT		
ratio of brightness in the Center Distant zone to Total brightness	-0.503	0.253
Max. Difference in Brightness	-0.534	0.285
Horizontal * Vertical dimensions of the 20 mfL line	0.767	0.588
COMFORT regression model*	**0.792**	**0.628**

The R^2 values shown in Table 2 indicated the regression models explained the following amount of variance in the data for the five factors: uniformity(68%), aim(89%), power(85%), shape(60%), and comfort(63%). The F statistic for each model exceeded the critical value indicating the amount of variation in the data explained by each model was significant.

FUTURE RESEARCH ISSUES

Verification of the proposed models should be conducted by an evaluation using additional headlamp systems. Photometry data should be collected on a number of new "good" and "bad" (high and low subjective scores) headlamp beam patterns. This data would serve as input into the models to predict the factor scores. Then a subjective beam pattern evaluation should be conducted and the data compared to the predicted factor scores. Following successful verification of the models, limits on each photometric independent variable could be developed to assure that beam patterns can be created that will provide improved levels of subjective impressions on visual quality.

When completed the beam pattern design and evaluation process should be considered as a potential supplement to other photometric requirements (eg. SAE and federal standards).

ACKNOWLEDGMENTS

The research reported in this paper was conducted jointly by the Lighting Technology Group and the Human Factors Engineering and Ergonomics Department of Ford Motor Company. We gratefully acknowledge the effort of Jose Cruz of LTG for the photometric measurements on the headlamps and the help of evaluators who participated in the many night drives.

Daytime Running Lamps with Low Power Consumption

Abstract

During the last few years the function of daytime running light (DRL) has been applied more frequently. According to road safety experts it is an important factor in reducing daytime collisions.The number of countries allowing or requiring the DRL continues to increase. A frequent argument against DRL is the increase in fuel consumption caused by the rise in power consumption.

The development target, therefore, was a separate daytime running lamp, which would have a reduced power consumption in comparison to the low beam function frequently used.

A prototype with an approved light source was to be developed to allow immediate series production.

The increasing quality standards in the automotive industry are also challenging for the component life of the bulb. With the optimisation of the "bulb - lamp" system, new concepts may be introduced, which will comply with future component life requirements.

1 Introduction

1.1 Reliability of the Daytime Running Light

Studies (Source: 1.3) show, that the daytime running light increases road safety. Since the introduction of the DRL in several countries, a reduction of approx. 10 % of the daytime collisions was noted.

It is noticeable, that particularly northern countries, where the daytime light periods are short, and twilight, rain and snow are frequent, have shown interest in this subject.
As a result, the DRL has become mandatory in Sweden, Norway, Finland, Denmark - but also in Canada since 1989, in Poland and Hungary in the 1990s.

In the USA, Australia and Great Britain, DRL is permitted, but not mandatory.

Since 1992 the European Union (EU) have a uniform regulation stipulating that the daytime running light is permitted as a signal lamp.

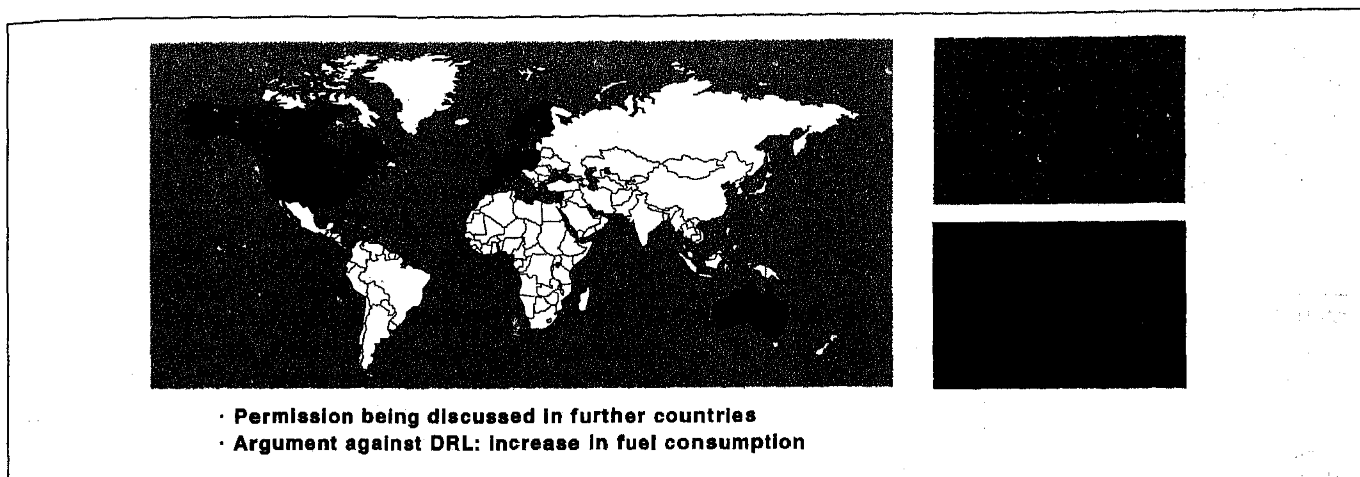

Fig. 1 Daytime running light - current situation

One of the most frequent arguments against DRL is the increase in fuel consumption. The minimum values given in this context are 0.1 l per 100 km with switched-on headlamps. For all of Europe an additional consumption of approx. 288 million l fuel is given per year (Source: 1.5). Therefore, special attention needs to be paid to the energy requirement of this continuous function.

In this project, the use of light sources with drastically reduced power consumption was to be realised. The bulb life and possible optimisations were analysed for this purpose. The example of a separate daytime running lamp allowing for series use in EU and US was the result.

1.2 Definitions and Regulations

According to ECE-R No. 87, the DRL is defined as follows:

"Lamp for daytime running light" is a lamp pointed in the driving direction used to make the vehicle more visible, when it is driven during daytime light.

In national definitions (e.g. in Sweden) this special lamp function is also called **"perception lamp"**.

DRL may be generated by the low beam function, a reduced high beam, front fog lamp, front direction indicator or clearance lamps or by special additional daytime running lamps (depending on the regulations).

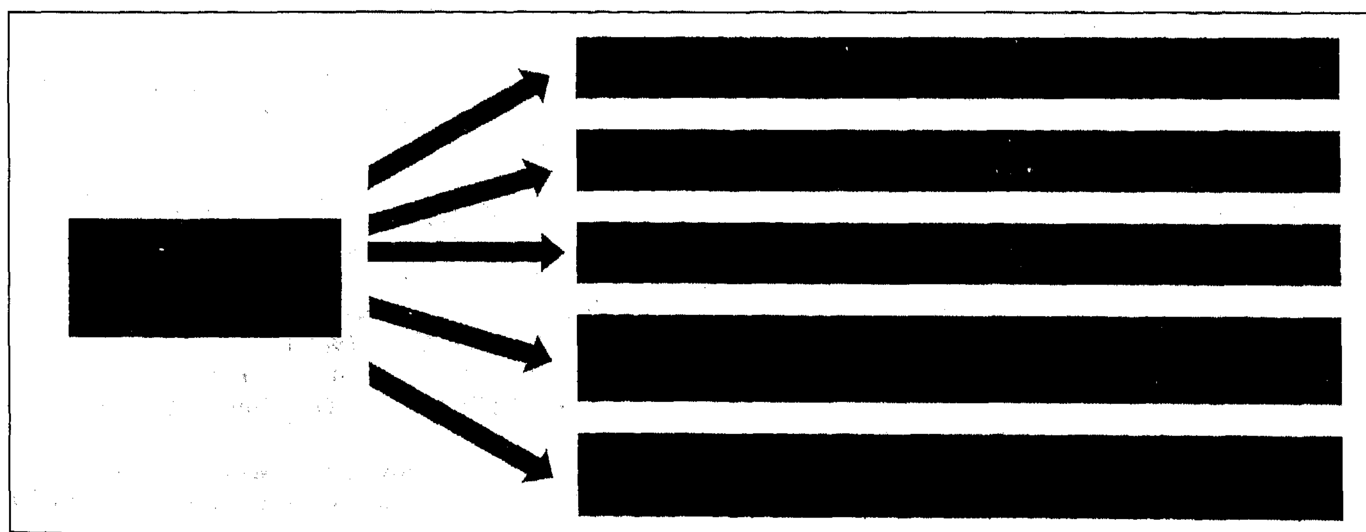

Fig. 2 Daytime running light - Existing solutions

In Europe the daytime running lamp is permitted within the installation directive ECE-R 48 (2/1995), i.e. the responsibility lies with the vehicle manufacturer. In addition to the various national regulations, ECE-R No. 87 is accepted. (see fig. 3).

Country: **Europe**		Light intensity **[cd]**			**Daytime running lamp - white**		
Basis of requirement:					**ECE-R 87**

1.3 Studies

The articles listed below refer to the findings about the reduction of daytime collisions since the introduction of the daytime running light:

- "Daytime Running Light- Reduce Daytime Collisons" (PAL-Symposium 1995) by Kåre Rumar, Swedish National Road Administration

The following table documents the reduction of daytime collisions since the introduction of the daytime running light.

Year	Test fleet / Area	Accident reduction
1962	Greyhound Bus	-10 %
1965	US truck fleet	- 44 %
1968	NY car fleet	- 18 %
1970	Chicago taxi fleet	- 12 %
1976	**Nation Finland**	**- 21 %**
1979	US truck fleet	- 7 %
1980	Nation Schweden	- 11 %
1985	US company fleet	- 7 %
1986	**Nation Norway**	**- 15 %**
1989	Canadian company fleet	- 12 %
1990	**Nation Denmark**	**0 % (left turn - 37 %)**
1991	Cars Israel (Campaign)	+ 19 %
1993	**Nation Norway**	**0 % (- 15 % summertime)**
1994	**Nation Canada**	**- 11 % (oncoming)**

Fig. 5 Reduction of daytime collisions due to application of the DRL [Kåre Rumar]

- "Study of Daytime Running Light - TP 6716 E" (Canada 1985)

- "Effectiveness of Daytime Running Lights in Canada - TP 12298 (E)" von H. Arosa, D. Collard, G. Robbins, E. R. Welbourne, J. G. White (Dez. 94)

This analysis shows, that with the application of the DRL, collisions have been reduced by 8,3 %.

1.4 Development of a separate lamp

In the daytime running light version used primarily - the combination with the low beam - a long life bulb is required. This means that the filament is larger, the reach of the beam is reduced and the glare caused by straylight can increase. Therefore, the use of a separate daytime running light function is to be preferred. One advantage of a single function lamp is a more homogeneous signal when compared to DRL realised with headlamps

For the development of the prototype, the light source and the lamp were considered together. The target was the fulfilment of the European and American lighting and surface requirements.

The power input should be as small as possible when compared to the usual H4/HB2 bulb with its 68 W.

The following elements were used:

• Lamp

One of the targets was to develop a lamp which meets all the requirements of the various countries.

The reflector is a rotationally symmetrical spherical reflector with metallised prisms. The minimum requirements for the illuminated surfaces of $\geq$ 40 cm² are fulfilled (Europe, FMVSS 108).

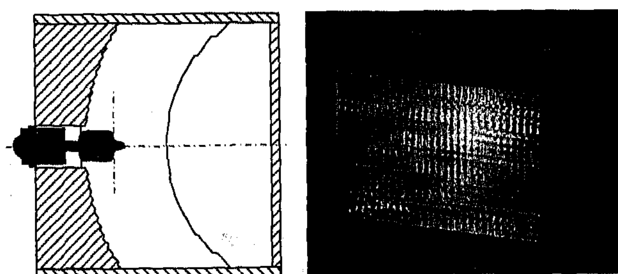

Fig. 6 DRL / schematic drawing and illuminated example with stepped spherical reflector

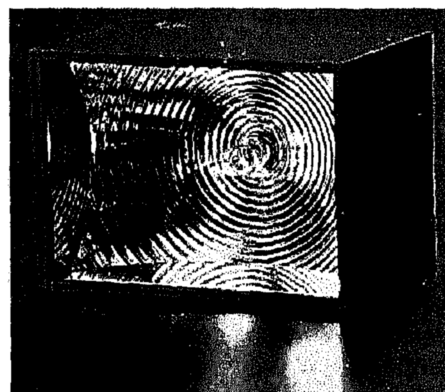

Fig. 7 View of the stepped spherical reflector without lens

A particular challenge was the ECE light distribution requirement. Here the cd value at $\pm$ 20° horizontally is 25 % of the max. value.

Alternatively, a paraboloid was considered as a reflector shape. This example is deeper and more efficient.

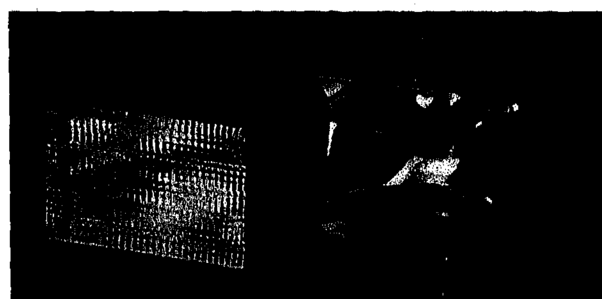

Fig. 8 Spherical reflector with lens (left) Paraboloid without lens (right)

• Light bulb

To support an immediate series application with type-approved bulbs, bulbs which are permitted according to ECE-R 37 were taken into account. Upon consideration of appropriate types and an adequate power consumption, the H6W bulb with a light flux of 125 lm was chosen. Its properties are discussed in point 1.6.

1.5 Power consumption

The additional power consumption of the DRL is one of the major arguments held against this function. The values given lie between 0.1 l and 0.2 l per 100 W of electrical power. A Canadian study of 1995 [Source: Preliminary economic evaluation of the costs and benefits of the DRL regulation - TP 12517 (E)] quotes a typical excess consumption of 0.19 l per 100 km at an average speed of 40 km/h. Power consumption lies between 40 W and 200 W. Vehicle manufacturers usually speak of 0.1 l of excess consumption.

According to the German Government, an additional 288 million l of fuel per year would be consumed in Europe, should all passenger vehicles use DRL during daytime driving [Source: Verkehrsnachrichten 3/96 - Ministry of Traffic].

In the Hella analysis, a relative reduction in consumption is the decisive parameter. The application of the halogen bulb **H6W** having a power consumption of 7 W would result in a **90 %** reduction when compared with the 68 W **H4/HB2** bulb. Looking at the standard bulb **P21W/1156** for lamps with a consumption of 25W, the savings would still amount to **72 %**. - In other words, a major reduction in primary energy consumption can be achieved.

1.6 DRL bulb life

Consideration of the bulb life is a primary concern especially with regard to warranty periods. In the US, the current warranty period is 3 years, however, the target should be 4 years.

Based on a driving performance of 20,000 km per year [Source: Highway Statistic 1994], an average speed of 50 km/h and an average use of the headlamps of 9.2 h per 1000 km [Source: Use of Car Lighting, Mercedes 1995], and taking into account a warranty time of 4 years, we reach a calculated value of 864 illuminated hours for the DRL function.

Until today it is normal practice to characterise the bulb life by means of the B_3 and T_C values. These two values have proven to be useful since they accurately characterise the failure well, while keeping the number of required measurements reasonable. Smaller values (e. g. $B_{0.1}$) would require a far larger number of bulbs to be tested in order to achieve a high level of confidence. Nevertheless, these data should allow the derivation of B_3 and T_C values from a theoretical $B_{0.1\ theor.}$ value. The characterics can be determined in line with these thoughts, if the $B_{0.1\ theor.}$ value is set ≤ the operation time.

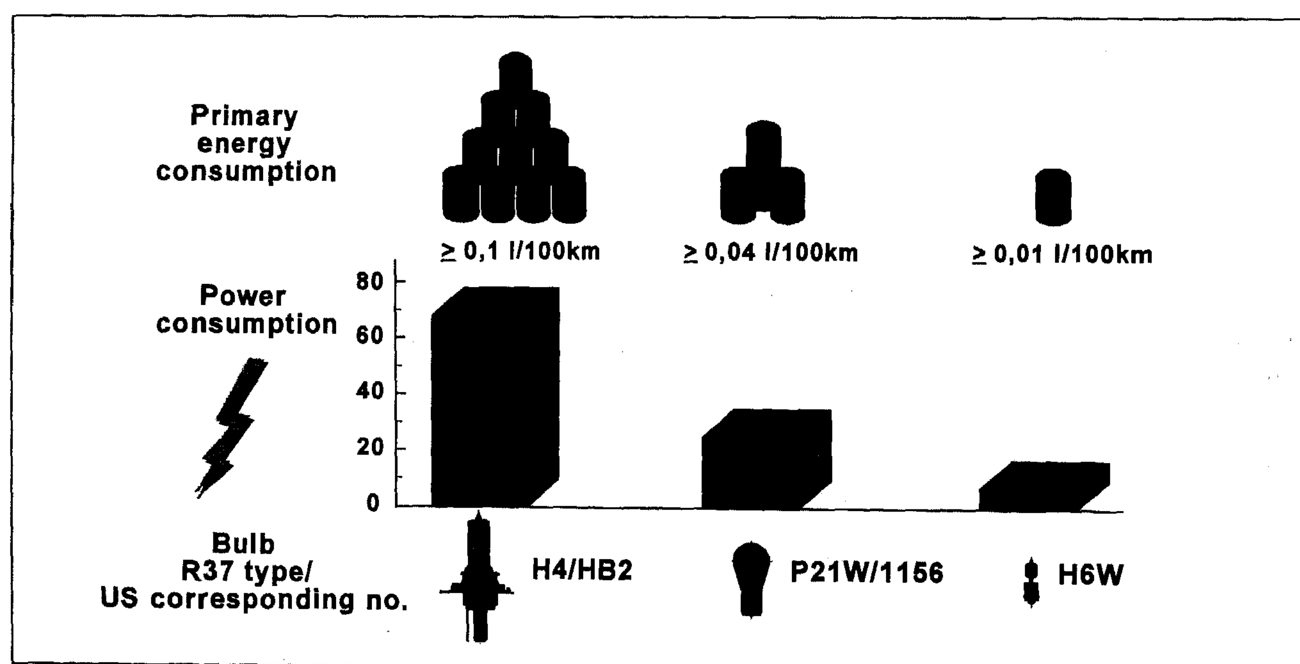

Fig. 9 Power consumption of the DRL function
Comparison of various bulb types

Considering a typical slope of the Weibull curve, we can calculate the corresponding B_3 and T_C values using the following formula:

$$t = \sqrt[b]{\ln(1-F(t))/\ln(1-F(T))} * T$$

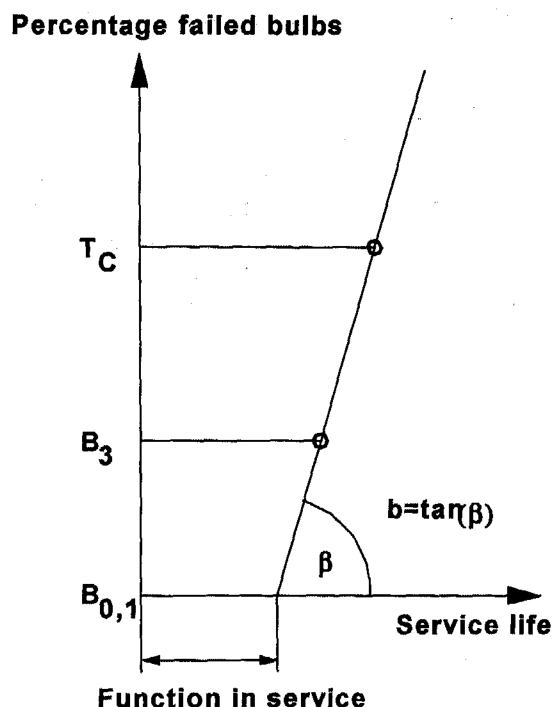

Fig. 10 Model of a *Weibull* graph

t = Bulb life to be calculated

b = Slope of *Weibull* curve

F(t) = Desired cumulative probability B%/100

T = Known bulb life

F(T) = Known cumulative probability B%/100

The result of this calculation are values of B_3 = 2200 h and T_C = 5300 h.

Obviously, if the luminous flux losses are not to be excessive and the performance over the period of the bulb life is to be acceptable, such life values can only be achieved with high pressure halogen bulbs.

The H6W, being a halogen miniature bulb with special design features offers the best conditions for use in DRL.

- Shock resistance
  - Solid inner mount
  - Short clamping of the filament
- Best optical qualities
  - Tight tolerances
- Service life
  - High pressure xenon filling

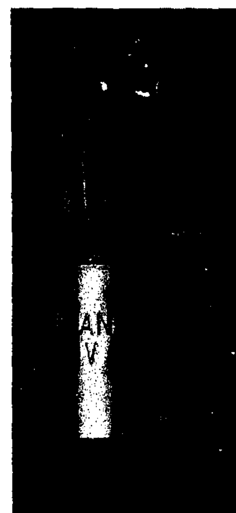

Fig. 11 Halogen miniature bulb HxW

Considering the service life we must notice, that this in accordance with ECE-R37 authorized bulb is specified in his operating range for other applications. If the obtainable values for the service life are compared with these which are required after above considerations, we notice, that the requirements are fulfilled only to approximately 12 %. It is obvious, that development work is required on this subject in the near future.

Values at 14 V	B_3 [h]	T_c [h]	$B_{0,1}$ [h] theoret.
H6W	210	480	100
HxW	2200	5300	864

Fig. 12 Comparision of H6W and HxW bulb, fulfilling the life requirements

To allow the immediate introduction of the DRL with low energy consumption, the system must be designed for the H6W, but at the same time, a bulb needs to be developed, which is comparable to the H6W in its photometrical properties. This would allow a change to a longlife bulb without having to change the lamp.

Based on an identical component volume, the same filament alignment and length, we assume for the long life bulb the following changes in parameters related to the H6W data:

at 13.5 V	Value	Differences [%]
Luminous flux	133 lm	+ 7 %
Power consumption	10.5W	+ 50 %
Filament temperature		- 7 %
Filament diameter		+ 80 %

Fig. 13 Parameter differences between H6W and HxW

1.7 Summary

The prototype of a separate DRL equipped with halogen bulb H6W indicates an imminent series application for the countries where its use is permitted.

The savings achieved in power consumption amount to 90 % of that of the H4/HB2 bulb.

Increasing bulb life demands require further optimisation on the manufacturer's side. The consideration of the power consumption will be of increasing importance for future developments - particularly with view to the US requirement that approx. 10 % of the produced vehicle will have "0-emission vehicles" or electrics from the year 2003 onwards.

Effects of Large-Radius Convex Rearview Mirrors on Driver Perception

Michael J. Flannagan, Michael Sivak, and Eric C. Traube
University of Michigan Transportation Research Institute

Copyright 1997 Society of Automotive Engineers, Inc.

Abstract

The U.S. currently requires that rearview mirrors installed as original equipment in the center and driver-side positions be flat. There has recently been interest in using nonplanar mirrors in those positions, including possibly mirrors with large radii (over 2 m). This has provided additional motivation to understand the effects of mirror curvature on drivers' perceptions of distance and speed. This paper addresses this issue by (1) reviewing the concepts from perceptual theory that are most relevant to predicting and understanding how drivers judge distance in nonplanar rearview mirrors, and (2) reviewing the past empirical studies that have manipulated mirror curvature and measured some aspect of distance perception.

The effects of mirror curvature on cues for distance perception do not lead to simple predictions. The most obvious model is one based on visual angle, according to which convex mirrors should generally lead to overestimation of distances. But convex mirrors affect other perceptual cues (including vergence and accommodation) in ways that lead to predictions of underestimation.

Empirical investigations of the effects of mirror curvature have produced a strong consensus that convex mirrors cause overestimation of distance, but several factors can moderate or compensate for that effect. All quantitative studies of the effects of the radius of convex mirrors have demonstrated less overestimation of distance than predicted by the visual-angle model. Shorter-radius (more strongly curved) mirrors generally lead to greater overestimation of distance. Previous studies have examined the effects of mirror radius up to 2 m. There is strong evidence that 2-m mirrors still cause substantial overestimation, and little indication that reductions in overestimation have asymptoted at that radius.

New empirical efforts to study the effects of larger-radius mirrors, beyond 2 m, could both contribute to basic understanding of how mirror curvature affects distance perception, and provide practical information about the possible benefits of using large-radius rearview mirrors.

Introduction

A major issue in optimizing the safety of rearview mirrors is how to provide a field of view that is large enough to eliminate blind zones near a vehicle without distorting perceptual information about the speed and distance of rearward vehicles. Planar mirrors provide undistorted information about speed and distance, but relatively small fields of view. Convex mirrors can provide much larger fields of view, but they alter information about the size and distance of objects (Seeser, 1974). The most important effect is probably a reduction in image size that may lead to an increase in the perceived distances to objects. This has led to a concern that drivers who use convex mirrors may misjudge the locations of other vehicles. It is therefore difficult to provide rearview mirror fields of view that are acceptable both in terms of quantity and quality.

Certain aspheric mirror designs may offer a good solution to this dilemma. Aspheric mirrors, which typically combine an inboard section that is relatively gently curved with an outboard section that is progressively more strongly curved, provide a large field of view primarily because of the more strongly curved outboard section. The images of vehicles seen in the outboard section are strongly distorted. However, vehicles that appear in that part of the mirror will be close enough to the observer's vehicle that, it can be argued, the driver merely has to detect their presence to know that a maneuver such as a lane change is not safe. Quantitative judgments about their speed and distance are moot. Vehicles that are some distance behind the observer's vehicle will be imaged in the inboard, more gently curved section of the aspheric mirror, and their images will therefore be less distorted than they would be in a spherical convex mirror with an equal total field of view.

Aspheric mirrors have been used on the driver's side in Europe for a number of years (Pilhall, 1981). They meet European regulations as long as they incorporate a spherical convex section that by itself meets the regulatory requirements. The aspheric section is then considered an allowable, unregulated addition. A certain type of aspheric mirror would be permitted on the driver's side in the U.S. under a similar rationale. However, because U.S. Federal

Motor Vehicle Safety Standard (FMVSS) 111 specifies that the driver-side mirror must have "unit magnification," an aspheric mirror in the U.S. would have to combine an aspheric section with a flat section, rather than with a spherical convex section as in Europe. This constraint introduces a manufacturing difficulty (e.g., Erickson & Allen, 1989). It is difficult, using manufacturing processes that are conventional for automotive mirrors, to reliably produce a mirror that combines flat and aspheric sections.

Some manufacturers have suggested exploring whether it is possible to relax the constraint in FMVSS 111 for "unit magnification" on the driver's side, thus easing manufacturing problems, without introducing perceptually significant distortions of speed and distance information. This might be done by allowing spherical convex mirrors with very large radii to be considered effectively "unit magnification." However, such an approach would depend on clear evidence about the perceptual effects of large-radius convex mirrors. The unit-magnification constraint is based primarily on a concern for providing the driver with undistorted information about speed and distance. Planar mirrors (with effectively infinite radius of curvature) do provide such information, but it is unclear what range of radius of curvature might provide virtually the same information. The range of curvature currently permitted on the passenger side in the U.S. (35 to 65 inches [0.89 to 1.65 m]) is too low to include mirrors that might be considered to have virtually unit magnification. New studies of driver perception may be needed to establish how much larger the radius of curvature must be to allay concerns about distortions of speed and distance perception.

This paper reviews what is known about the effects of rearview mirror curvature on drivers' perceptions of distance. This is motivated both by the general importance of understanding those effects, and by the current specific interest in the effects of large-radius mirrors. We first review theoretical considerations, and then past empirical work on the issue.

Theoretical Considerations

The aspects of convex-mirror images that are most relevant to perception of distance are illustrated in Figure 1. In this example, a simple convex rearview mirror with a radius of 1.4 m is installed on the driver side of a right-hand-drive car. The distance from the driver's eyes (assumed here for simplicity to be at single location between what in reality would be two laterally displaced eye positions) to the mirror is 0.6 m. An object with a projected width of 0.5 m is present 50 m behind the mirror location. The driver sees a minified virtual image of the rearward object located 0.7 m behind the mirror. The minification factor is 0.014 and the virtual image therefore has a width of 7 mm.

These circumstances lead to conflicting perceptual distance cues. The distance cue that is probably most important in this situation is the visual angle (as viewed from the driver's eye position) of the virtual image seen in the mirror. If the rearview mirror were planar, that angle would be 0.57 degrees, but in the 1.4-m convex mirror the combination of changes in size and location of the virtual image produces a visual angle of 0.31 degrees. In order to form such an image, assuming that the object did not actually change size, the object would have to be 93.5 m from the driver's eyes. Assuming a simple model in which the driver's perception of distance is based entirely on visual angle (and accurate memory for the actual sizes of familiar objects, such as the widths of vehicles) the object should be perceived as being 93.5 m away.

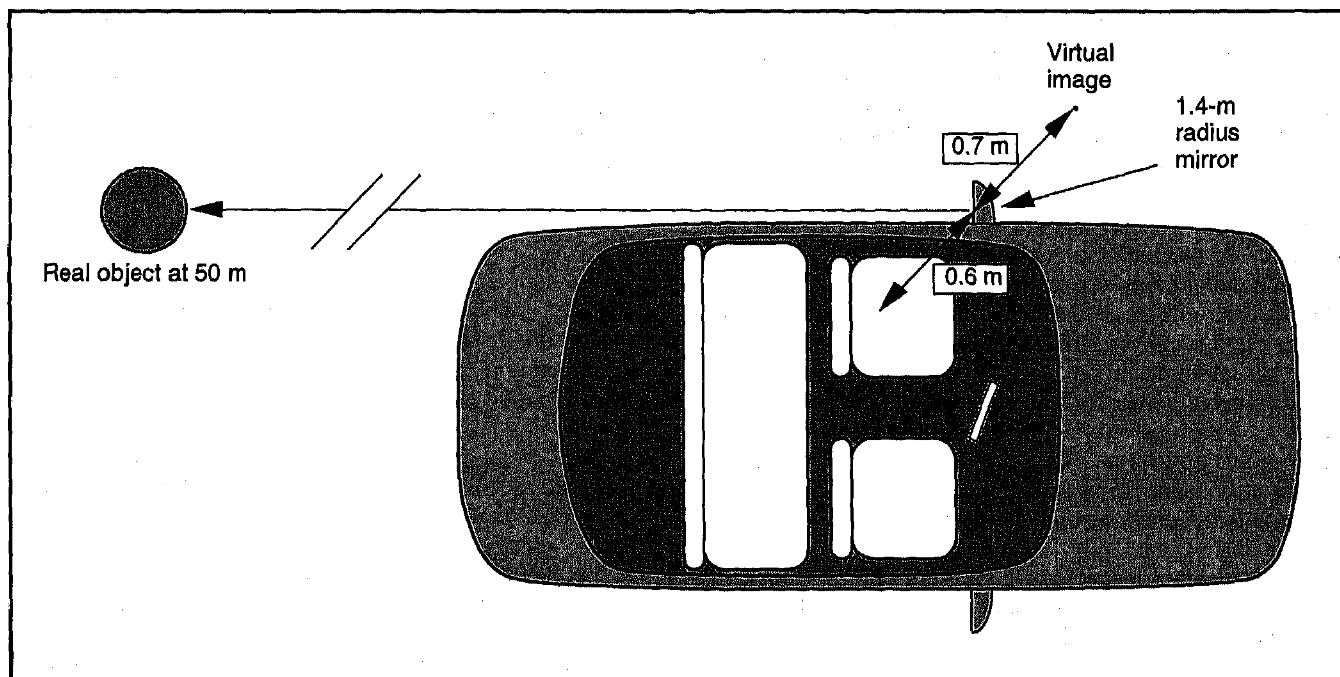

Figure 1. The locations and sizes of an object seen by means of a convex driver-side mirror, and of a virtual image of that object (approximately to scale except for the break indicated in the 50-m distance).

Figure 2 shows the predictions of such a model for a range of mirror radii (0.5 m to 10.0 m) and for three different eye-to-mirror distances (0.55, 0.65, and 0.75 m), for a single object-to-mirror distance (20 m). (Object-to-mirror distance affects predicted distance perception, but to a much smaller degree than the other two variables.) According to this model, even for a mirror with a 10-m radius of curvature the overestimation of distance would be nontrivial (overestimation by a factor of 1.13 for the 0.65-m eye-to-mirror distance).

The visual-angle model thus predicts that convex mirrors will lead to overestimation of distance, even at large radii. However, the distortion of certain other distance cues by the convex mirror might be expected to cause an underestimation of distance.

In the example in Figure 1, the virtual image is located 1.3 m from the driver's eyes. Because of this, in order to see the image as a single, fused image in proper focus the driver's eyes must actually be converged and accommodated at 1.3 m. In many situations, the binocular cues of vergence and binocular disparity, as well as accommodation, have powerful effects on distance perception. In this case, a simple model that predicts distance perception on the basis of either binocular cues or accommodation would predict that the object would be seen as extremely close (and implausibly small). Putting aside for a moment the common experience that objects seen in convex mirrors are indeed closer (at least to some extent) than they appear, it is worth considering how all of these cues might contribute to the driver's actual perception of distance. From a purely theoretical perspective, it is not clear how we should expect the conflicting cues to be resolved.

The actual distance and the two conflicting predictions for the perceived distance of the object are summarized in Table 1. There are at least two reasons that one might expect a rational observer to give greater weight to the visual-angle prediction. First, the prediction based on vergence or accommodation is implausibly short for objects that are normally seen in the driving environment. It is possible to imagine that, through either conscious or unconscious inference, a driver might simply reject the evidence provided by vergence and accommodation. Second, the distances about which it is most important to make judgments while driving are mostly too long (say 10 m or more) to be within the relatively short range in which vergence and accommodation are likely to be useful distance cues. It may be that drivers have learned to generally disregard those cues while driving.

On the other hand, it does not seem safe to assume that vergence and accommodation play no role in distance perception in this context. It may be that a driver's perception of distance in a convex mirror is determined by some combination of these cues. Empirical results, as reviewed in the following section, suggest that something like this may indeed be the case. Although convex mirrors do in fact make distances appear somewhat longer than they actually are, the predictions of the visual-angle model have been violated in every quantitative study of the effects of nonplanar mirrors, and always in the direction that the visual-angle model predicts greater overestimation of distance than actually seems to occur. Although the reasons for this are not fully clear, the possibility of a moderating influence of conflicting distance cues seems worth considering.

Table 1
Actual distance, and two predictions for perceived distance, from the driver's eyes to the rearward object in Figure 1.

	Distance (m)
Actual distance	50.6
Predicted (visual angle)	93.5
Predicted (vergence or accommodation)	1.3

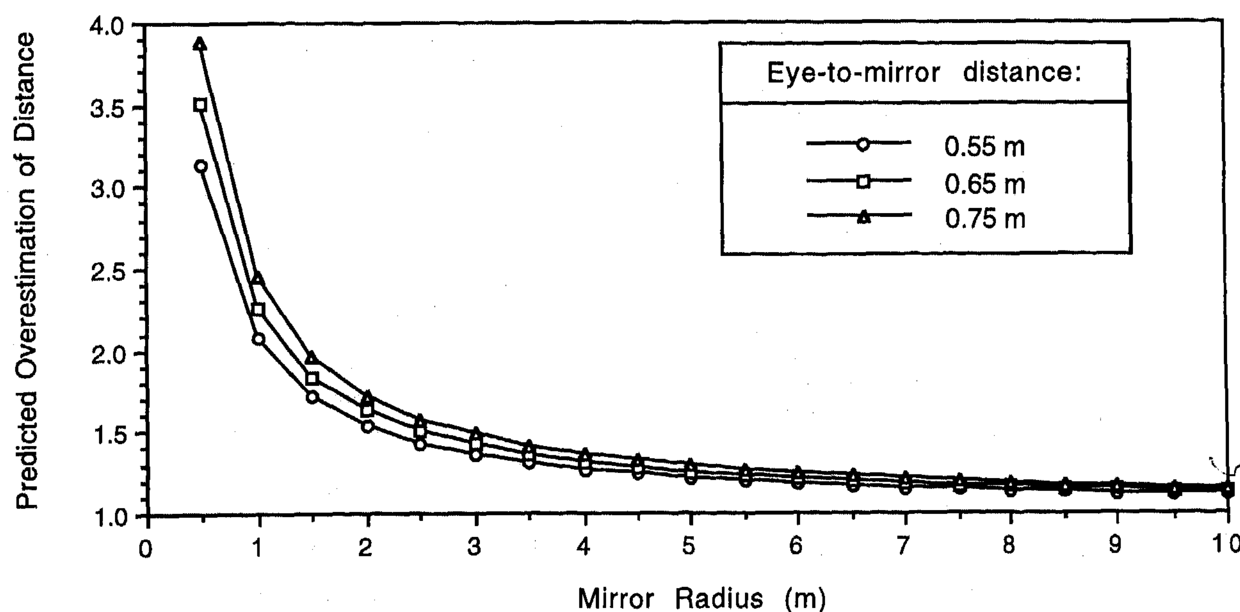

Figure 2. Predicted overestimation of distance (perceived distance divided by actual distance) based on visual angle, as a function of convex mirror radius, for three eye-to-mirror distances. In all cases, the distance from the mirror to the object is 20 m.

Summary of Empirical Work

Table 2 lists 10 studies in which the radii of convex mirrors have been varied, and the effects of that manipulation on distance perception (and sometimes on other aspects of driver performance) have been observed. Following an earlier review by Flannagan (1988), the studies have been divided into two sets on the basis of what is probably the most important distinction among the tasks that they required subjects to perform. One set of studies (labeled "distance-perception" studies in Table 2) involved relatively direct measures of subjects' perceptions of distance. These studies required subjects to make judgments about the distances of vehicles seen in mirrors of various radii, but with no connection to a specific driving task. The second set (labeled "lane-change" studies) required subjects to make judgments about how they would perform a specific maneuver that depends on perception of distance and speed: changing lanes at the last possible safe moment into the path of an overtaking vehicle seen in a rearview mirror. The implementation of the lane-change task varied from laboratory studies using stimuli presented on film, where no actual maneuver was possible (Fisher & Galer, 1984), to field studies in controlled traffic in which subjects actually performed the lane-change maneuver (Mortimer, 1971).

Our purpose here was to extract from as many of these studies as possible a quantitative estimate of the effect of mirror radius on distance perception. The variety of experimental methods, and of data-analysis and reporting styles, that were used in these studies makes it a nontrivial task to assemble results in a unified format. However, the task was made tractable because our goals were somewhat limited. In each case, we tried to select data that would reflect the effect of mirror radius on distance perception in its simplest form, without possible influences from mechanisms such as learning a new calibration between distance and the stimuli seen in the convex mirror, or adopting strategies that reduced reliance on the convex mirror. So, for example, from the study by Flannagan et al. (1996) we selected data that were collected prior to a set of training trials, in which subjects had an opportunity to recalibrate their judgments by comparing views through a convex mirror with direct views to the rear of their vehicle. Similarly, in the study by Mortimer (1971) we selected data from a condition in which subjects had to make judgments using only a convex exterior mirror, rather than another condition in that same study that allowed them to use both a convex exterior mirror and a planar interior mirror.

For each study, we quantified the effect of mirror radius in terms of an index that compared perceived distance while using one or more nonplanar mirrors to perceived distance while using a planar mirror. This index is therefore not strictly a measure of how subjects' performance with nonplanar mirrors compared to a standard of objective correctness, but rather how it compared to their performance of the same task while using a planar mirror. For data from the lane-change studies, we calculated effects on perceived distance by assuming that subjects perceived criterion distances in nonplanar mirrors to be equal to the criterion distances that they selected in planar mirrors.

Fisher & Galer (1984)
Mortimer (1971)
Mortimer & Jorgeson (1974)
Walraven & Michon (1969)

[1] This study involved both types of task.

The following notes discuss each of the studies listed in Table 2, indicating whether parametric data on the effect of mirror radius on distance perception could be extracted, and identifying the specific sources of the data that we did select.

Burger, Mulholland, Smith, & Sharkey (1980) This was a major study that involved several parts, including variations of mirror radius in both a direct assessment of distance perception and in a lane-change task. However, a small number of subjects were given extensive training with a large variety of mirrors, and the data are not reported in a way that would allow separating performance early in training from performance later in training. We have therefore not used data from this study (or from subsequent experiments performed by the same researchers on substantially the same group of subjects when the subjects were even more experienced: Burger, Mulholland, Smith, Sharkey, & Bardales, 1980).

Flannagan, Sivak, & Traube (1996) The task was magnitude estimation of the distance to a vehicle seen in an exterior rearview mirror. Subjects were given moderate amounts of experience with nonplanar mirrors. The data selected here are from prior to the learning phase of the experiment. The data are from their Figure 3, page 9, averaged over five actual distances.

Rowland, Silver, Volinsky, Behrman, Nichols, & Clisham (1970) This report covers a set of 15 experiments on planar and convex mirrors, but the treatment of data is almost entirely in terms of average absolute error. The report therefore cannot be used to estimate whether changes in mirror radius cause perception of distance to be generally longer or shorter.

Smith, Bardales, & Burger (1978) Subjects estimated the distance of a vehicle that was seen approaching from the rear (in a laboratory setting, using filmed stimuli). The presentation of data is primarily in terms of average absolute error, which does not allow for an estimate of a possible general increase or decrease in perceived distance as a function of mirror radius. A limited summary of average signed error is presented in their Figure 20, page 54. The data appear to be noisy, but no inferential statistics are reported. We used data from that figure for session 4 (when variable error was lowest) to estimate an effect on distance perception, assuming that their Figure 20 presents data collapsed over all the actual distances that were involved in the study.

Sugiura & Kimura (1978) Subjects indicated when a vehicle, seen in a planar mirror or one of several nonplanar mirrors, reached a criterion distance that had been shown to them in a planar mirror. The data used here are from the "Day" condition in their Figure 2, page 3.

Bowles (1969) Subjects performed a version of the lane-change task. We used data from the right panel of the report's Figure 1 (no page number). These data are averaged over three closing velocities, for a condition in which the mirrors were mounted on the door. (There were also data from a fender-mount condition, which we have not used because the eye-to-mirror distance involved is not typical of more recent practice.)

Fisher & Galer (1984) Subjects performed the lane-change task. The data used here are from their Experiment 1, the "true minimum safety margin" from their Table 1, page 1217, averaged over three closing speeds.

Mortimer (1971) Subjects actually performed the lane-change task in traffic. The data we used are from his Table 1, page 4, for the "exterior mirror only" condition. His experiment also included a condition in which exterior mirrors (of varying radius) were provided along with an interior mirror that was always planar.

Mortimer & Jorgeson (1974) This was similar to the earlier study by Mortimer (1971). A major difference for our present purposes is that it did not include a condition without a planar mirror. We have therefore not used data from this study.

Walraven & Michon (1969) Subjects performed the lane-change task. The data we have used are from their Figure 8. They are combined over two different groups of subjects and three closing speeds.

Summary across studies

Figure 3 shows a summary of results from the seven studies from which we extracted parametric estimates of the effect of mirror radius on distance perception. In all cases, the overestimation index has been calculated relative to performance with a planar mirror in the same study and in the same circumstances.

There is a strong consensus among these studies that convex mirrors result in overestimation of distance, and that the degree of overestimation increases with decreasing radius of curvature. However, there is a wide range in degree of overestimation across the studies. This is particularly interesting given that the data shown here are in many cases subsets of the data from their respective studies, selected so that the conditions represented are relatively homogeneous across studies.

The distinction that we made earlier between distance-perception and lane-change studies is reflected in Figure 3 by the use of solid lines and symbols (for lane-change studies) and dashed lines and open symbols (for distance-perception studies). There is no obvious difference between these two types of studies in the extent of overestimation that they demonstrate.

These studies provide evidence about the effects of mirror radius up to 2.0 m. Although there is strong evidence for a decrease in overestimation with increasing radius, this change does not seem to be asymptoting within the range covered.

Comparisons of the effects of mirror radius shown in Figure 3 to predictions based on visual angle are shown in Figure 4. The predictions were derived as in our earlier treatment of the situation represented in Figure 1, and as discussed in more detail by Platzer (1995). Although mirror radii were always well specified in the reports summarized here, in many cases the published descriptions of method did not indicate exact values of the other two parameters that are needed to calculate predictions from the visual-angle model: eye-to-mirror distance and object-to-mirror distance. In such cases we used 0.75 m and 20 m as default values for those two parameters, respectively.

In every case, the predictions of the visual-angle model are violated, always in the direction that there is less overestimation than predicted. In most cases the discrepancy is large. As discussed earlier, the visual-angle model does not reflect all the theoretically plausible effects of convex mirrors on distance perception. Accommodation and vergence cues suggest that convex mirrors should cause strong underestimation of distance, and a moderating effect of these cues might be at least a partial explanation for the failure of the visual-angle model.

Summary and Conclusions

Previous data offer empirical evidence about the effects of mirror radius up to 2.0 m. The evidence indicates that distances are overestimated, and that overestimation is still substantial at a radius of 2.0 m.

The simplest, and perhaps to many people the most compelling, model of the effects of mirror radius—the visual-angle model—predicts that convex mirrors will cause overestimation of distance, and that the overestimation will be nontrivial even when the radius is as large as 10 m (for which the overestimation factor is predicted to be about 1.13). However, the visual-angle model is strongly violated in all existing results.

Given the current practical interest in mirrors with radii above 2.0 m, the lack of empirical evidence above 2.0 m, and the theoretical uncertainty caused by the substantial violations of the visual-angle model, it seems worthwhile to conduct further empirical work using mirrors with radii over 2.0 m. At a more theoretical level, the lack of a satisfying account of the effects of mirror radius suggests that more work should be done to evaluate the predictions of the visual-angle model, for example with respect to the relative importance of eye-to-mirror and object-to-mirror distances.

Acknowledgments

We wish to thank Ichikoh Industries, Ltd. for their generous support of this research.

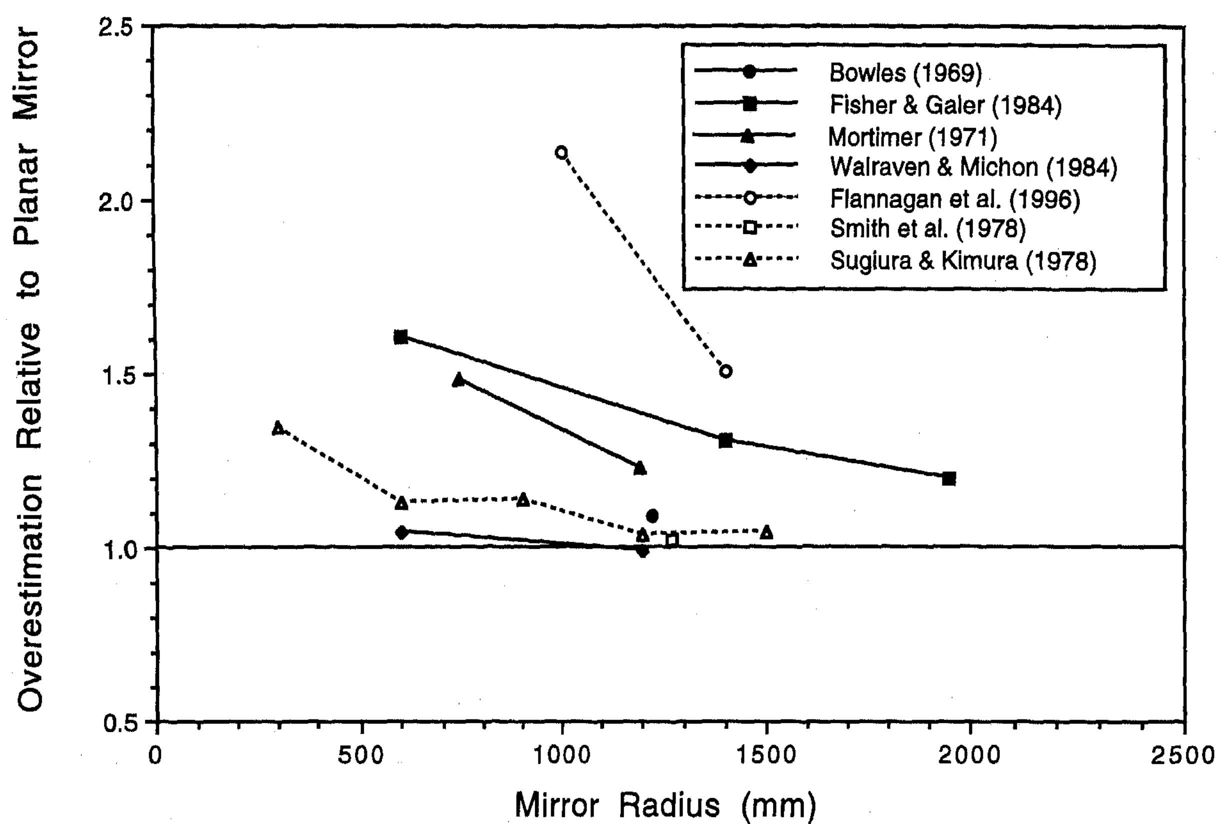

Figure 3. Effect of mirror radius on estimation of distance. Distance estimates in each study are shown relative to performance with a planar mirror in the same study. The horizontal line at 1.0 represents performance that would be the same as with a planar mirror. Data from lane-change studies are shown with solid lines and symbols, and data from distance-perception studies are shown with dashed lines and open symbols.

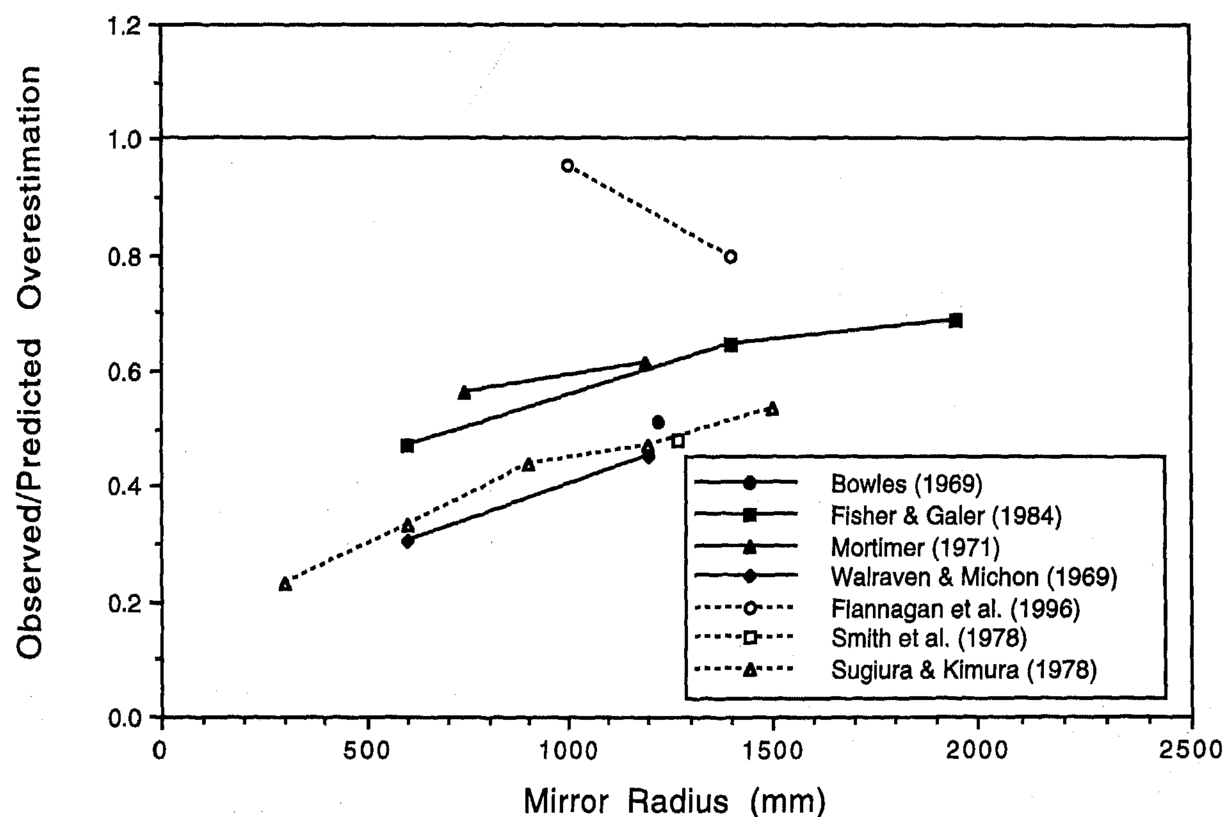

Figure 4. The data from Figure 3 plotted as ratios of observed distance overestimation relative to predicted overestimation based on the visual-angle model. In every study, observed levels of overestimation were lower than predicted, usually by a large margin.

Comparison of Models for Detection of Highway Obstacles with Headlamps

Walter J. Kosmatka
GE Lighting

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Models using contrast as the measure of discernibility or detection of roadway obstacle on non-lighted roadways have not recognized the lighting effects caused by the lateral spacing of headlamps on the vehicle. When the only significant sources of roadway light are a vehicle's headlamps, shadows on the roadway behind and to the left and right of the obstacle are viewed simultaneously with the obstacle itself. It can be shown that in certain obstacle-sighting situations, where there is little or no significant background light from sources other than the headlamps themselves, sufficient contrast is provided by the shadow outlines. Shadows created by the lateral spacing of the headlamp light sources and the driver's eyepoint, framing one or both sides of the obstacle, serve to outline the illuminated obstacle on the roadway in front of a vehicle. In the context of detecting a roadway obstacle, the contrast requirements are satisfied (or obviated) and threshold luminance becomes a relevant measure of obstacle discernibility. Comparison of the results of field experiments with the predictions of both *contrast predictive* and *luminance predictive* models shows that, within the limits of the situations tested, the luminance model gives a better measure of detection distance and obstacle luminance at detection.

INTRODUCTION

This paper is composed of two parts. The first part discusses the implications of an obstacle-detection model relying on threshold luminance compared with a model using contrast as the predictor of obstacle detection. The second part compares the results of a contrast-predictive model and a luminance-predictive model with the results of dynamic field test of young and old subjects and varying levels of obstacle reflectance.

PART I - HISTORICAL BACKGROUND

Contrast models are used for a variety of visibility and legibility assessments. The sighted "object" is two-dimensional and is on the surface of a two-dimensional background. Using Blackwell's [1] visual performance curves and given knowledge of the back-ground luminance, the threshold contrast requirement is defined. Comparison of this threshold contrast with the known contrast gives an indication of the likelihood of detection or legibility.

Contrast models employing these visual performance curves for obstacle detection on unlighted roadways commingle the effect of the observer's (driver's) adaptation level with the background luminance that produced the contrast in the basic lab experiments upon which these contrast models are based.

There are situations where the Blackwell data could be applied where there is no fundamental difference between the empirical experiment and the predictive application. If the data is used to predict detection or legibility in a format similar to the experiment, the immediate surround-background of the test object is continuous and extends up to the periphery of the object. This situation exists in many street lighting situations. For instance Janoff [2] uses the performance curves to analyze detection criteria for lighted roadways. In this case, the use of these curves is appropriate because the application is consistent with the experiment itself.

HEADLIGHTING ROAD SCENE FACTORS

In many nighttime automotive driving situations headlights are the only (significant) source of illumination, When a model using contrast as the predictor of detection of a roadway obstacle is applied, subtle differences in the way the scene is illuminated by the headlamps and viewed by the driver, tend to limit the

predictive utility of threshold-contrast models. There are two arguments favoring threshold-luminance-predictive models.

Contrast-Adaptation Dependencies Given the manner in which Blackwell's experiment was performed, it is likely that the contrast-background dependency is partially the result of eye adaptation to the non-zero background luminance. This was probably appropriate for the purposes of the experiment and is valid for some specific situations to which it is applied.

In roadway situations, where the only sources of light are the vehicle headlamps, the illuminated roadway section now represents a relatively small, nonuniform portion of the visual field. It extends visually from approximately 200 feet away (about a degree below the driver's horizon) to about 30 feet away (about 7 degrees below the driver's horizon). On the left, the lighted roadway extends beyond the center of the left headlamp and on the right, to the edge of the roadway or berm. Within this lighted scene, the road luminance is mostly a function of the beam pattern distribution and the distance from the source to the pavement. The pavement luminance, which often is the background for an obstacle, varies over a wide range. It is not uncommon to find 10 or even 20-to-1 ranges in pavement luminance. So it is reasonable to believe that an obstacle on the roadway, which can be located anywhere in this roadway scene, will find itself surrounded by backgrounds varying by 10 or 20-to-1.

However, the driver's adaptation level probably does not respond to such localized variations. Adaptation does not vary instantaneously over a range of 10 or 20-to-1. Normal visual tracking movements will expose the driver's eye, over a short interval of time, to most if not all of the illuminated road scene. Adaptation level will not so much depend on where in the scene an obstacle is located but more on the gross characteristics of the luminant road scene. i.e. the roadway luminance affecting the driver's adaptation level is relatively constant for a specific headlamp system beam pattern and adaptation is not a function of a localized obstacle-background contrast relationship.

This is not consistent with use of Blackwell's curves to define the threshold contrast because, as noted above, the hypothetical driver's adaptation luminance is identical with background luminance. The conventional application of the Blackwell visual performance curves results in commingling the adaptation-induced brightness threshold with the inferred contrast threshold in such a way that their independent effects cannot be separated.

Shadows and Background Discontinuities In roadway situations, the viewed object is not generally two-dimensional, nor does it lie on the background. In fact, the object and background are not coplanar nor even parallel; they intersect in almost all cases. Even more important, the object sits on the plane of the roadway and, as a result, can cast shadows on the illuminated background. As the driver observes it, the surrounding roadway background, illuminated by both headlamps, is not contiguous with the periphery of the obstacle. For this to be the case, the background would have to be either 1) back-lighted by roadway luminaires for instance or 2) illuminated with the source very near the observer's eye location. In reality, the light sources (the headlamps) are laterally spaced away from the observer. And, located where they are, they cast shadows from the perspective of the driver.

The presence and significance of shadows in detecting roadway obstacles is noted by Huculak. [3] He states that the visibility of an object "can be governed" by the luminance difference of the object's shadows. I will attempt to quantify the significance of the contrast and obstacle-framing effect of these roadway obstacle shadows. It can be shown (at least by calculation) that the shadows that serve to outline a roadway obstacle are of sufficient width and provide sufficient contrast by Blackwell's contrast definition, for detection of an obstacle over a fairly wide range of distance. Moreover, we can also show that the gradients in a headlamp beam pattern combined with the geometry of the observer-object-light source, result in a relatively constant contrast level. This makes discrimination of differences in detection distance using contrast thresholds prey to the subtle, almost undetectable changes within the light distribution in the headlamp beam pattern.

OBSTACLE-BACKGROUND CONTRAST REQUIRED

Driver's Eye Location Measurements were made of both the headlamp location on a sample of both small and large passenger vehicles. A second set of measurements was made of the location of the steering column. Given that the steering column is a practical measure of the driver's lateral head location, the difference in centers should be a good indicator of the driver's lateral position with respect to the headlamp and the sighted obstacle.

This informal sampling of vehicles shows that the steering wheel (and the driver-observer) would be located from 9 inches to 15 inches to the right of the left headlamp. In all cases, the steering column was right of the left headlamp. The headlamps were generally spaced from 3 to 5 feet apart. Given this information as a basis, the following analyses were based on lateral headlamp separation distance of 4 feet, with the driver centered 1 foot right of the left headlamp.

Eye height for passenger vehicle drivers is in the range of 40 to 44 inches. A height of 42 inches (3.5 feet) was used for the sake of simplicity and the purposes of the following calculations.

Location of Roadway Obstacle Background Using the locations noted above, and an isocandela plot of a headlamp beam pattern (and making some other general assumptions), it is possible to calculate the luminance in the general location of the shadows from each of the two headlamps as they would be seen by the driver. Assume for the sake of simplicity the following:

- Driver's eye height at 3.5 feet above ground plane
- 2-foot high obstacle centered at a height of one foot
- Headlamp mounted at a height of 2 feet

Then an angle, A to the center of an obstacle 250 feet away with respect to the driver eyepoint is,

A = atan [(3.5-1) / 250] = atan (.01) = .57o (down)

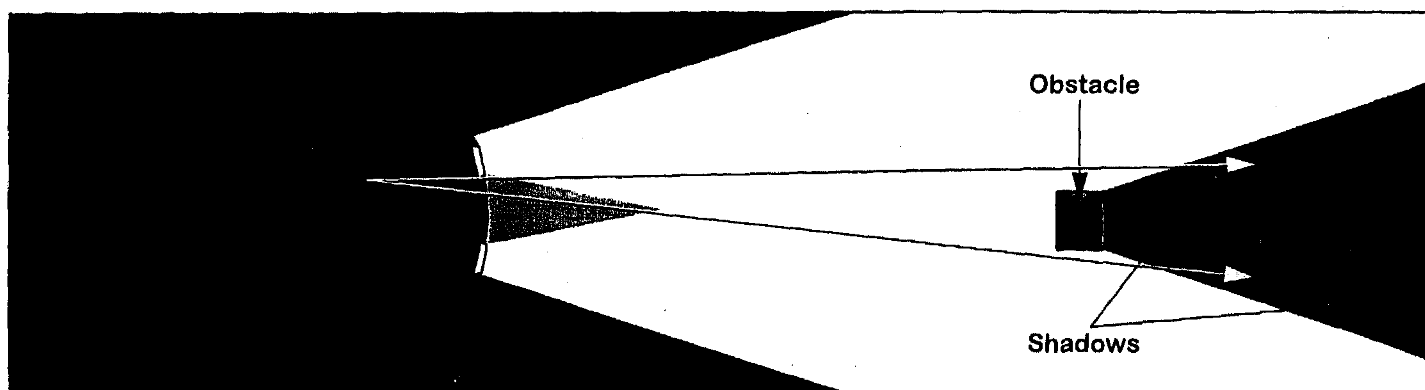

figure 1 - Plan View of Roadway

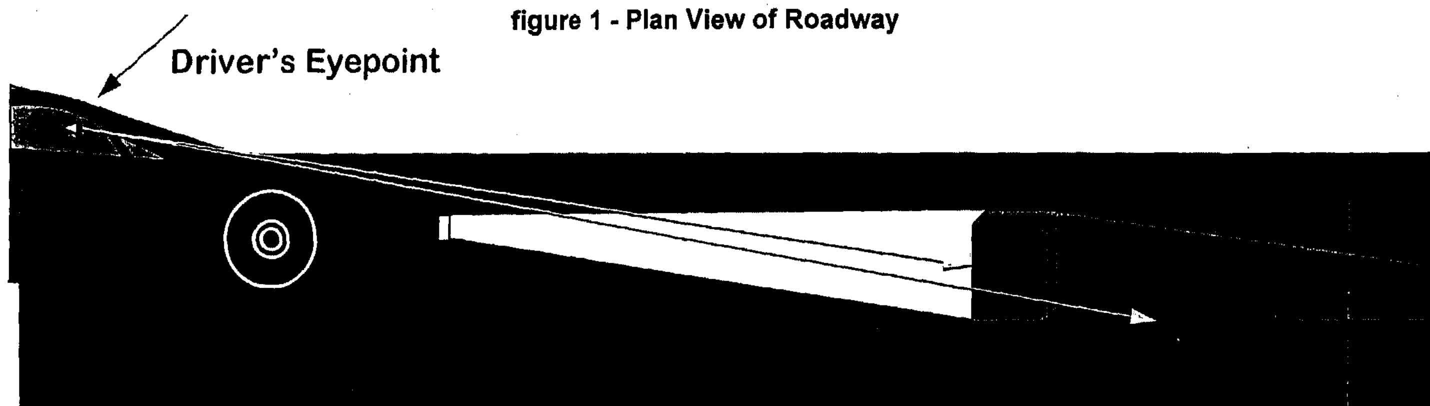

figure 2 - Side View of Roadway Scene

The location (shown schematically in **figure 1**), at distance, S, on the roadway surface which would serve as a background to the obstacle center located one foot up, 250 feet away, is defined by angle, A and the distance to the obstacle.

S = 3.5/tan .57 = 3.5/0.01 = 350 feet (from the driver's eyepoint)

A driver viewing the center of a 2 foot high object from 3.5 feet above the roadway would see, as a background, the roadway surface 350 feet away. This point would be approximately .33 degrees (atan 2/350) below the horizontal plane of a headlamp mounted at a 24 inch height.

Roadway Illumination If the lateral location of the headlamps with respect to the obstacle is given, the illumination of the background which surrounds (and contrasts with) the obstacle can be calculated.

For obstacles located almost anywhere in the lane of travel of a vehicle, the light distribution of low-beam headlamps will cause stronger contrast (lower background luminance) on the right side of the obstacle. As **figure 2** demonstrates, an obstacle located approximately between the headlamps will be to the right of the left headlamp (and to the left of the right headlamp). At this location the light directed on the roadway, past the right edge of the obstacle will be coming from the right headlamp, while the more intense light from the left headlamp is shadowed in that location by the obstacle itself. Because of the beam distribution found in all

headlamps, the left headlamp normally illuminates the roadway (obstacles) more strongly than the right lamp. On the right side of the obstacle, this illumination from the left headlamp beam is shadowed.

[Note that for objects located to the left of the vehicle the driver will see no right-side shadow. But the left-side shadow will be all the more contrasting because now the beams of both headlamps cast shadows to the left of the obstacle.]

The roadway illumination from a representative SAE low beam (shown in isocandela form in **figure 3**) was approximated to be 3000cd on the left side of the beam at .32 degrees down from the lamp's horizontal axis. The background illuminance:

$$I_{background},\ I_b = I_{hdlp}/d^2 = 3000 \times 10.76/350^2 = 0.26 \text{ Lux}$$

Shadow-Outline Contrast for Distant Obstacles At the same time the centerpoint of the obstacle (250 feet away, located 1 foot above the roadway, *i.e.* .23° below the headlamp's horizontal centerline) is receiving illumination from both headlamps. Moreover, the illumination from the left headlamp is much greater owing to the obstacle's location farther right in the headlamp's High-Intensity-Zone (HIZ).

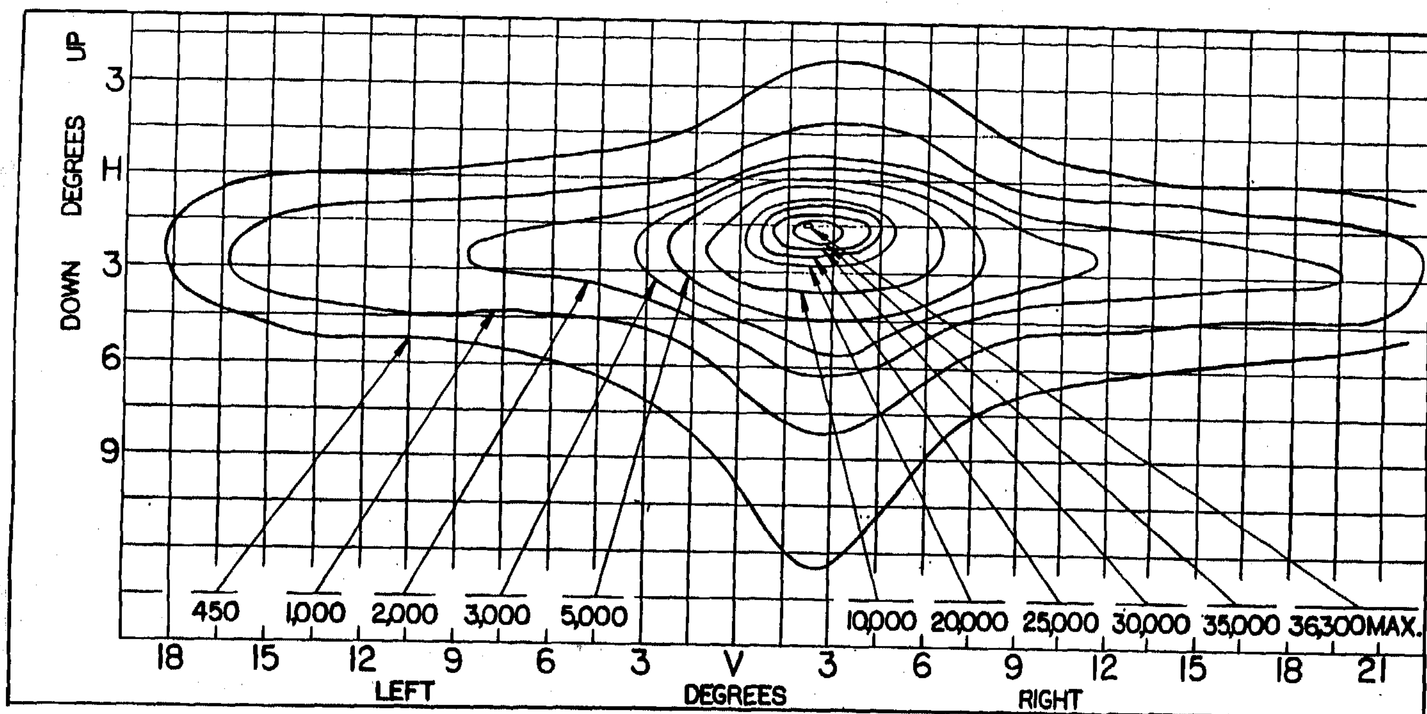

Figure 3 - Isocandela Curve for GE H6054 Headlamp

For this case, the obstacle illumination was interpolated from **figure 3** to be

$$I_{obstacle},\ I_o = (I_{rt} + I_{lt})/d^2 = (2800 + 9000) \times 10.76 /250^2$$

$$I_o = 2.03 \text{ Lux}$$

The contrast for the right edge of the obstacle and the background shadow will be

$$C_{(d=250)} = (I_o - I_b)/I_b = (2.03 \times r_o - 0.26 \times r_b)/(0.26 \times r_b)$$

If a simplifying assumption is made for the purposes of illustration, that the reflectance of the obstacle, r_o, is very close to that of the back-reflectance of the road surface, r_b (.1 for instance), the equation simplifies to

$$C_{(d=250)} = (0.203 - 0.026) / 0.026 = 6.8$$

Interpolation of Blackwell's graphical data (**figure 4**), for t = 1/3 second[a] , a 16-minute target, a 90% performance level, and B (calculated in the graph's foot-lambert units[b]) can be done for:

B = .026 x Pi/10.76 = .0076 f-l; Log B = -2.12.

[a] The target acquisition duration of 1/3 second was chosen based on the authors opinion. Huclack [3] measures rates of 3 to 5 times per second.
[b] The abcissa units on the Blackwell curves are expressed in "foot-lamberts".

We find from the **figure 4** graph, log C = approximately 0, and threshold contrast, C = 1.0.

The obstacle-shadow contrast is well above the threshold (6.8 > 1.0) at 250 feet.

Shadow Outline Size The width of the shadow around the obstacle is a function of both the lateral separation between the observer eye-point and the headlamp position. For the case above, the width is about 4 inches for the right side shadow and about 12 inches for the left side shadow. For a distance of 250 feet to the obstacle, with the shadow reference location at 350 feet, the shadow will subtend 4 to 16 arc-minutes. For shorter obstacle locations, the shadow will subtend a larger arc in the visual field. This width of shadow outline is probably sufficient for visual discrimination. Versace [4] indicates that normal visual acuity is one minute of arc except for very low luminance (.34 cd/m^2, .099f-l) and very low contrast (<.25).

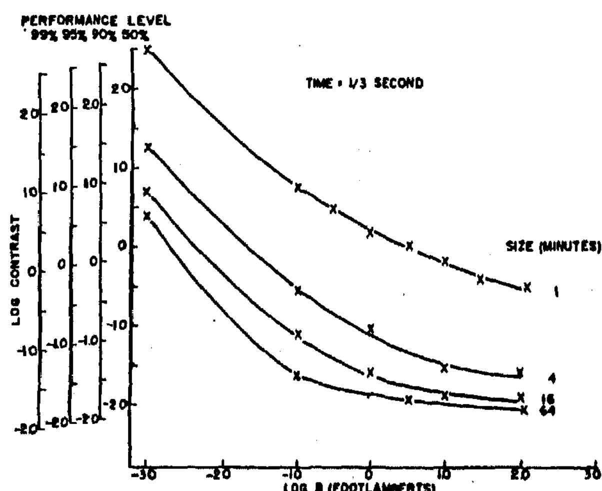

Figure Data obtained with a time of exposure of 1/3 second. Each point represents at least 500 responses by two subjects.

Figure 4 - Blackwell Visual Performance Curves

Shadow-Outline Contrast for Close Obstacles A similar analysis was done for the situation where the object is at a distance of 100 feet. The obstacle that is centered on the vehicle centerline falls approximately .57 degrees (atan 1/100) below the headlamp system's horizontal plane. The headlamps' illumination at that point can be interpolated from **figure 3**,

$$I_o = (3000 + 15000) \text{ cd} \times 10.76/100^2 = 19.4 \text{ lux}$$

The background roadway is located at about 140 feet from the headlamps (.81 deg. below the headlamp horizontal). It is illuminated by approximately 4500cd from the right headlamp,

$$I_b = 4500 \text{ cd} \times 10.76/140^2 = 2.5 \text{ lux, and}$$

$$C_{(d=100)} = (19.4 \times r_o - 2.5 \times r_b)/(2.5 \times r_b)$$

Making again an assumption of equality of the background and obstacle reflectance ($r_b = r_o = .1$), the contrast,

$$C_{(d=100)} = (1.94 - .25)/.25 = 6.8$$

Using Blackwell's curves (**figure 4**) for the now, visually larger target, (for t = 1/3 second; a 64 minute target; 90% performance level), we interpolate for log C at

$$B = .25 \times Pi/10.76 = .073 \text{ f-l} \quad (\log B = -1.14)$$

We find log C equals approximately -1.3 and thus $C_{Threshold} = 0.05$.

The contrast of the obstacle with its shadow is far above the indicated threshold (6.8 >> 0.05).

CONTRAST MODEL ASSUMPTIONS

Contrast-based models typically do not address the shadow-frame in defining the background luminance. The illumination in the immediate area of the obstacle is based on an assumption that the background is illuminated by the light from both headlamps.

Considering the *250 foot case* above, at approximately .32 degrees down from horizontal in the area of the hypothetical obstacle, the light was estimated from the isocandela plot (**figure 3**) to be about 3000cd from the right headlamp and about 7000cd from the left headlamp. Then the background illumination:

$$I_b = (3000 + 7000) \times 10.76/350^2 = 0.88 \text{ lux; and contrast}$$

$$C = (2.03 \times r_o - 0.88 \times r_b)/(0.88 \times r_b) = 1.31$$

(Assuming again, for the sake of simplicity, that the relative reflectance of the background and obstacle are coincidentally equal at 0.1.) In this case the background luminance,

$$B = .1 \times 0.88 \times 0.292 = 0.026 \text{ f-l}, \ \log B = -1.59.$$

Interpolation from the curve for t = 1/3 sec.; a target size of 16-minutes; 90% performance level, log C = -0.5, and the threshold contrast C = 0.31.

The contrast model predicts detection (*i.e.,* 1.31 > 0.31) at 250 feet but with less of a margin than the contrast of the obstacle and the shadow-frame (6.8 > 1.0) would indicate.

For the *100-foot* example used above, the illumination in the region of the obstacle from two headlamps was interpolated from the isocandela curves in **figure 3** to be 20,000 cd for the left headlamp and 4500 cd for the right headlamp. The background illuminance used for contrast-defined detection is then:

$I_b = (4500 + 20000)\text{cd} \times 10.76/140^2 = 13.5\text{lux}$

Contrast, $C = (19.4 \times r_o - 13.5 \times r_b)/(13.5 \times r_b) = .43$

(assuming again that $r_o = r_b$)

then B = .l x 13.5 x .292 = .39 f-l; and Log B = -.4

The value of Log of C, extrapolated from the curve is -1.6. Threshold contrast is 0.025.

The contrast model correctly predicts detection for the contrast threshold (0.43 > 0.025) in the *100-foot* case, but this time with a more significant margin than it predicted in the *250-foot* case.

DISCUSSION

The shadow-contrast calculations show that over the distances considered (and most likely beyond), the contrast between a road obstacle and its shadow is sufficient by Blackwell's measure for detection-discernibility.

A corollary statement could be that the contrasting shadow of an obstacle is present in almost all (or at least many) roadway situations in which the obstacle is illuminated primarily by the headlamps and that the resulting contrast is sufficient over a relatively wide range. If this hypothesis is acceptable, then it might follow that an appropriate determinant for obstacle detection using automobile headlamps is threshold luminance.

One could argue that since threshold luminance is implicit in visual performance curves, it is implicit in the contrast models using these curves. This is true, of course. However, the visual performance curves do not use threshold luminance as the independent variable but commingle threshold-luminance with adaptation level. In contrast-based models, contrast is actually a function of varying background luminance, not varying obstacle luminance. And it is the luminance of the background which induced adaptation level changes in the experiment's subjects at the same time they responded to the varying contrast. However, in actual dark roadway driving situations, adaptation is mostly a function of the interaction of the projected light pattern and roadway reflectance. It is therefore relatively constant.

If one accepts the these arguments, it would follow that the models which use the threshold contrast curves to determine thresholds, infer that observer-driver adaptation levels are essentially defined by obstacle-background contrast, when in reality they are not. Contrast deterministic model(s) used for vehicle headlighting evaluations tend to overstate the luminance of the background (the shadow) which is actually surrounding the obstacle. At the same time they use the background luminance implied by the ratio-difference contrast as a *de facto*, constantly varying, determinant of driver-observer adaptation level.

In the hypothetical examples given, the contrast model demands over 12 times (0.31/0.025) more contrast for the more distant obstacle located at 250 feet than for the same one located at 100 feet. The subtended visual angle alone does not account for the difference. The main reason for the excessive ratio is the high contrast implied for the distant obstacle owing to the lower background (lower observer adaptation) luminance.

This argument having been made, it is true that the contrast-based model would predict detection-disernibility for a 2-foot by 2-foot, 10% reflectance obstacle at 250 feet, as would a luminance-based model. As we shall see however, when it is necessary to predict the point at which a driver test subject is able to first discern an obstacle, or to predict what level of illumination is necessary for detection, some inconsistencies of contrast-based models become evident.

PART II - COMPARISON OF FIELD TEST RESULTS

CONTRAST MODEL PREDICTIONS

While attempting to test the validity of an existing contrast detection model under study by the National Highway Traffic Safety Administration, the University of Michigan Transportation Research Institute (Olson, Aoki, Battle and Flannagan) [5] performed actual dynamic field experiments. The model that UMTRI used relied on calculated contrast between the obstacle and the nearby roadway area. It predicted obstacle luminance levels 16 to 24 times that which Olson's report shows in table 7 for the younger driver test subjects.

For instance, with a small, .06 reflectance (.06 fl/fc[c]) target, a driver traveling at 25mph using low beam headlamps, detected the target with an average luminance of 0.078 cd/m^2 (.023 f-l) at 207 feet. At 207 feet, the contrast model required a contrast of .76 and target luminance of 1.9 cd/m^2 (.556f-l). The luminance required to satisfy the contrast model was about 24 times that found in the dynamic experiment.

---

[c] Reflectance factor units of f-l/fc require a conversion factor of 3.42 to convert to cd/m^2-lux

For a small, 0.12 reflectance-factor target, actual detection occurred at 269 feet on low beams, with a target luminance of .085 cd/m^2 (.025f-l) and contrast ranged from 1.1 to 2.1. However, at 269 feet the model required 1.61 cd/m^2 (.471 f-l of luminance and 2.2 contrast). The ratio of target luminance in the contrast model versus experimental target luminance is 18.8 times.

For a small 0.25 reflectance factor target, actual detection occurred at 387 feet on low beams, with a target luminance of .078 cd/m^2 (.023f-l) and contrast of 1.9. However, the contrast model at 387 feet, required 1.28 cd/m^2 (.376 f-l) of luminance and 4.7 contrast. The ratio of the target luminance in the contrast model versus the experimental target luminance is 16 times.

The conclusion that one might infer from these results and the data in the report is that this contrast model, at the very least, was not a predictor of obstacle detection in the dynamic highway situation where there is no significant overhead illumination.

Other research generally supports the detection distances found by Olson. Meese and Westlake [6] report detection distances of 244 feet to 266 feet for SAE lower-beam headlamps. Mortimer and Olson [7] report detection distances of 130 feet to 170 feet for 6% reflectance objects. They report 180 feet to 230 feet for detection of 12% reflectance obstacles and 240 to 300 feet for detection of 24% reflectance obstacles.

LUMINANCE MODEL PREDICTIONS

A proposed luminance model (Kosmatka) [8] was used to determine the location at which the obstacle luminance was sufficient to allow obstacle detection. This model uses a *base case* luminance (for detection) of 0.130 cd/m^2. The luminance requirement is modified by a size (angular area) factor, F_A, in order to account for the subtended visual angle of the obstacle or target. The 0.130 cd/m^2 (.038f-l) *base case* value was established from tests by Meese and Westlake for a variety of SAE beam patterns.

The luminance requirement divided by the target reflectance gives the illumination requirement ($I_{required}$):

$$I_{required} = L_{required} \times 1/r \times F_A = 0.13 \times 1/r \times F_A$$

The luminance of the test targets resulting from the headlamp illumination was determined by comparison of the target location in the beam pattern of the respective right and left headlamps. The obstacle illumination interpolated for each headlamp from isocandela plots was used in the general equation:

$$I_{obstacle} = I_{headlamps} \times 1/d^2$$

A graphical comparison of illumination required versus illumination provided yields the distance at which the detection requirement is satisfied. When this was done using Olson's lower beam, "small target, young driver tests", the results shown below in table 1 were obtained. (This graphical method is depicted in Appendix *A*. See also Kosmatka [8])

Table 1 - Detection Distances and Obstacle Luminance at Detection for Two Models and Olson's Field Experiment

	Experimental - Olson [5]		Kosmatka [8] Luminance Model		Contrast Model
Obstacle Reflectance	**Detection Luminance**	**Detection Distance**	**Detection Luminance**	**Detection Distance**	**Detection Luminance**
6%	0.078 cd/m^2 (.023 f-l)	207 ft.	0.085 cd/m^2 (.025 f-l)	192 ft.	1.90 cd/m^2 (.556 f-l)
12%	0.085 cd/m^2 (.025 f-l)	269 ft.	0.095 cd/m^2 (.028 f-l)	235 ft.	1.61 cd/ m^2 (.471 f-l)
25%	0.078 cd/m^2 (.023 f-l)	387 ft.	0.133 cd/m^2 (.039 f-l)	290 ft.	1.28 cd/m^2 (.376 f-l)

It should be pointed out here that the beam pattern isocandela diagrams for the lamps used in Olson's test could not be interpolated with sufficient precision to be used in determining the light intensity from the two headlamps directed at specific points. Instead, data from typical 7-inch Par 56 headlamps, the same type as the test headlamps, were used. To the extent the beam patterns could be compared, the light levels used appeared to be consistent with that found on copies of the isocandela plots for those test headlamps.

DISCUSSION OF FIELD TEST COMPARISONS

The results for the 6% and 12% targets are very similar to the luminance-based model predictions, particularly for the obstacle luminance required for detection. In the case of the 25% target, the similarity is not as good. There might be valid reasons for this but they would be difficult to verify. A small, isolated crest on the test track could momentarily direct more intense light at the test target. The observer might then have advanced warning of the target location allowing him or her to concentrate on the immediate vicinity and sight the target earlier than normal. Vehicle load changes can have a similar effect.

There appear to be inconsistencies between the experimental data and the visual-solid-angle-size (spatial summation) effect. The luminance at detection reported by Olson is more-or-less constant between 207 and 387 feet. The luminance model requires some level of increasing luminance to compensate for the decreasing size of the projected retinal image (Hills) [9]. Though it is intuitive (at least to the author) that larger obstacles or targets should be more visually prominent, the relatively constant target luminance over a two-to-one range of detection distances does not show this. Whether this is attributable simply to the probabilistic nature of human responses and experimental error or whether there is a more profound physiological basis is not apparent.

SUMMARY

A luminance-based model appears to be valid based on results of obstacle-detection observations and object luminance-at-detection measurements made in dynamic roadway tests using the vehicle headlamps as the primary light sources. Comparatively, a contrast-based detection model, tested for its ability to predict detection of roadway obstacles with vehicle headlamps, did not predict either detection distance or detection luminance very well. Two reasons are offered for this:

1. There is a framing effect caused by the shadows resulting from the lateral spacing of vehicle headlamps and their relative location with respect to the driver's eyepoint. The use of Blackwell data for obstacle detection on unlighted roadways may not be appropriate because it does not consider the shadow effect, but makes an assumption that the background is contiguous with the periphery of the obstacle.

2. Unstated in the use of Blackwell's visual performance curve is that driver (or observer) adaptation is a function of the contrast by virtue of varying back-ground luminance. In reality, adaptation is relatively static for any particular headlamp-beam distribution and road surface reflectance. Adaptation is not a function of varying obstacle contrast nor does it vary as the location of the obstacle changes over small angles within the driver's view of the road scene.

Comparison of experimental data and predictions shows that the luminance-based model fairly predicts obstacle luminance and detection distance. In one test case, using a higher reflectance object detected at greater distances there is a more significant difference between the detection luminance and the detection distance predicted by the model. The exact reason for the discrepancy cannot be determined from the information available.

ABSTRACT

The thermal performance of an automotive fog lamp reflector is predicted with a computational fluid dynamics program. The 2D, steady-state heat transfer model accounts for convection and radiation within the enclosure, conduction through the reflector walls, external convection and radiation losses, and transmission through the lens. A good comparison of the predicted reflector temperatures with experimental thermocouple and infrared data suggests that the specular component of the inner metal coating plays a secondary role in the overall heat transfer and that a detailed thermal model of the bulb is not required. The radiant exchange with the tungsten filament and the conductive energy losses through the bulb connections are accounted for by specifying an appropriate heat flux at the bulb surface, and the transmission of radiant energy through the lens is modeled with an appropriate heat sink. Driven by the thermal expansion of the air near the bulb surface, 4 counter-rotating recirculation zones are predicted within the reflector enclosure. The highest temperatures are predicted at the intersection of these zones on the inner surface of the shelf above the bulb. The thermal model can be used to assess the importance of different heat-transfer mechanisms. For example, sensitivity studies show that thermal radiation within the reflector enclosure redistributes the energy so that the wall temperatures are more uniform. In addition, thermal radiation losses to the environment surrounding the reflector need to be included in the thermal model; otherwise, the predicted wall temperatures are higher than the experimental data.

INTRODUCTION

Two key criteria for part design in automotive lighting applications, such as head lamps and fog lamps, are thermal performance and beam shift caused by thermoelastic deformation of the lens and reflector assembly. These criteria are especially important for head lamps as designers are moving the optics from the lens to the reflector. Lenses that were previously faceted for optics are now smooth and clear, and reflectors that were previously smooth parabolas now have complex faceted surfaces. The situation is further exacerbated as the beam adjustment function is changed from the lens and reflector assembly to an inner movable reflector. To meet the thermal and beam shift requirements, the automotive industry currently uses a thermoset polyester composite for the reflectors, providing high-heat capability and low thermal expansion, and a polycarbonate (PC) thermoplastic resin for the lens. The disadvantages of thermoset reflectors are their higher weight, non-recyclability, secondary trimming operations, and base coating for metallization. Recently, an amorphous polyetherimide (PEI) thermoplastic resin has been introduced for the reflector applications, reducing the part weight, introducing recyclability, and eliminating secondary trimming and basecoat operations. Coincidentally, tests have shown that the PEI reflectors provide improved beam patterns over thermoset reflectors because the faceted corners are not rounded off by the basecoat necessary for thermosets. In order for the PEI resin to be successfully implemented, the thermoplastic reflector must meet the high operating temperatures and tight beam-shift tolerances under which thermoset materials currently perform. The focus of this work was to develop a predictive methodology based on available computational tools that would link the automotive lighting requirements with the material

properties of thermoplastics. A numerical sensitivity analysis could then be used to suggest design improvements and to drive material formulation changes that would help position the PEI resin as a viable material option in the automotive lighting market.

The strategy for predicting the thermal performance and beam shift of automotive lighting applications is illustrated in Figure 1. Whereas sophisticated ray-tracing software is commonly used to optimize the reflector geometry for optics at the outset of the design process, material selection, thermal performance, and thermoelastic deformation are usually addressed later through experimental trial and error. It is proposed that the last 2 steps also be modeled. The thermal analysis can be accomplished with a computational fluid dynamics (CFD) package that is capable of simulating coupled conduction, convection, and thermal radiation inside the reflector enclosure. The required material properties include the thermal conductivity, specific heat of the air, and surface emissivity. Once the temperature distribution of the reflector is calculated, the resulting thermoelastic deformation can be predicted with a structural analysis package. The additional material properties include the coefficient of linear thermal expansion (*CTE*) and the elastic modulus. The deformed surfaces can then be used in a ray tracing analysis to predict the beam pattern and to compare with the results obtained with the undeformed geometry. The maximum operating temperature and beam-shift predictions provide the information needed to change the reflector geometry or to improve the material's thermal performance while maintaining flow, impact resistance, and coating adhesion. Using a fog lamp reflector as an example, this report focuses on the third step in the design process, summarizing the minimum-complexity thermal model developed within the limitations of available computational tools, comparing the predicted temperatures with experimental data, and presenting a sensitivity study on the effects of changing some of the heat-transfer mechanisms, material properties, and operating conditions.

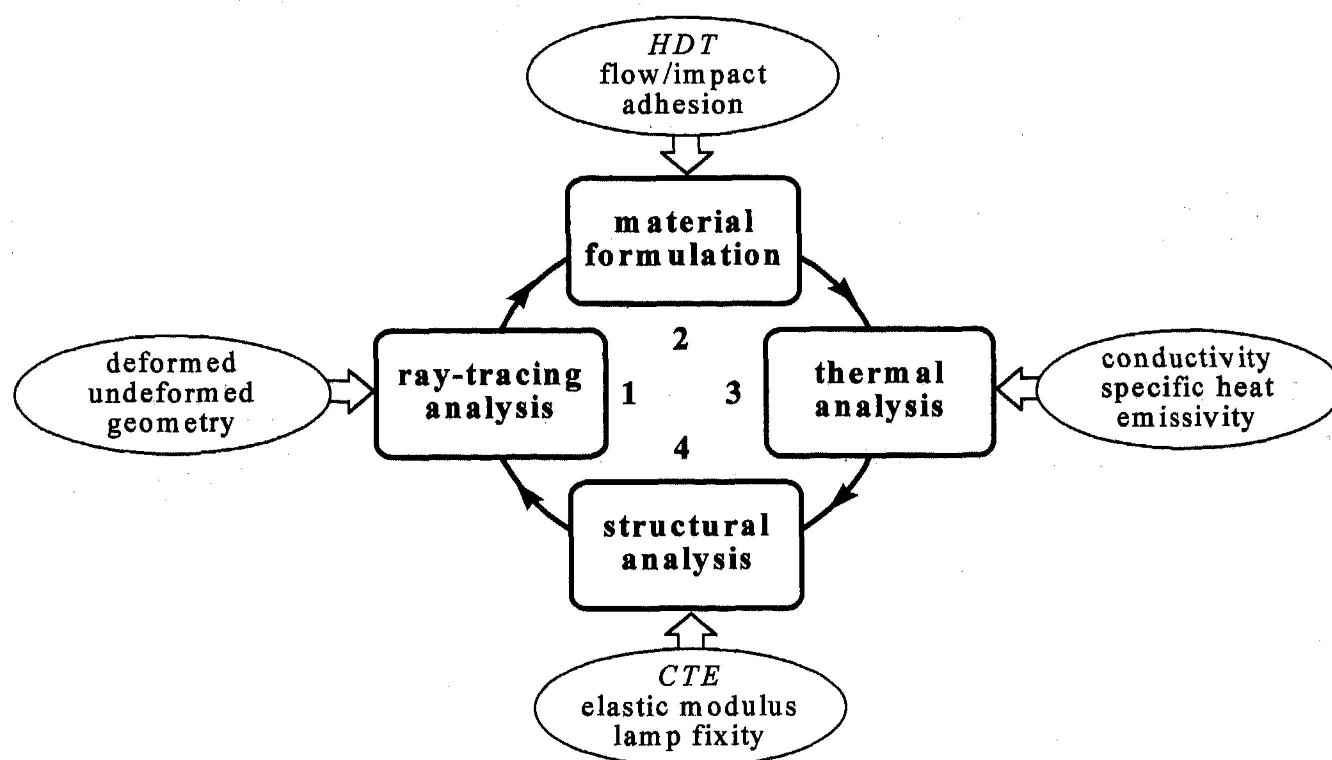

Figure 1: Strategy for predicting the thermal performance and beam shift of automotive lighting applications.

RADIATIVE PROPERTIES

Because the surface temperatures of an illuminated bulb and a tungsten filament are on the order of 500 and 2,700C, thermal radiation plays an important role in the overall heat transfer, and the radiative properties of the bulb, filament, and reflector surfaces are required. These include the absorptivity, reflectivity, and transmissivity, which respectively measure the fraction of absorbed, reflected, and transmitted radiation relative to the incident flux arriving at the surface from other sources. The amount of radiation given off by a surface is characterized by its emissivity, the ratio of emitted radiation relative to the maximum amount possible given off by a black body at the same temperature. In general, the radiative properties exhibit angle, wavelength, and temperature dependence; in the present approach, the radiant exchange is assumed to be gray-diffuse (wavelength and angle independent) and the enclosed air does not participate in the radiation heat transfer. For a gray-diffuse surface of an opaque body, all the incident radiation is either reflected or absorbed by the body. Furthermore, Kirchoff's law states that the surface emissivity $(0 < \epsilon < 1)$ is equal to its absorptivity $(0 < \alpha < 1)$, the sum of the emissivity and surface reflectivity $(0 < \rho < 1)$ equals unity, and the emissivity is thus the only surface property required in the analysis. To further simplify the problem, the emissivity is assumed to be independent of surface temperature.

Pure, smooth metals are known to exhibit low emissivity and absorptivity and therefore high reflectivity; whereas, the opposite is generally observed for dielectric materials such as thermoplastics [1]. Rather than relying on published values and introducing a potential source of error in the numerical calculations, the radiative properties of the thermoplastic resins making up the fog lamp reflector and lens were directly measured. Small plaques were molded out of the PEI and PC resins, and some of the PEI samples were metallized on 1 side with a relatively thick aluminum (Al) coating. To confirm the gray-diffuse assumptions, all 3 properties—emissivity, transmissivity, and reflectivity—were measured using an imaging infrared (IR) radiometer in the wavelength regions where most of the radiant exchange occurs. An inspection of the curves for the emissive power of a black body as a function of wavelength reveals that for temperatures between 200 and 500C significant exchange occurs in the mid-IR region. Consequently, average values were obtained in 2 bands of 2-6 μm and 7-14 μm with 3 simple tests. First, the opacity of each sample was verified by measuring the transmission of radiation through the sample from a black body source. The emissivity was then obtained by simultaneously comparing the IR intensity emitted from the sample and a previously characterized reference, both heated to the desired temperature on a hot plate. Finally, the reflectivity at various angles of an incident IR beam from a blackbody source was determined by comparing the reflected intensity with that of a reference gold mirror.

The IR measurements show that between wavelengths of 2 to 14 μm both the PEI and PC samples are essentially opaque and the radiative properties, summarized in Table I, are approximately constant. Of course, the PC sample is transparent between wavelengths of 0.3 and 2.0 μm [2]. The aluminum coating layer on top of the PEI resin is somewhat specular (reflects in a *mirror-like* manner). When dealing with specular surfaces, it is necessary to account for the directional paths that the reflected radiation follows since multiple reflections are possible. Within enclosures, these directional effects are usually small because of the many reflections taking place between the surfaces [1]. In the fog lamp reflector, multiple reflections are not likely to occur because most of the radiant energy emanating from the tungsten filament and passing through the bulb is reflected by the aluminum coating toward the unmetallized portions of the PEI reflector and the PC lens, where it is either absorbed or transmitted to the external environment. In an effort to develop a minimum-complexity model, the specular component of the metal coating is neglected; the error associated with this approximation is quantified by comparison of the predicted temperatures with experimental data. The additional surface that needs to be considered is that of the quartz bulb. Published radiative properties [3] show that quartz exhibits wavelength-dependent properties in the range of interest. Typically, quartz becomes highly absorbant above 3.0 μm; however, it is transparent between wavelengths of 0.3 and 3.0 μm. Within this relatively narrow band, the quartz exposes the lens and reflector surfaces to the hot tungsten filament. Consistent with the assumptions made for the thermoplastic resins and metal coating, the bulb surface is considered to be gray-diffuse and the filament radiation is accounted for by specifying an appropriate heat flux at the bulb surface; these additional sources of error are quantified by comparison with experimental data.

TEMPERATURE MEASUREMENTS

THERMOCOUPLE DATA -- Steady operational temperatures of a fog lamp reflector were measured in a controlled oven environment [4]. Black pigmented PEI reflectors were partially metallized with an aluminum coating without the use of a basecoat. Based on the extinction coefficient of aluminum [1], the mean penetrating distance of incident radiation is about 0.1 μm so that the coating in the present study can be assumed opaque. Only the parabolic portion of the reflector was metallized; the top and bottom shelves were masked during the metallization process. The parabolic portion of the

reflector extends forward and forms the side walls. Six thermocouples were mounted on the inner and outer surfaces of the reflector with a glass-reinforced PEI tape as shown in Figure 2. Subsequently, a PC lens was bonded to the reflector using an adhesive, a light bulb rated at 37.5 W was inserted into the socket, and the reflector assembly was placed in a non-circulating oven at approximately 50C. The bulb was illuminated at an abusive condition of 14 V (12.8 V standard) for approximately 1 hr, with the temperatures being recorded via computer every 5 sec. A steady state was reached within 10 to 15 min; the final temperatures at each of the 6 locations are recorded in Table II. Additional tests with a lower power, 28 W bulb and different oven temperatures are also shown in the table for comparison. The hottest temperature is observed on the inside surface of the top shelf as hot air is being convected upward from the bulb. In contrast, the air circulation cools the inside surfaces of the bottom shelf and side walls. The lowest temperatures are recorded on the sides where the aluminum coating reflects most of the radiant energy back into the enclosure. The high reflectivity and inner convective cooling also cause the temperature drop through the side walls to be lower than the drop through the top and bottom shelves. Changes in the oven temperature have a less significant effect on the reflector's thermal performance in comparison to changes in the input power. For example, the data show that a 45C increase in the oven temperature results in a 15-20C increase on the reflector temperatures. In contrast, a 10 W increase in the input power can cause an increase as high as 100C.

INFRARED DATA -- The imaging IR radiometer used to measure the radiative properties of the thermoplastic materials was also used to image the steady operational temperatures of the fog lamp reflector and the bulb. An example of the IR data for the outside surfaces of the top shelf and the lens, obtained by illuminating the bulb inside the reflector at the standard operating condition of 12.8 V in an ambient environment of approximately 25C is shown in Figure 3. The internal reflector temperatures are accessible only if the PC lens is replaced by a material transparent in the IR wavelength range. In contrast to the single-point thermocouple data, a contour map is easily produced, pinpointing the actual location of the maximum values. A circular pattern of isotherms is observed with the hot spot centrally positioned on the top shelf of the PEI reflector. The darker band toward the front of the reflector in Figure 3(a) is an extended rib around the periphery attaching the lens, a portion of which can be seen in the top view. The PC lens temperature is significantly lower than the top shelf with the hottest temperature shifted toward the upper half. Although the experiment was carried out at room temperature and at a lower voltage, the overall temperatures are not much different from the thermocouple data in Table II. Table III lists the quartz surface temperatures measured with the infrared radiometer by illuminating the bulb outside the reflector at 3 voltage levels in an ambient environment of approximately 25C. The electric current was also obtained to compute the power input to the bulb. The results show that the top surface is hotter by about 60 to 70C than the lower surface due to air convection inside and outside the bulb. Both surfaces exhibit a wide but similar temperature spread. The highest temperatures are recorded on the blackened surface in front of the hot tungsten filament.

Table III: Quartz surface temperatures as a function of the applied voltage and power.

NUMERICAL MODEL

As illustrated in Figure 2, the thermal performance of the fog lamp reflector is determined by convective and radiative heat transfer in the enclosure, by conduction through the reflector walls, and by convection and radiation to the external environment. The FIDAP® CFD package is used to develop a 2D heat transfer model. In this section, a brief overview of the FIDAP features relevant to the present problem is first discussed, followed by a description of the governing equations, the boundary conditions, and the radiation modeling. Several numerical solution schemes and their convergence performance are also described.

® FIDAP is a Registered Trademark of Fluid Dynamics International, Inc.

FIDAP SOFTWARE – The FIDAP package is a general-purpose computer program for simulating, among other phenomena, fluid flow and heat transfer in either 2- or 3D domains. Based on the finite element technique, the domain of interest is divided into small regions (finite elements) and the governing equations are then replaced by a set of algebraic equations in each region. The algebraic system is then solved numerically for the dependent variables such as velocity, temperature, and pressure. This software is capable of solving steady-state or transient, laminar or turbulent, and incompressible or compressible flows. The program can simulate heat transfer in the fluid and solid regions, coupled with heat convection in the fluid and gray-diffuse radiant-heat exchange between the solid surfaces. Although extensions to a non-gray analysis are possible, transmission and specular behavior cannot be

modeled in the current version of the software. For further information, consult the *FIDAP Theory Manual* [5].

GOVERNING EQUATIONS -- In the 2D thermal model, the thermoplastic reflector and lens are modeled as solids that transport energy by conduction. The partial transparency of the PC material in the visible and near-IR wavelength range cannot be modeled. In turn, the air within the enclosure is described as an incompressible viscous fluid, which undergoes laminar flow, transports energy by conduction and convection, and does not participate in the radiation heat transfer. The radiant heat exchange between the bulb and inner reflector surfaces is coupled with the energy balance equation for the air through appropriate boundary conditions. The light bulb is implicitly modeled by replacing its volume in the finite-element mesh with a heat flux boundary condition along the bulb surface as described in ***Boundary Conditions***.

The equations governing the flow of a non-isothermal single-phase viscous fluid are mathematical representations of the conservation of linear momentum, mass, and energy. The momentum balance equation for a steady flow of an incompressible fluid with the buoyancy body force added to account for the thermal expansion of the air is given by:

Momentum Balance (1)

$$\rho_0 \mathbf{u} \bullet \nabla \mathbf{u} = -\nabla p + \mu \nabla^2 \mathbf{u} - \rho_0 [\beta_T (T - T_0)] \mathbf{g}$$

where $\mathbf{u}$ is the velocity vector, p is the pressure, μ is the dynamic viscosity and ρ_0 is the fluid density at the reference temperature T_0. The last term in Eq. (1) represents the Boussinesq approximation for the density-driven buoyancy force resulting from a non-uniform temperature distribution, with β_T representing the thermal expansion coefficient, T, the local temperature, and $\mathbf{g}$, the acceleration vector due to gravity. The momentum equation has to be solved in conjunction with the following mass balance equation:

Mass Balance (2)

$$\nabla \bullet \mathbf{u} = 0$$

For incompressible fluids, the conservation of energy under steady-state conditions with negligible viscous heating effects and no other heat sources is expressed by:

Energy Balance (3)

$$\rho_0 c_p \mathbf{u} \bullet \nabla T = k \nabla^2 T$$

where c_p is the specific heat, and k is the thermal conductivity. In the solid region, the convective term on the left-hand side does not apply, and Eq. (3) reduces to the Laplace equation for the temperature. The material properties appearing in Eqs. (1) to (3) are listed in Table IV; they are taken from the Engineering Design Database [6] produced by GE Plastics and literature (e.g., [7]).

Table IV: Thermophysical properties required for the thermal analysis.

Properties	PEI	PC	Air @ 200C
ρ_0 (kg/m^3)	1270	1200	0.746
k (W/m/K)	0.22	0.19	0.0378
c_p (J/kg/K)	1100	1250	1025
μ (kg/m/s)	—	—	0.0000258
β_T (K^{-1})	—	—	0.00211

BOUNDARY CONDITIONS -- Along the domain boundary, appropriate boundary conditions must be applied to complete the flow and heat transfer model. The air enclosed by the fog lamp assembly is the only fluid medium to be analyzed, and a no-slip boundary condition is imposed on the bulb surface and along all the inside surfaces of the reflector:

Flow Boundary Condition (4)

$$\mathbf{u} = \mathbf{0}$$

In addition to specifying the ambient temperature, the following heat flux condition is prescribed along the normal to each of the domain boundaries $\mathbf{n}$:

Heat – Transfer Boundary Condition (5)

$$-k \nabla T \bullet \mathbf{n} = q_a + q_r + q_c$$

accounting for any applied q_a, radiative q_r, and convective (or conductive) q_c contributions. The energy balance at the surface of the light bulb is modeled with an applied and radiative heat flux ($q_a > 0$, $q_r > 0$, $q_c = 0$), and the bulb volume is eliminated from the finite-element mesh. The convection of heat away from the bulb surface is accounted for by the energy balance in Eq. (3).

Table V: Heat transfer coefficients on the outer reflector surfaces.

Surface	h_c (W/m^2)
Top shelf	9.75
Bottom shelf	4.73
Side walls	8.26

On the exterior surfaces of the reflector, heat is both radiated and convected to the external surroundings so that both the radiative and convective heat-flux boundary conditions are included in the heat transfer calculations ($q_a = 0, q_r > 0, q_c > 0$). Newton's law of cooling:

External Convection Condition

$$q_c = h_c(T - T_\infty) \quad (6)$$

is substituted for the convective part, and the ambient temperature is used as input for the reference temperature T_∞. Assuming that the heat transfer from the fog lamp to the external surroundings is laminar, the heat transfer coefficients h_c can be estimated from generally accepted empirical correlation for free convection past the outer surfaces of the reflector [7]. The results calculated at an ambient temperature of 50C are listed in Table V. Along the boundaries dividing the reflector and the enclosed air, heat is conducted into the walls or radiated back to the enclosure ($q_a = 0,\ q_r > 0,\ q_c > 0$). Fourier's law is substituted for q_c so that the temperature gradients on both sides of the solid-fluid interface are offset by the ratio of solid to fluid thermal conductivities and the amount of energy radiated back to the enclosure. Heat convection along the inner reflector walls is accounted for by the energy balance in Eq. (3).

RADIATION MODELING -- The calculation of radiant exchange between a pair of surfaces requires the determination of a geometrical configuration factor, or view factor, between the 2 surfaces. The view factor ϕ_{ij} is defined as the ratio of the radiant energy arriving at surface j relative to the total radiant energy leaving surface i. By definition, the net radiative heat flux leaving from surface i due to emission and reflection can be written as:

Flux Leaving Surface i

$$q_r^i = se_i T_i^4 - \sum_{j=1}^{N} \phi_{ij} \left[se_j T_j^4 - (1 - e_j) q_r^j \right] \quad (7)$$

View Factor

$$\phi_{ij} = \frac{1}{A_i} \int_{A_i} \int_{A_j} \frac{\cos\beta_i \cos\beta_j \, dS_i dS_j}{\pi r^2} \quad (8)$$

where $s = 5.67 \times 10^{-8}$ W/m^2 K^4 is the Stefan-Boltzmann constant, and β_i , β_j are the angles formed by the intersection of the surface normal vectors $\mathbf{n}_i$, $\mathbf{n}_j$ with the line of length r connecting the 2 points i , j. Each finite element on the bulb and reflector surfaces radiates thermal energy, and the view factor between any 2 elements must be calculated as part of the numerical solution. Because the light bulb obstructs the radiant exchange between the reflector surfaces, it is considered as a blocking surface in the view factor calculation. The external reflector surfaces also lose heat by radiation. Thus, Eq. (7) reduces to the simpler form of the Stefan-Boltzman law:

External Radiation Condition

$$q_r = se(T^4 - T_\infty^4) \quad (9)$$

NUMERICAL RESULTS

2D DISCRETIZATION -- The present numerical calculations are based on the 2D cross-sections shown in Figure 2: perpendicular and parallel to the lens and passing through the bulb center. A finite-element model of the cross-section perpendicular to the lens is shown in Fig. 4(a), where the wall on the right-hand side is the PC lens and the wall on the left-hand side is the metallized portion of the PEI reflector. The thin metal coating is modeled with surface elements in the analysis, and the low emissivity of the aluminum is used to simulate its high reflectivity. The finite-element model for the parallel configuration is symmetric with respect to the center of the light bulb, and it is shown in Figure 4(b). The upper and lower walls are the uncoated top and bottom shelves; whereas, the right and left walls are the metallized portion of the PEI reflector.

Table VI: Comparison between predicted and experimental temperatures (°C).

DATA TYPE	TOP/IN	TOP/OUT	BOTTOM/IN	BOTTOM/OUT	WALL/IN	WALL/OUT
Perpendicular (8,000 W/m^2)	255	215	240	205	—	—
Parallel (17,500 W/m^2)	248	216	219	197	122	112
Thermocouples	252	190	222	173	116	89
IR measurements	—	205	—	150	—	80

EXPERIMENTAL COMPARISON -- Numerical calculations were performed for the fog lamp reflector using the gray-diffuse approximation for internal radiation, and accounting for both convection and radiation on the exterior surfaces of the reflector. The applied heat fluxes of $q_a = 8{,}000$ W/m^2 and $q_a = 17{,}500$ W/m^2 were estimated for the perpendicular and parallel cross-sections based on the reflector geometry and the total power input. The comparisons between the simulated results and the thermocouple and IR measurements for the 2 cross-sections are summarized in Table VI. Note that the infrared temperatures were obtained at the same voltage as the thermocouple data (14 V), but at a room temperature of 25C, and have been raised by approximately 10C to compensate for the different oven condition of 50C. This correction factor is based on the change in overall temperatures calculated with the heat transfer model as discussed in **Sensitivity Studies**. The predictions for the top and bottom shelves in both cross-sections are in reasonably good agreement with the experimental data, given the model assumptions and the discrepancies in the measurements. One possible improvement, especially in the perpendicular is the application of a smaller heat flux on the bottom surface of the bulb in accordance with the lower surface temperatures in Table III. The smaller heat flux may bring the predicted temperatures on the bottom shelf of the reflector closer to the actual data. The higher temperature drop across the bottom shelf in the perpendicular case is due to the thicker wall. In fact, the temperature gradient across both sections is about 14 C/mm.

Figure 5 shows the predicted temperature distribution in the perpendicular and parallel cross-sections. For the perpendicular cross-section, the contours are asymmetric due to the different radiation properties of the metallized reflector on the left-hand side and the PC lens on the right-hand side. Because more energy is reflected from the metallized reflector onto the bulb, the peak bulb temperature of about 400C is located towards the rear on the top surface. Directly above, the heat is convected upward creating a hot spot on the top shelf. The experimental IR contours in Figure 3 show that the hot spot is located more toward the center of the reflector. In reality, the reflected energy from the side walls to the bulb probably shift the hot zone forward; this 3D effect cannot be captured with the present 2D model. The temperatures on the front, bottom, and back surfaces of the bulb are similar and, in an average sense, close to the measured data listed in Table III for the bottom surface. The front of the actual bulb is covered with a black coating to prevent the light from traveling directly to the lens. Because the emissivity of the other bulb surfaces is close to unity (ϵ = 0.9), using a black-body approximation (ϵ = 1) for the front surface does not sufficiently increase the temperature to match the high values measured with the imaging IR radiometer. Application of a higher heat flux on the front surface of the bulb may bring the predicted bulb temperatures closer to the actual data. For the parallel cross-section, the temperature distribution is symmetric. The peak bulb temperature is approximately 480C on the top surface in agreement with the averaged measured values, and the hot spot is located directly above on the upper shelf.

Figure 6 shows the temperature distribution along the centerline from the bottom to the top shelf in the perpendicular and parallel cross-sections. The results in this figure are used to determine the temperature data of the top and bottom shelves listed in Table VI. The curves for both cross-sections are similar, showing that the air above the light bulb is close to 300C, about 100C hotter than below. Figure 7 shows the temperature distribution along the centerline of each cross-section in the horizontal direction. This figure is used to obtain the wall temperature data listed in Table VI. The air temperature on the sides of the bulb is about 200C, rapidly dropping near the reflector walls. Consistent with the results in Figure 5(b), the temperature distribution in Figure 7(b) for the parallel cross-section is symmetric, and the predicted temperatures for the metallized walls at x/a = 0, 1 are similar to those in the perpendicular cross-section at x/c = 0, where a, b, c are the depth, height, and width of the reflector. The calculated velocity vectors for the air flow

inside the housing are shown in Figure 8. Two recirculation zones are observed due to the expansion and buoyancy of the air near the hot bulb and the contraction near the cool walls. The recirculation zones are better observed in the streamline contours shown in Figure 9. The strongest air flow occurs near the light bulb and along the inner surfaces of the reflector, where the streamlines are closest to each other. The location of the hot spot corresponds to the point at which the recirculation zones meet. Based on the calculated velocity field, the highest Reynolds number, Re—which measures the ratio of inertial to viscous forces—found in all the simulations is less than 20; therefore, the laminar flow assumption is justified (i.e., Re < 2100 [8]).

LENS TRANSMISSIVITY APPROXIMATION -- Examining Figures 5(a) and 7(a) reveals that the temperature of the PC lens is around 180C, considerably higher than the measured 115 to 120C values. As discussed in **FIDAP Software** and **Governing Equations,** the present model does not account for the radiant energy that is transmitted through the PC between wavelengths of 0.3 and 2.0 μm. One way to account for this phenomenon is to impose a heat sink along the interface separating the lens and the enclosed air. The heat sink can be modeled by approximating the radiant energy coming from the other reflector surfaces between wavelengths 0.3 and 2.0 μm with a constant heat flux. Additionally, 3D effects may need to be included in the heat sink approximation. The heat sink can also be equally applied to the external lens surface, or throughout the lens volume. Alternatively, a more accurate heat sink distribution can be imposed if the light intensity hitting the PC lens can be calculated with a ray-tracing analysis.

The effect of the lens heat sink on the reflector temperatures is shown in Table VII. The heat sink is applied on the inner surface, outer surface, and throughout the volume of the PC lens. All 3 methods yield similar results; the smoothest transition of the temperature through the lens is obtained with the volume-based heat sink. A surface heat sink of 1600 W/m^2, or equivalently a volume heat sink of 640,000 W/m^3 for a 2.5-mm thick lens, is required to bring the lens temperature predictions closer to the experimental data. The remaining reflector surfaces are minimally affected by the addition of the heat sink in the model.

Higher Applied Flux	277	233	291	241
Lower Ambient Temp	244	207	227	193

SENSITIVITY STUDIES -- As a demonstration of using the thermal model for material formulation changes and reflector design, the effects of changing some of the heat transfer mechanisms, material properties, and operating conditions are investigated next. The baseline case selected for the sensitivity studies is the gray-diffuse analysis of the cross-section perpendicular to the lens described in **Domain Discretization**. The predictions of the various heat transfer models are compared with the baseline temperatures in Table VIII.

CONDUCTION/CONVECTION MODEL -- Radiative heat transfer is a highly nonlinear phenomenon; therefore numerical simulations exhibit convergence difficulties associated with the dependence of the radiative heat flux on T^4, where T is the absolute surface temperature. Because of this complexity, the first simulation only considered heat conduction and convection, and its solution was used as an initial condition for the other analyses with radiation. The contribution of radiation heat transfer to the thermal distribution is examined by comparing the results obtained with and without radiation. Comparison of the conduction/convection model with the base case in Table VIII shows that the radiative heat transfer tends to render the temperature distribution inside the enclosure more uniform, significantly lowering the upper shelf temperatures by 445C and slightly raising the bottom shelf temperature by 20C. Therefore, radiation must be included in the heat transfer model to accurately predict the thermal performance of any lamp reflector.

EXTERIOR CONVECTION MODEL -- Initially, the boundary condition on the exterior of the housing was assumed to be natural convection only. However, the combination of high temperatures along the top surface, the high emissivity of PEI, and the low convective heat-transfer coefficients in the non-circulating oven, suggested that radiative heat transfer might be an important energy transfer mechanism. Hand calculations confirmed the relative importance of the external radiation to the ambient, which was then included in the numerical simulation. The results obtained without external radiation are shown in Table VIII for comparison. Both the top and bottom shelves in the external convection model experience dramatic temperature increases of about 185C and 195C, respectively. Another indication of the importance of external radiation is the resulting increase in temperature gradient through the shelves, which is closer to the experimental data.

HIGHER CONDUCTIVITY MODEL -- To simulate a different reflector material, the thermal conductivity of the solid walls is increased by a factor of 5 to 1.0 W/m K. Compared with the baseline, the temperature difference across the thickness of the shelf is reduced by about 30C on the top and 25C on the bottom shelves as shown in Table VIII. The temperature sensitivity with respect to the material thermal conductivity is only modest because the heat removal from the enclosure is limited by convection and radiation on the outside surface, not by conduction through the plastic.

HIGHER APPLIED HEAT-FLUX MODEL -- The effect of a higher heat flux was investigated by increasing the heat flux in the perpendicular cross-section from 8,000 to 10,000 W/m^2. Table VIII shows that the temperatures in the perpendicular cross-section are very sensitive to changes in the heat flux in agreement with the experimental observations. The temperatures rise by about 20C and 40C for the top and bottom shelves. In contrast, Table IX shows that the parallel cross-section is not as sensitive to a similar change in the applied heat flux. A 1,500 W/m^2 decrease changes the temperatures by less than 20C. Most likely, the decreased sensitivity in the parallel case is due to the larger cross-sectional dimensions.

LOWER AMBIENT TEMPERATURE MODEL -- To gauge the effect of external conditions on the temperature predictions, an analysis was performed with a lower ambient temperature, $T_\infty = 25$C. The results show that the thermal model is not very sensitive to the external conditions; Table VIII shows that a decrease of about 10C is observed in the overall temperature distribution in agreement with the experimental observations. As the external temperature is raised closer to the temperature of the heated reflector walls, it is expected that the cooling ability of the external environment decreases and the temperatures will be much more strongly affected.

CONCLUSIONS

A thermal analysis of an automotive fog lamp reflector that includes conduction, convection, and radiation heat transfer within the lens and reflector assembly has been developed based on the FIDAP CFD analysis package. Comparison of the temperature predictions with and without thermal radiation included in the model confirms that radiative heat transfer has a significant effect, decreasing the temperature of the top shelf and increasing the temperature of the bottom shelf. Radiation loss to the external environment also plays an important role, decreasing the overall temperature distribution by as much as 200C. In general, the temperature predicted by the 2D models is in good agreement with the experiments. However, the predicted temperatures are not able to match the measurements for all the reflector surfaces simultaneously. One reason for the temperature being too high at the top shelf and too low at the bottom shelf could be the uniform heat flux boundary condition applied at the bulb surface. In reality, the heat flux from the light bulb is higher at the top and front bulb surfaces than at the bottom surface. Another contributing factor is the deficiency of using a 2D model to predict 3D

fields. For example, the location of the hot spot on the top shelf may be incorrectly predicted because of missing radiant exchange between the bulb and reflector in the third direction. The transparency of the PC lens is approximated in the present model with a heat sink applied throughout the lens volume, which is required to properly predict the temperature distribution in the lens. At the material selection and design stage of a new lighting application, there will be no temperature data for the light bulb, and it is necessary to establish a systematic methodology for estimating the appropriate 2D heat flux and heat sink. For the analyses performed in this study, the value of the heat flux emitted from the light bulb has been estimated based on the reflector geometry and the total power input. The heat sink is based on the radiant energy emitted from the tungsten filament, reflected with the metalized surfaces and transmitted by the PC lens between wavelengths of 0.3 and 3.0 mm, where PC is transparent.

This work has also demonstrated that the thermal model can be used to guide the material selection and design of lamp reflectors. Sensitivity studies show that increasing the thermal conductivity of the reflector does not appreciably change the overall temperature distribution. The predicted sensitivity of the reflector temperatures to normal power fluctuations or uncertainties in the 2D thermal model suggest that the softening temperature of the material should be at least 50C higher than the predicted maximum values at standard operating conditions. The results also show that the thermal performance of the fog lamp reflector is not very sensitive to changes in the external conditions; however, it is expected that the cooling ability of the external environment will decrease as the ambient temperature is raised closer to the temperature of the heated reflector.

World Harmonization and Procedures for Lighting and Signaling Products

ABSTRACT

Lighting and signaling regulations vary considerably around the world. There are 3 main regulatory regions: the United States, Europe and Japan. Rules vary in scope as well as in strictly technical requirements. The ECE has published the most comprehensive regulations, covering even headlamp leveling and cleaning devices. Japan has, for the time being, the least extensive ones.

Standard lamp Regulations are pretty much alike, with the center high mounted stop lamp being the most notable exception. The most pronounced differences are for headlamps: all values above the horizon line are lower in Europe where being dazzled is not accepted. The cutoff line is also sharper in Europe, where visual aim has been common practice for 70 years.

Europe specifies amber rear side markers and amber rear turn signals but prohibits red contour markings as well as rear turn signals and red rear side markers.

Differences are more acute in the field of procedures. In the US, components are not subject to previous approval by the authorities as in Europe. The NHTSA checks *a posteriori* the compliance of those products which have caused complaint or damage, but the general rule consists of trusting the automobile manufacturer as long as no adverse event has occurred.

Those manufacturers who need to export have to pay high costs for tool duplication and administration. The rationale for this is not quite convincing since one has to admit that each country is consistent on its own territory.

INTRODUCTION

Laws relative to lighting and signaling have been developed over time, country by country. The need for harmonization has not historically been an important criterion. Trade resulting from the import and export of automobiles, or from tourism, was relatively insignificant until the middle of the 1950s. The first technical regulations regarding lighting and signaling appeared in Europe and in North America between 1920 and 1930. Traffic conditions, traditions and chance resulted naturally in laws which were framed differently, though each system had its own specific coherency.

Geography explains certain differences. The vast American spaces led to the creation of wider roads, with larger areas between lanes. This is often thought to be the explanation for the higher lighting levels permitted in the central zone above the low-beam cutoff. The federal structure of the United States and Canada left low-beam regulation to the legislature of each state, which explains the diversity of adjustment methods. Yellow headlamps in France can be explained by the now obsolete need to be able to identify the nationality of a car at night. And daylight running lamps appeared naturally in countries closer to the pole, where twilight periods are longer.

Pure chance, or history, are the reasons for driving on the right or left, the source of so much duplication of effort and investment for the industry. But nobody knows why certain functions such as identification lamps were invented in the USA or Canada or speed indicator lights in Japan, while they remain unknown elsewhere.

Legislative customs leave their mark, and sometimes their weight, on the law. Two doctrines exist: : auto-certification in Anglo-Saxon countries and type approval in Europe and now in Japan - with a corollary fraught with consequences for technical progress: the prohibition by omission which is the consequence of the latter system is an *a priori* obstruction to the introduction of new techniques which are not the subject of any law or regulation.

European texts are thus much more voluminous than their equivalents in the USA or Canada. Take the example of position lamps and parking lamps (European denominations) and compare this to American *parking lamps* or Japanese *clearance lamps.*

ECE: R7 and 77 respectively total 34 and 21 pages, while the 3 pages of R48 specify the installation of these functions.

USA: Regulation FMVSS 108 deals with the question in 14 lines, but incorporates by reference SAE J 222 and J 585e.

Japan: The Blue Book accords 49 lines in its September 1995 issue.

The incorporation of regulations by reference alleviates official texts by dispensing governments from such technico-legislative tasks.

GENERAL PRINCIPLES

a) Prohibition by omission in Europe and Japan has been elevated to a legal principle. The result is a considerable hindrance to progress, since everything which is not permitted by the law is deemed forbidden. This was for example the case for gas discharge light sources and the headlights that incorporate them. In the USA and Canada, the opposite principle applies; a function is permitted as long as its utilization is not shown to be harmful.

b) Each country has regulations which establish the minimum and maximum values for each low beam or high beam measurement point. Certain headlights fitted with very small parabola and HB2 or H4 bulbs (100X165 mm) are legal, but are close to the legal minimum. The legislation guarantees however that their utilization a) is technically feasible and b) ensures minimum but adequate safety.

c) In Europe, the performance of bulbs is dissociated from the lighting functions that use them. Bulbs are the subject of separate legislation, while headlamps and signal lamps are measured under standard laboratory conditions which are a long way from the normal usage of the vehicle.

d) US legislation is applicable to all vehicles or vehicle parts in the state where they are sold. In Europe, less demanding regulations, known as conformity of production, "COP", are applied to traded products.

Comparing statutory specifications is difficult in absolute terms, since the manufacturer has considerable leeway between required minimum and maximum values. In this investigation we have chosen to compare products which are comparable, by selecting headlamps designed for vehicles which are identical or very similar in dimension. We have excluded three sources of divergence associated with the utilization of the vehicle :

i) The voltage available at the bulb terminals, which varies considerably:

- new / used, cold / warm alternator, connectors, battery,
- engine idling or running at maximum revs, or not running,
- few or many electricity consumers in use simultaneously,
- left or right, rear lamp or headlamp.

It is not unusual to find voltages ranging between extremes of 15 to 9 volts, and in normal practice from 14 to 11 volts on a single vehicle. This is a factor greater than 2 for all photometric values.

ii) The maintenance of the vehicle. Dirt can cause a loss of up to 80% in the effectiveness of lighting systems. The age of the vehicle too is a decisive factor, as wind pollution affects all reflective surfaces over time however carefully the lighting units are sealed. The slow degradation of the light sources also is a contributory factor, and for all these reasons it is not unusual to observe a loss of 50% in the efficacy of lighting and signaling units after six years of use.

iii) Vibration often causes the vertical misaim of low beams. In this case any comparison of regulations becomes meaningless.

In the remainder of this investigation, we have therefore chosen to examine standard headlamps or signal lamps which are new, clean, powered at identical voltages, well-aimed and incorporating standard light sources as defined in ECE R37. Figures 1 thru 4 concern a single side of the automobile.

Low Beams

Figures 1 thru 4 were generated by computer from light sources powered at 12.8 volts. These curves represent the mean isocandelas of three identical headlamps, selected from a production run, fitted with the same bulb, used successively in each lamp. Relative to European laboratory practice, the 12.8 volt voltage increases the photometric values by approximately 25%, but it was necessary to choose identical voltages in order to compare products.

The left-hand cutoff was situated at 0.4° below the horizon line HH for all three products, in compliance with US legislation. This setting is higher than that specified by ECE R48 Rev1 by approximately 0.3°, which came to artificially increasing the glare levels tolerated in Europe. Here too the need to compare like to like took precedence.

Figure 1a is the mean isocandela curve of a European complex shape headlamp. Its opening was 159X93 mm and it was fitted with an H7 bulb producing a flux of 1100 lumens as defined by regulation ECE R37. This curve represents the average of three same side headlamps. Figure 1b also represents the average of three headlamps on the same side of the same automobile, but on the version sold in the US.

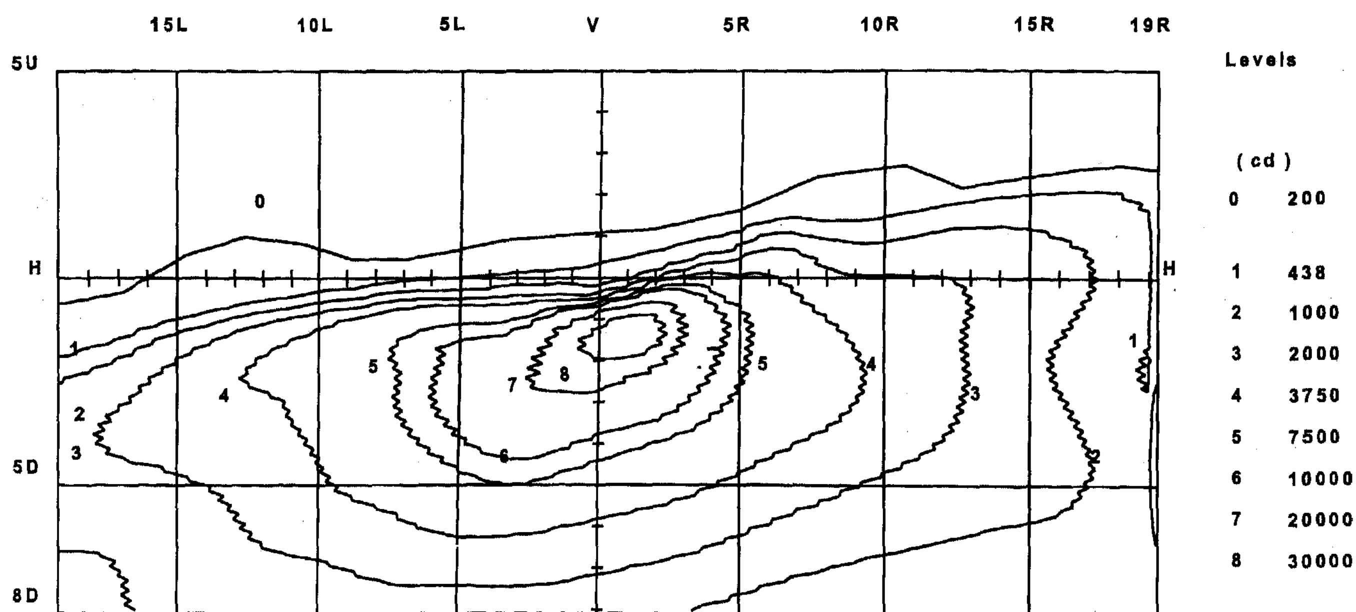

Fig 1a - Low Beam ECE MAX = 38808 cd

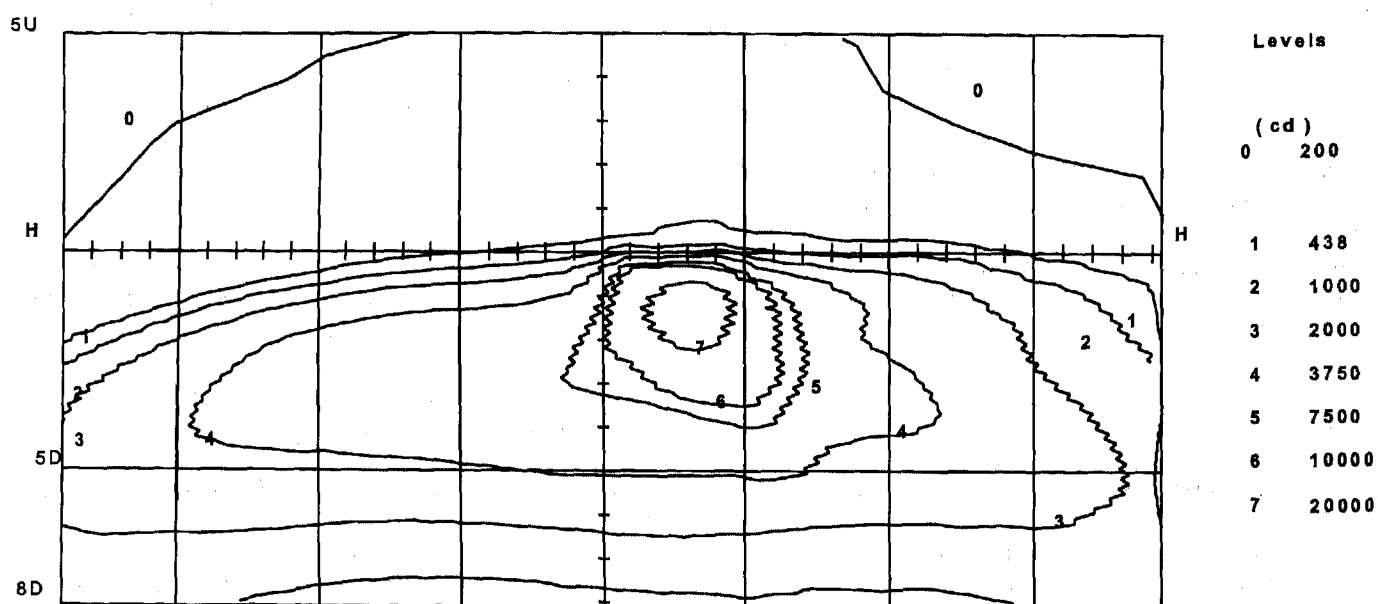

Fig 1b - Low Beam US MAX = 28474 cd

Figure 1

Headlamp 1a satisfies the "COP" photometric prescriptions of ECE R8 Rev. 4. Although "mis-aimed" upward, its maximum intensity reaches 38,800 cd, and is located at 1.3D-1R. The 10,000 cd contour extends from 6L to 5R, and the 2,000 cd contour from 18L to 13R.

Headlamp 1b satisfies the photometric requirements of US federal regulation 108 table 17a. Its hot spot reaches 28500 cd and is located at 1.8D-3R. The 10,000 cd contour extends from 0.5L to 6R, and the 2,000 cd contour from 23L to 18R.

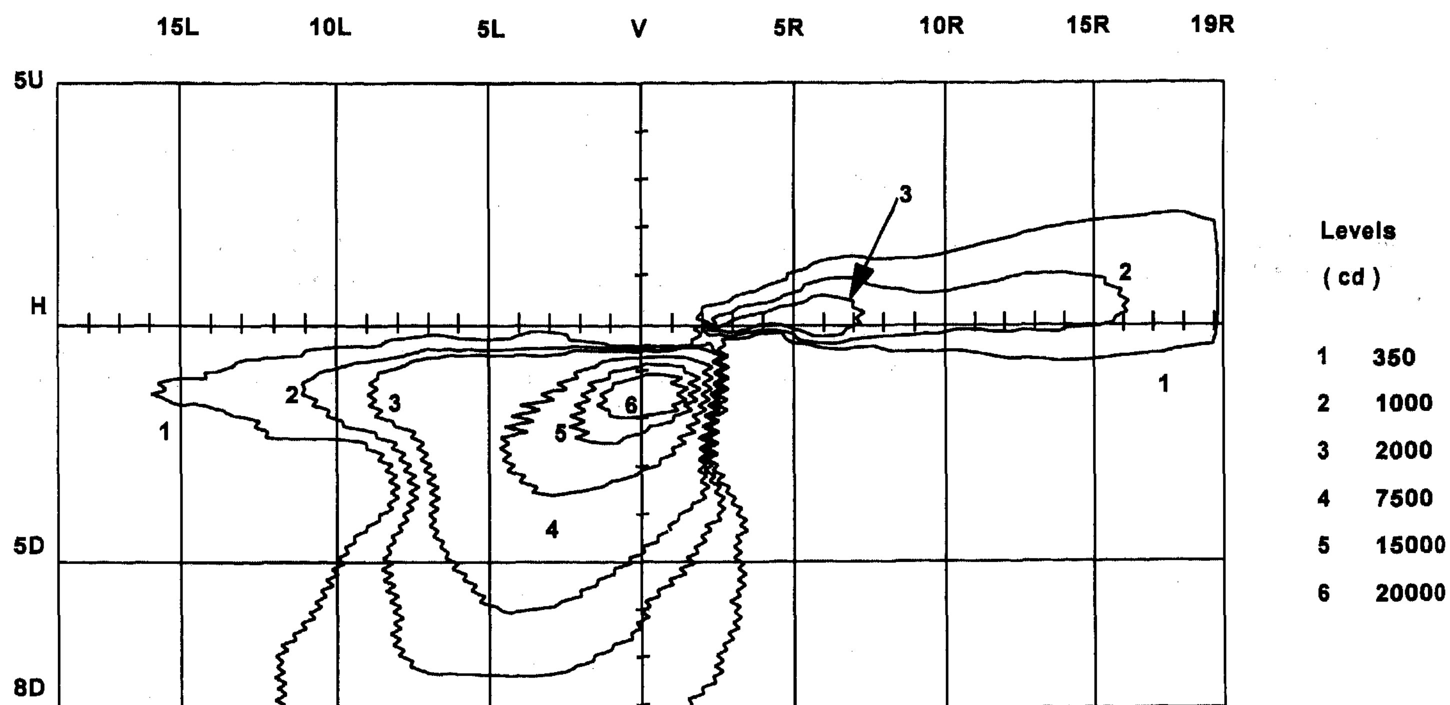

Fig 2a Low Beam (ECE - US) MAX = 26274 cd

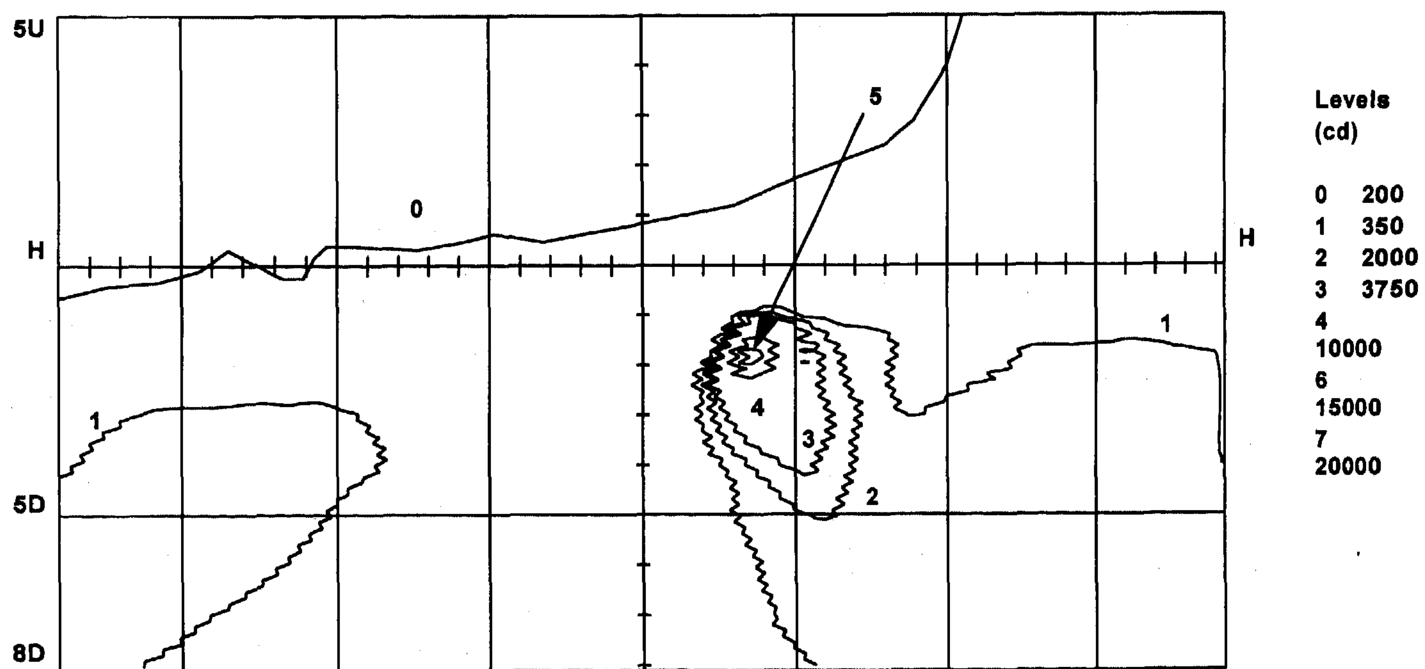

Fig 2b : Low Beam (US - ECE) MAX = 13699 cd

Figure 2

Figure 2a, which is computer-generated, is the differential beam obtained by subtracting the values of 1b from 1a. It shows the advantage of the European beam over the US equivalent. The two products correspond to the regulations in force in each zone, and also to the choices made within the limit of those regulations by the engineers of the different manufacturers. As this is the same vehicle, tested and evaluated by the same persons with, it can be presumed, the same degree of objectivity, it can also be presumed that the essential differences between the two are the result of differences in legislation. The European beam shows the following advantages :

- in the upper right quarter, contours 2 and 3 give a far better legibility of road signs located on the shoulder. The difference can be explained by the absence of a high cutoff line at 15° in US beams, and a minimum of only 200 cd on the segment 1.5U/1R-3R.

- straight ahead of the vehicle, beyond 20m, the European beam is significantly more intense. The difference of 26,300 cd corresponds almost to the hot spot of headlamp 1b, which in driving terms means a 40% increase in the obstacle detection distance.

Figure 2b is the differential beam obtained by subtracting the values of 1a from those of 1b. It represents the advantages of the US beam over the European equivalent. The American beam shows the following advantages:

- the shoulder is much better illuminated to a distance of about 20 meters. Contour 5 reaches 12,500 cd and contains the hot spot of 13,700 cd. The American beam is generally wider than its European equivalent. The maximum limit at 20,000 cd at 0.5D/1.5R gives greater width to the flux .

- above the horizon line, contour 0 shows a better illumination of overhead road signs. The part of this line to the left of 5L is not generated by a legal requirement but is useful to read road signs installed on the left side, a situation which is quite common on country roads in the US.

The oncoming vehicle glare criterion is more important for Europeans. The point representing the statistically average position of the oncoming drivers' eyes is limited to 460 cd. American beams allow this zone to reach 1,000 cd along the line 0.5U/1.5L, which is twice the European values. This is the greatest legal difference between the two sides of the Atlantic. In 1998 Japan will legislate for an ECE beam for left-hand traffic, but without a cutoff.

Because such fundamental differences make special tooling inevitable, low beams are the most costly for the automobile industry. A world car today requires three separate low-beam tooling systems: ECE for left hand traffic, ECE for right-hand traffic (+Commonwealth, Japan), and USA. Depending on the techniques used, either the lenses, or the reflectors, or both, need to be duplicated to ensure worldwide market coverage.

To this we need to add the cost of specific aiming devices in the USA where non-mechanical aiming is not yet authorized.

High Beams

Figures 3a and 3b show the isocandela curves of a high beam fitted with an H7 bulb for the American and European versions of the same headlamp studied in the previous paragraph. The opening of the high beam reflector is 127 X 110 mm. The unit was initially aimed using the low beam, the lamps then being displaced horizontally by a distance equal to that separating the two H7 bulbs. There was no separate adjustment of the high beam. The two reflectors were mounted in the same dimensionally stable part.

See Figure 3

US legislation limits high beam intensity to 75,000 cd at HV. The European limit is higher - 112,500 cd per lamp. The differential beams in 3d naturally show the greater width of the beam designed for the USA, which shows two zones of greater illuminance located at approximately 5° on the HH line. This facilitates driving on winding roads.

Conversely, curve 3c confirms the stronger concentration of the European high beam, which corresponds perhaps to the habit of driving faster at night.

Even so the legislative differences concerning high beams are much less problematical than those of low beams. The window of compatibility is sufficiently large that no specific study is necessary. In economic terms that means identical tools.

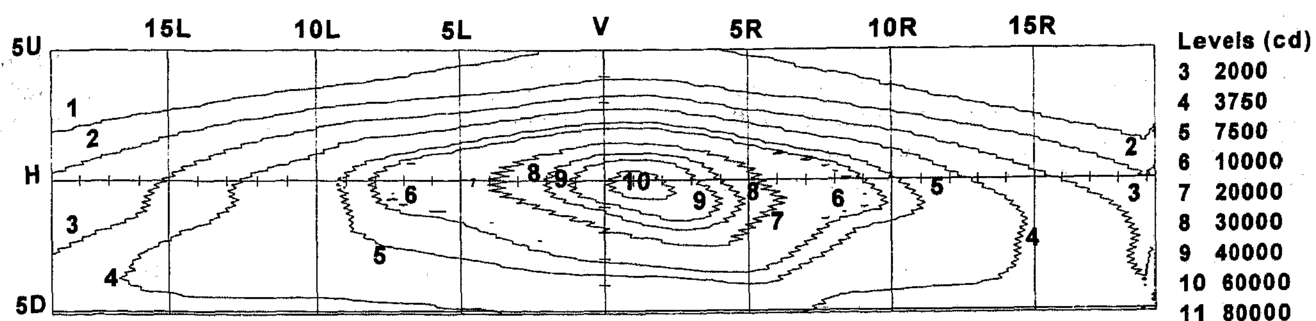

Fig 3a High beam US. MAX = 69976 cd

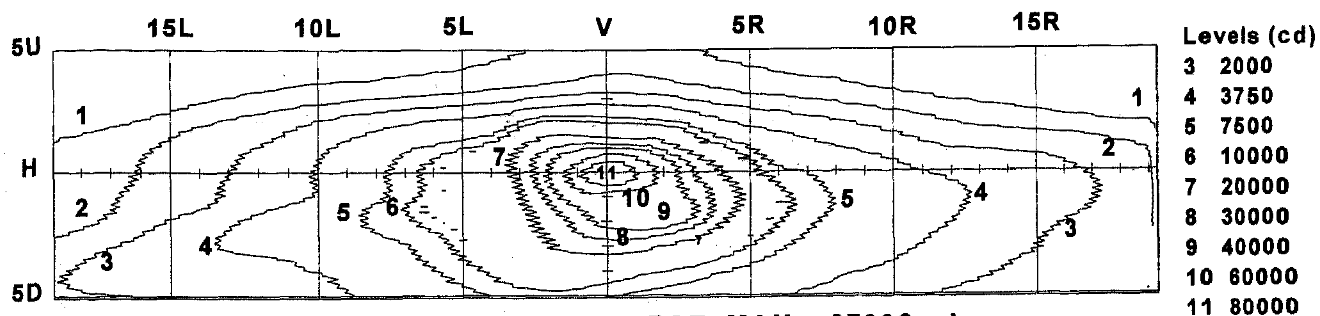

Fig 3b High beam ECE. MAX = 97336 cd

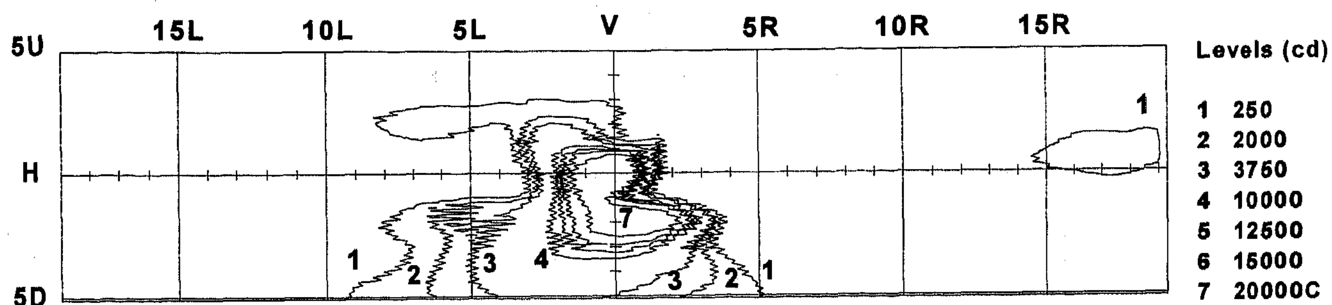

Fig 3c High beam (ECE - US). MAX = 42276cd

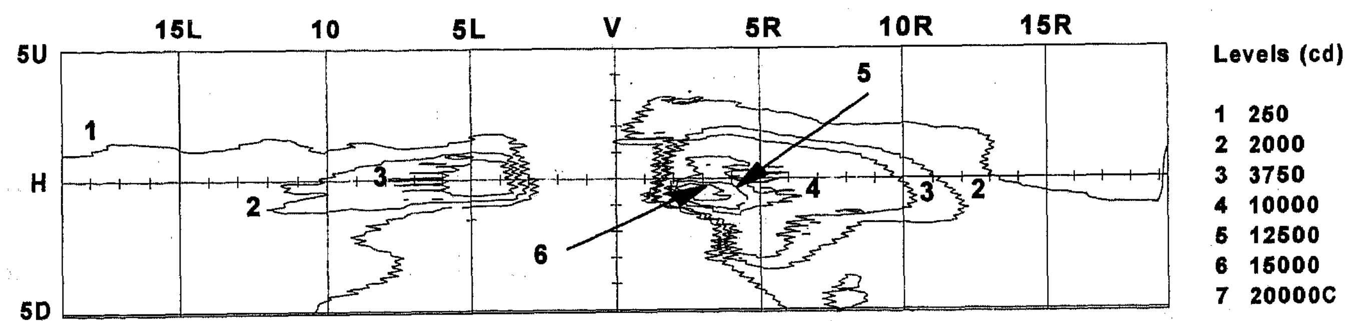

Fig 3d High beam (US - ECE). MAX = 18359cd

Figure 3

Non-regulatory Divergences

Laws and regulations can only be effectively compared if we eliminate the choices imposed by the customer, and which are the consequence of his own subjective experience or of his specific idea of night-time driving. Figures 4a and 4b show the isocandelas of the low beams of two products which comply with the regulations but which are very different in their execution.

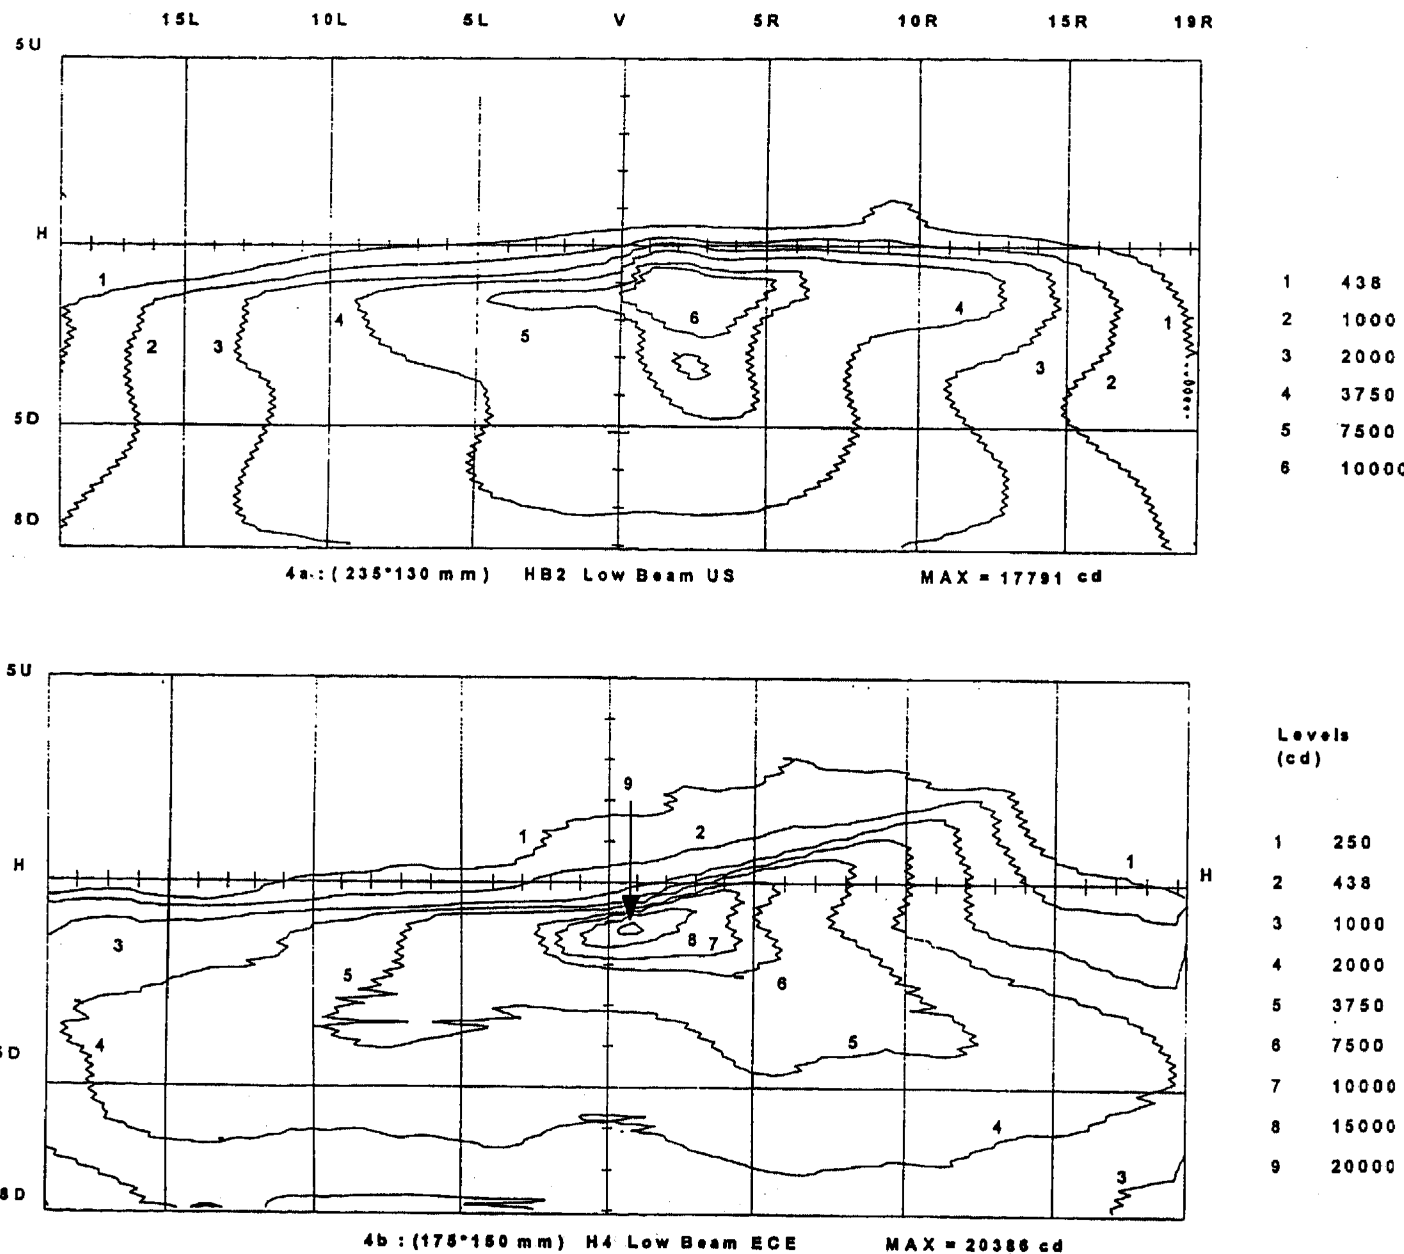

Figure 4

The lamp in 4a is a parabolic bifocal fitted with an HB2 bulb for a light truck sold in the USA. The technique is traditional, comprising a glass lens with optics, inclined at 27° in the horizontal section and at 11° in the vertical section. For this utility vehicle, the customer has opted for beam width and homogeneity, and Figure 4a shows regularly shaped isocandelas with a modest maximum of 17,800 cd.

Lamp 4b benefits from the most recent complex surface technology. It is designed for Europe, for a passenger car and is fitted with an H4 bulb with a completely smooth plastic lens. Its inclination is 40° and 17° respectively in the two sections. The reflector has two slight vertical ribs. The performance and the styling were the two main criteria of choice. The isocandela curves in Figure 4b are wider than those in 4a, and the maximum is also greater at 20,400 cd.

The H4 and HB2 bulbs which are fitted to these products differ only in terms of their mechanical characteristics. Their filaments are identical. Because of the angle of its lens, lamp 4b would be significantly less effective than lamp 4a without the complex surface technique. The deliberate choice of the designers has reversed the classification of the beams while nevertheless remaining within the legislative framework.

Such non-statutory divergences too often confuse the debate on international low beam harmonization, since they introduce subjective, or even emotional criteria. The choice which determined the structure of our investigation in paragraphs 3 thru 5 eliminates this variability.

Signal Lamps

Signaling functions are particular in that they are only partly uniform even as regards their definition.

Table 5 shows these divergences:

X: means "no requirement"

Table 5 (continued)

Japanese law has no mention of daylight running lamps, rear fog lights and front reflectors. US legislation nowhere refers to front and rear fog lights. ECE regulations fail to mention truck identification lamps while directives of the European Union, bogged down by translation into 11 different languages, continue officially to prohibit daylight running lamps, central high mounted stop lights and gas discharge light sources "by omission"...

It is not however the function of signal lamps that most hampers designers. In fact points of fundamental divergence between countries or groups of countries are relatively rare. Legislators could however simplify the task of exporters by concentrating on the following issues:

a Eliminate the minimum surface areas required for all functions in the USA and Japan,

b Authorize amber as the color of rear side position lamps in the USA and Canada,

c Harmonize the terminology for all functions,

d Authorize amber front position lamps in Europe,

e Eliminate all requirements regarding simultaneous use of the low beam with front fog lights, and of daylight running lamps with rear position lamps,

f Require the presence of rear window glass during photometry tests of CHMSLs in Europe and Japan.

g Eliminate the restrictive character of ECE R 37 regarding bulbs in Europe,

h Harmonize the two photometric variants of side position lamps in Europe.

The "Harmonization" group of the ECE working on angles of visibility should resolve certain of these contradictions.

CONCLUSIONS

None of the legal or regulatory differences of the different regions of the world seems to have a decisive influence on the safety of night-time traffic. It seems that the range of tolerance or adaptability of the manufacturers is at least as wide as the legal differences. Each country or group of countries has its own legislative coherency.

But these legal or regulatory differences are strong enough to necessitate the duplication of production tools, thus creating a financial and technical burden which is not justified by night-time driving. Therefore, it is necessary to harmonize legislation in such a way that we can focus on safe customer satisfaction, based on continuous technological innovation and standardization at most competitive cost.

ABSTRACT

The numerical optimization techniques coupled with a three-dimensional Navier-Stokes solver have been developed to design an automotive cooling fan. The conjugate gradient method is used to look for the search direction and the golden section method is used for the one dimensional search. Concerning the constraints, exterior penalty functions are employed. In the applications of this numerical optimization technique to the design of an automotive cooling fan, using the object functions defined as an increase in the pressure coefficients and a ratio of production rate of turbulent kinetic energy to the pressure head, the final shapes are obtained after sixth and seventh changes of shape function, respectively.

INTRODUCTION

Recent developments in computer hardware have increased the utility of the numerical optimization techniques in aerodynamic design. While the inverse design methods[1] are efficient for the design of simple aerodynamic geometries of which ideal flowfields are prescribable, the numerical optimization methods[2] can be general design tools because of many advantages, such as the automated design capability, varieties of constraints, and multidisciplinary applications. This numerical optimization can obtain optimal design by minimization or maximization of object function, even without any information of ideal flowfields.

Item and Baysal[3] performed a supersonic wing-section optimization considering the viscous effects of the flow to increase the lift-to-drag ratio using two-dimensional analysis. And, Huan and Modi[4] reported on design of minimum drag bodies in incompressible laminar flow in order to obtain maximum static pressure rise with two-dimensional Navier-Stokes solver. Massardo and Satta[5] carried out a design optimization of axial flow compressor with a pitchline analysis. Most of the optimization methods reported so far, have used inviscid flow analysis or two-dimensional viscous flow analysis. However, the object function evaluated with three-dimensional viscous flow analysis is desirable for the numerical optimization of complicated shapes.

The present work reports on a numerical optimization of an automotive cooling fan, for which object function is evaluated with three-dimensional Navier-Stokes solver[6]. The exterior penalty method is used with the constraints for geometric design variables related to a radial distribution of sweep angle.

DESIGN FORMULATION

The optimization problem requires the definitions of design variables, object function and constraints. General optimization problems can be expressed as follows.

$$\text{minimize} \quad f(x)$$

$$\text{subject to} \quad \begin{array}{ll} x_i^l \le x_i \le x_i^u & i = 1,n \\ g_j(x) \le 0 & j = 1,m \\ h_k(x) = 0 & k = 1,l \end{array}$$

where, $x = \{x_1, x_2, x_3, x_4, \cdots, x_n\}^T$.

In the optimization algorithm, conjugate gradient method[7] which uses the gradient vector and the information on previous search direction is used to find the search direction. In order to minimize the object function along the search direction, the golden section method is employed in this work.

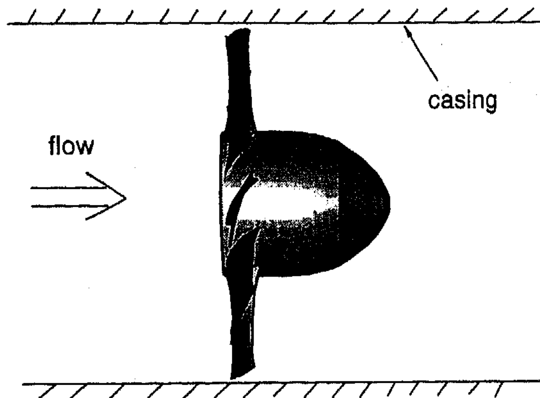

Figure 1. Automotive cooling fan model

In the design of an automotive cooling fan shown in Fig. 1, there are many geometric design parameters. The initial shape of the automotive cooling fan considered here has its own radial sweep angle distribution. The amount of sweep angle changed is defined by the following quadratic distribution function. Fig. 2 shows the design variables defined by sweep angles.

$$\gamma = a \cdot Rn^2 + b \cdot Rn + c$$

$$Rn = 0, \quad \gamma = 0$$
$$Rn = 0.5, \quad \gamma = \gamma_m$$
$$Rn = 1, \quad \gamma = \gamma_t$$

where, $Rn = \dfrac{(R - R_{HUB})}{(R_{TIP} - R_{HUB})}$.

So, in this work, two variables related to radial distribution of sweep angle are chosen as design variables; one(γ_m) is a sweep angle at the mean blade height, and the other(γ_t) is that at the tip.

In this work, the following two kinds of object function are applied to the optimization.

CASE 1 :

In case 1, the object function is chosen as an increase in the pressure coefficients between the leading edge of the fan and the outlet of duct. And, side constraints are imposed to the design variables. Thus, the numerical optimization problem of the case 1 can be stated as follows

maximize Δc_p

subject to $-0.5 \le \gamma_m \le 0.5$, $-1.0 \le \gamma_t \le 1.0$

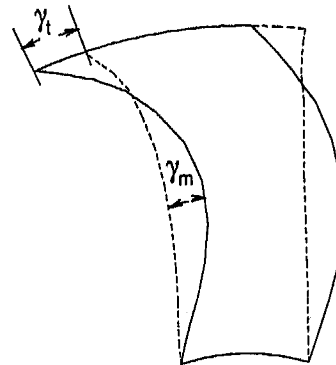

Figure 2. Definition of design variables

The pressure coefficient, c_p is defined by $(p - p_0)/\rho U_0^2$, where p_0 is the reference pressure and U_0 is the flow inlet velocity.

CASE 2 :

The object function of case 2, is chosen as a ratio of the production rate of turbulent kinetic energy(G) to the pressure head(H). And, no constraint is imposed to the design variables. The production rate of turbulent kinetic energy is considered to be related to the noise level.

minimize $\dfrac{c \cdot G}{H}$

where c is a weighting factor.

FLOW ANALYSIS

In the present optimization method, the flow analysis is repeatedly applied to the calculations of the object function and its derivatives, for the three-dimensional flow through a rotating axial-flow fan. The governing equations in Cartesian coordinates are transformed to a non-orthogonal curvilinear coordinate system. The governing transport equations are discretized by the finite volume approach[8] where the equations are integrated over a finite number of control volumes. As a numerical scheme for the convection terms, the linear upwind difference scheme is employed. The system of linear algebraic equations are solved by strongly implicit procedure(SIP)[9]. And SIMPLEC algorithm[10] as a velocity-pressure correction procedure is used in this work. In conjunction with this procedure, we employ the grid system which is not staggered. For the computation of turbulence, the present work employs k-ε model[11]. And, the empirical wall functions are used to provide the near wall boundary conditions for the momentum equations and the k-ε model.

The governing equations of elliptic type require boundary conditions at all surfaces of computational domain which consist of inlet, wall and periodic surfaces. At the inlet boundary, the axial velocities are assumed to be uniform, and the uniform turbulent kinetic energy and its dissipation rate are assumed. At the outlet boundaries, all axial gradients of the dependent variables are neglected. At the wall boundaries, no-slip condition and empirical turbulent wall law are employed. And, the periodic conditions are applied to all variables at the periodic boundaries.

RESULTS AND DISCUSSION

Fig. 3 shows the computational domain which is one ninth of whole domain. There is a motor cap in the rear of the fan. The hub-tip ratio is 0.418. The number of grid is 106×16×28. The length of the computational domain from inlet to leading edge of the blade is 2.5R, and that from trailing edge to outlet is 5R, where R is the radius of fan. And, the Reynolds number of the flow is 136,000. The effects of blade thickness are neglected. In the computation, the motor cap is treated as an obstacle, in which very large viscosity is given. The average axial velocity and the radius of casing are taken as velocity and length scales of the flow, respectively.

For the noise test, we also have carried out simple experiment. The experimental system is composed of microphone, sound level meter, FFT, and a personal computer. The measurements are made 3.3R upstream of the fan which is installed in the automobile.

The results of the case 1 are shown in Fig. 4 - 8. In Fig. 4 which shows the history of object function, it is found that the function increases steadily during the iterations. The design variables which are modified during the optimization procedure is shown in Fig. 5. It is very rare that the step size for the search along the direction is fixed in the optimization algorithm. Thus, the efficient algorithm to find the moving distance has a great role in the cost of optimization. Fig. 6 shows the history of scalar multiplier, that is the moving distance along the search direction.

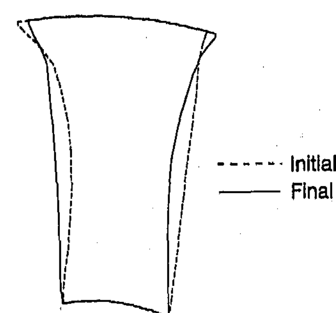

Figure 7. Initial and final shape of the blade in the case 1

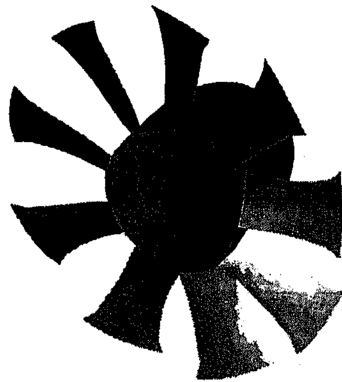

Figure 8. Final shape of the fan in the case 1

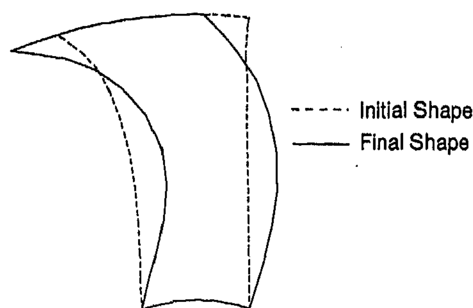

Figure 9. Initial and final shape of the blade in the case 2

After six design modifications, final shape of the blade is obtained. Fig. 7 compares initial and final shape of the blade. Fig. 8 shows the final shape of the fan in the case 1.

In the case 2, the object function is reduced from 107.9 to 89.6 after seventh update of design variables. Fig. 9 shows the initial and final shape of the blade, and the final shape of the fan is shown in Fig. 10.

Fig. 11 shows the noise spectrums of initial and final fans in the case 2, where the object function is defined as a function of the production rate of turbulent kinetic energy and the pressure head. In these results, the final fan gives the lower turbulent boundary noises and the lower discrete peaks. It seems that the noise reduction results from the suppression of relative turbulent level by minimizing the object function. The noise level of the final fan is about 4.5dB lower than that of initial fan in the region of flow rate between 1,550 m^3/h and 2,150 m^3/h. However, in the case 1, we could not obtain the better noise characteristics.

In the present work, only two design variables are used for this numerical optimization method. But, if we use more design variables related to the shape of the blade, this method can be more practical and efficient design tool for the automotive cooling fan.

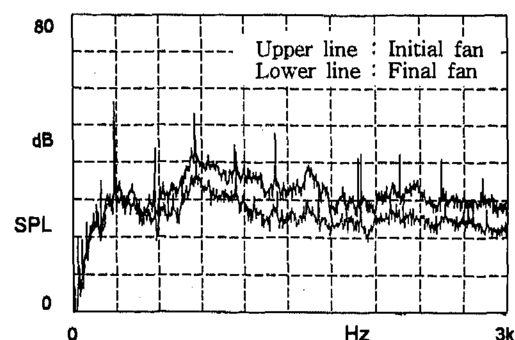

Figure 11. Noise spectrum

CONCLUSION

In the present work, the numerical optimization technique incorporated with three-dimensional Navier-Stokes solver is applied to the design of automotive cooling fan with two different object functions. The present optimization method with the conjugate gradient method obtains the final shapes after sixth and seventh updates of design variables, using the object functions defined as the increase in the pressure coefficient and the ratio of the production rate of turbulent kinetic energy to the pressure head, respectively. In the later case, we could obtain the final design with remarkable noise reduction.

ABSTRACT

Instruments and analytical techniques are described for in-vehicle monitoring of amounts of air (void fraction) in engine coolant systems and for evaluating the performance of degas reservoirs. This method, based on electrical conductivity measurements of flowing air / coolant mixture, provides measurement, acquisition and display of coolant system temperature, pressure, flow rate, instantaneous void fraction and rate of air removal by degas bottle. Embedded temperature compensation equations are used for essentially real time display of the void fraction.

INTRODUCTION

In recent years, changes in engine materials and construction have resulted in new concerns regarding air entrapped in cooling systems caused by improper fill procedures. For example, air captured in aluminum heads can cause local "hot spots" under certain operating conditions. These hot spots may cause thermal stress fracture due to the high thermal expansion characteristics of aluminum. Many engine coolant system designs now include degas reservoir (also known as quiescent bottle or Q-bottle) to afford the removal of entrapped air.

The degas bottle is a conical plastic bottle with internal baffles to increase the residence time of flowing coolant. The coolant is forced in tangentially and returned back from the bottom with a residence time of about 30 seconds. Most of the air remains in the air space above the coolant - air interface, thus facilitating continuous removal of trapped air from the coolant. These degas bottles have been is use for last few years but no comprehensive test procedure for evaluating their performance has been available. The proposed method is an attempt to develop a comprehensive test procedure for evaluating the performance and efficiency of the degas bottles in laboratory as well as in actual vehicles.

The proposed method is based on electrical conductivity measurements of the mixture of the flowing coolant - air mixture with real time temperature compensation of conductivity. The conductivity sensor is a plastic tube with four electrodes connected to a conductivity meter for signal conditioning and display. Conventionally, two electrode systems have been in use but the major disadvantage is that over a period of time, the electrodes may get coated with non-conductive contaminants. These coatings cause large changes in the apparent conductivity of the solution, making tru solution conductivity measurements inaccurate and non-reproducible. With a pair each of current and voltage electrodes as used in four electrode systems, the conductivitiy of the solution alone is measured and is unaffected by electrode fouling. A detailed description of conductivity meter used for monitoring the liquid conductivity for electrocoat paint system has been described and successfully used in electrocoat paint systems for ensuring a uniform coating by monitoring and controlling the conductivity of the paint[a]. Conductivity measurements have also been used in the two phase flow in nuclear reactors[b].

The conductivity of air is essentially zero and if it is present and well dispersed in the liquid (coolant), the conductivity of mixture should be proportionally reduced.

ıe drop in the conductivity due to presence of air can be ectly correlated to the void fraction (ratio of volume of air STP to the total liquid volume). This would normally ld true for constant temperature systems. But the nductivity rises with increase in temperature and ıpirical temperature compensation equations are veloped and used to convert the conductivity value to a iform base temperature of 20 °C.

After completing the calibration process, initial ts were done by installing a degas bottle in the test rig; ɔsequently, tests on three different vehicles - a pickup ck, a heavy diesel truck and a passenger car, were npleted. The data for the two trucks are presented e.

PERIMENTAL SET UP

DESCRIPTION OF CONDUCTIVITY METER - e conductivity sensors are fabricated of nylon, starting n a single solid rod and machining as required for ling a hole, preparing the ends and screwing in the ctrodes and fittings for thermistor probe. Sensors for , 1 and 2 inch coolant hose have been used. The ısor sizes were chosen so as to coincide with the typical t(s) and outlet diameters of the degas bottle for light ks and heavy diesel trucks. A sketch of the ıductivity sensor is given in Figure 1.

1: Sketch of Conductivity Sensor

As mentioned above, the conductivity rises with ɔerature and the relationship is used to compensate effect of temperature on the conductivity value. The sure and flow rate of the circulating liquid have no t on the conductivity in the absence of any air. ever, if air is present, the volumetric expansion of d and the air pressure have to be taken into account, cially for closed systems. Air bubbles of varying size ong as the volume of each bubble is much smaller than the cylindrical volume between the two central electrodes) do not affect conductivity values.

The temperature is measured using a linearized thermistor probe (1μA/°C) installed within the body of the sensor so that the temperature can be measured at a location very close to the conductivity measurement. The signal conditioning for the temperature readout and digital display is also built in the conductivity meter. The back of the conductivity display box accepts nine pin connectors, and each pin is specifically assigned to electrodes on the conductivity sensor and the thermistor probe.

DESCRIPTION OF CALIBRATION RIG - The calibration rig has been installed in the modular, fully portable fashion and stands on a 1 m^2 chassis with wheels. All the pipelines, pumps, motor and coolant reservoir rest on the self supporting structures. In addition, shelves have been provided for all display instruments and the notebook computer used for data acquisition and analysis. The schematic of the calibration rig is shown in Figure 2, including the connections for degas bottle, which are described later.

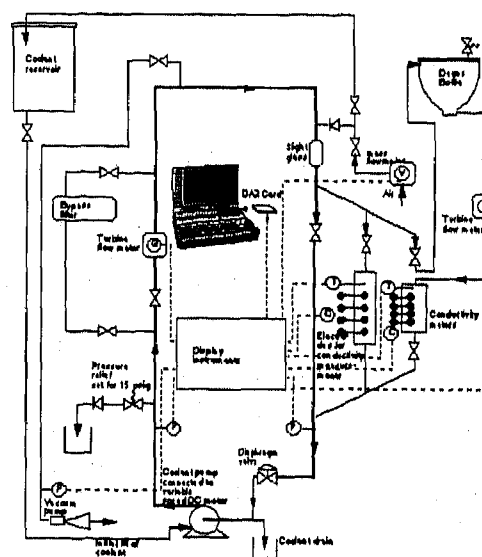

Fig 2: Schematic of Calibration Rig

A 5.5 liter truck pump for coolant circulation is rested on the base frame and connected to 0.5 hp, 3450 rpm dc motor. The pump has been completely sealed off to prevent any leakage. The speed of the motor is varied using a dc controller connected to the motor and is mounted on the instrument panel. The two discharge ends of the pump are merged together and the coolant is circulated through 1¼" copper pipe. The circulation loop forms a vertical rectangle, roughly 0.6 m x 1.8 m high. A turbine flow meter with oscillator / amplifier and digital panel meter is installed in the line to measure the circulation flow rate. Pressure transducers for 0-25 psig (0 - 175000 N/m^2) have been provided at the pump suction and discharge. Occasionally, the coolant may

need to be filtered, and thus, a bypass filter with isolation valves is provided midway between the pump discharge and the highest point in the system. The highest point is connected to a vacuum pump, through a liquid trap, so that the pipelines can be evacuated before the initial fill and subsequent topping up of the system.

The 1¼" copper pipe branches into three lines before the pump suction to accommodate installation of three conductivity sensors of sizes up to ½, 1 and 1½ inches. The diameters and angles of elbows of the network have been selected so as to distribute flow among different branches depending upon the cross sectional area of each branch. The flow of liquid through any or all branches can be controlled by partially closing the butterfly valves provided upstream of each conductivity sensor location. The three branches are merged together and connected to the pump suction through a diaphragm valve. By partially closing the diaphragm valve, it is possible to generate additional pressure inside the system, especially for the situation when no air is present so that the liquid compression boosts up the pressure. Air can be introduced at a controlled rate through a mass flow meter, capable of handling up to 1 liter / minute of air at STP conditions. A sight glass has been provided for visual observation of the air - coolant mixture.

DATA ACQUISITION / ANALYSIS - The data acquisition, on-line display and data analysis are made with IBM thinkpad 750C notebook computer using LabVIEW® for Windows version 3.0.1 software supplied by National Instruments. LabVIEW is an integrated graphical programming system for data acquisition, control, analysis and presentation. Instead of writing computer programs for data acquisition, virtual instruments (VIs) are built on the computer screen using graphical icons. VIs, with their pictorial representation, are easy to modify and maintain, and are completely self - documenting. Before building a VI, a front panel is created with all required knobs, slides, switches, graphs, strip charts and so on. The front panel serves as an interactive interface for supplying inputs to, and observing outputs from the instrumentation system. Once the VI is completed, the front panel alone is used to control the system - even while it is running - by clicking a switch, moving a slide, tweaking a knob, selecting items from menu, or entering values from the keyboard. The front panel immediately starts displaying the data, providing real time feedback from the system.

The data were acquired using a PCMCIA (Personal Computer Memory Card International Association) data acquisition card with IBM thinkpad notebook computer. The DAQCard-700, supplied by National Instruments is a type II PCMCIA I/O board, requiring very little power (120 mA at 5 volts DC) so that it can be used continuously with the battery powered PCs. The card has a 12-bit analog to digital conversions with 16 single ended analog inputs, an 8-bit TTL-compatible digital input port, an 8-bit TTL-compatible digital output port, and two user - available 16-bit counter / timer channels. All the instruments are wired using regular screw terminals to a 50 point connector block assembly, which, in turn, is connected to the data acquisition card through ribbon cable.

The combination of DAQCard 700 and LabVIEW software is capable of sampling up to 16 channels at a rate of up to several thousand data points per second. With the additional constraints of real time graphic display and use of temperature compensation equations and other correction factors, it was found that up to about 200 points can be sampled every second. For a typical configuration of about 10 channels in use at a time, each graph could be updated about 20 times per second. But in order to minimize the noise in signals, usually 10 to 30 point averages are used and thus, screen updating every one or two seconds is most practical.

CALIBRATION DATA

TEMPERATURE COMPENSATION OF CONDUCTIVITY - The most important and crucial calibration data is the effect of temperature on conductivity of the coolant (ethylene glycol - water mixture). The conductivity has been found to increase roughly 4% for every degree Celsius rise in temperature at ambient conditions, with the slope tapering down to about 1% at actual operating temperatures of 100° C or more. Because of a large temperature range to be considered (20° - 100° C), extreme care is required in temperature compensation of conductivity so as not to cause any great errors at high temperature range. Since each thermistor may have slightly varying temperature slopes, each sensor was individually calibrated using respective thermistor and conductivity meter. Most of the data were obtained by simultaneously using one 3/8 inch sensor and one 1 inch sensor installed in the two smaller branches of the calibration rig, while the largest diameter branch was used for bypass.

In a typical calibration run, the rig is evacuated using the vacuum pump to the best of its capability of about 25 mm Hg (3000 N/m^2) and filled with coolant from the reservoir. Some air is still trapped in the pipelines and is sequentially removed by using either or both of the following procedures, one or more times as necessary. Some liquid is drained from the rig, leaving extra air space at top, at which point vacuum pump is started again. Since there is lesser air to be removed (about 0.5 - 1 liter as against 7.2 liters at the beginning), an absolute pressure of less than 25 mm Hg (3000 N/m^2) is reached quickly, leaving very little residual air. The procedure may be repeated again, if necessary. Alternatively, the diaphragm valve near pump suction may be closed to compress the liquid, with all air accumulating at top, which can be discharged to atmosphere. The diaphragm valve is then opened, and more coolant allowed to flow from reservoir.

By switching on the motor controller, coolant is re-circulated at desired speed and flow rate. For pump rpm of about 3000, a discharge flow rate of up to 60 gallons / minute (0.0038 m^3/sec) can be obtained. Most of the experiments are conducted at 40 - 50 gpm (0.0025 - 0.0031 m^3/sec). These flow rates were chosen so as to be compatible with the actual water pump performance.

Three heating tapes are wrapped around different locations in the calibration rig. To get the conductivity data over a wide temperature range without concentration of data over any specific range, only one heater is started at the beginning, and the data acquisition is started. When the temperature slope tapers off, second heater, and then the third, as required, are started. The heat input through some of these heaters can also be controlled by adjusting the voltage in the variac. Most of the no void calibration data have been obtained for temperature range of ambient to 100° C. At the end of the run, heating tapes are switched off, and circulation continued for some time to avoid overheating of the pipelines.

During the entire period, pressure relief valve, set for 15 psig (10^5 N/m^2), is kept open to avoid excessive build up of pressure in the system. The liquid expands with the rise in temperature, and since there is no air space for expansion, the coolant starts dripping out through the pressure relief valve. The amount of liquid drained through the pressure relief valve should be the same as the increase in liquid volume from the onset of activation of pressure relief valve to the end of the run.

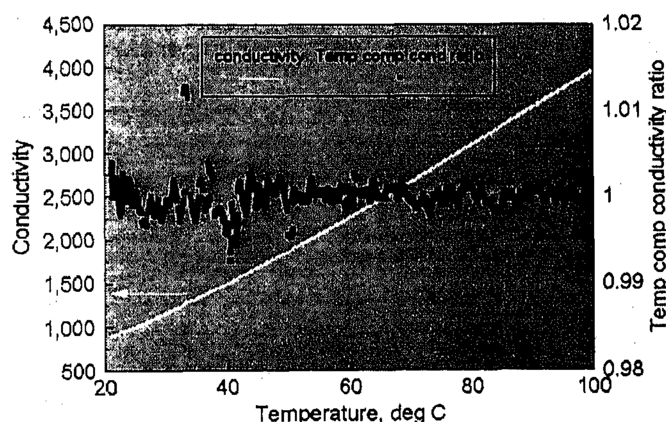

Fig 3: Conductivity - Temperature Graph for no-Void Calibration of 1 inch diameter sensor

The conductivity - temperature graph for a no void basis of a typical run is shown in Figure 3 for a 1" diameter sensor. Very similar graphs were obtained for other sensors also. The conductivity (in arbitrary units - only the change in conductivity is important rather than its absolute value), is found to depend on temperature according to quadratic equations. These equations are expected to be valid over the entire temperature range of 20 to 100° C for which data were taken at the calibration rig and can be extended up to 120° C, the highest system temperatures, expected in a vehicle cooling system. However, at lower temperatures cubic equations were found more appropriate, as described below:

<u>Sensor A (3/8 inch diameter):</u>

(T>91 °C):

$$C = 820.16 + 32.089(T-20) + 0.09781(T-20)^2 \quad (1)$$

(T≤91 °C):

$$C = 850.34 + 27.464(T-20) + 0.24308(T-20)^2 - 0.00121143(T-20)^3 \quad (2)$$

<u>Sensor C (1 inch diameter):</u>

(T>91 °C):

$$C = 838.77 + 31.618(T-20) + 0.09715(T-20)^2 \quad (3)$$

(T≤91 °C):

$$C = 864.15 + 27.824(T-20) + 0.21485(T-20)^2 - 0.00097178(T-20)^3 \quad (4)$$

For normalizing the conductivity to a base temperature, the temperature compensated conductivity ratio (TCCR) is defined according to equation (5).

$$TCCR = \frac{C_i}{\alpha + \beta(T_i - 20) + \gamma(T_i - 20)^2 + \delta(T_i - 20)^3} \quad (5)$$

In this equation, C_i and T_i refer to the instantaneous conductivity and temperature of a sensor. α, β, γ and δ are the coefficients of the conductivity - temperature relationships given in equations (1) to (4). Figure 3 also shows the temperature compensated conductivity ratio for sensor C over a temperature range of 20 - 100° C. The numerical value is reasonably constant and is found to be 1.0±0.005 over this range. The nominal noise is due to the limitations of the instruments and the data acquisition system.

CALIBRATION WITH KNOWN AMOUNTS OF AIR - To check the void fraction dependency of conductivity, several runs with known amounts of air were made. In a typical experiment, the calibration rig is completely filled with coolant as described earlier. An initial check of the complete fill (no voids) is made by circulating the coolant and checking the instantaneous temperature and conductivity for each of the two sensors at ambient temperature by running the data acquisition software and watching the temperature compensated conductivity ratio on computer screen as calculated using equation (5). If TCCR is 1.0±0.005 (allowing for experimental errors), the experiment is continued; otherwise, the fill of the calibration rig may not be completely void free, or another problem exists, and the whole process of filling needs to be repeated.

Once the system is completely filled, a known amount of air is introduced through the mass flow meter. Using a small air flow rate of 100-200 ml/minute at STP (1.7×10^{-6} - 3.3×10^{-6} m^3/sec), equivalent amount of liquid is continuously discharged from the bottom of the pump. Once the desired amount of air has been injected (as indicated by time elapsed, as well as the volume of the

liquid expelled), air line is shut off, immediately after which, the drain valve is closed. The collected volume of the liquid is weighed, and thus, the volume discharged is quantified. The system volume is known to be 7.2 liters and so the void fraction artificially introduced is determined. The pump is started and the homogeneity of the mixture is monitored through the sight glass. When the system is homogeneous (indicated by visual observation through the sight glass as well as constant conductivity value), 'START' button on the computer screen is pressed to start the data acquisition and display the results on the computer screen.

The temperature of the system is raised in the same manner as for no void basis, by sequentially starting the heating tapes one by one. With enough air in the system, the pressure relief valve should not be opened, and the pressure is allowed to rise till the upper limit of transducers (25 psig). With small amounts of air (void fraction < 0.04), the system pressure reaches 25 psig (175,000 N/m^2) before the 100° C temperature, at which point the system is shut down. For higher void fractions, data acquisition is continued till the temperature reaches 100° C. Results from several runs with varying amounts of air are shown in Figure 4.

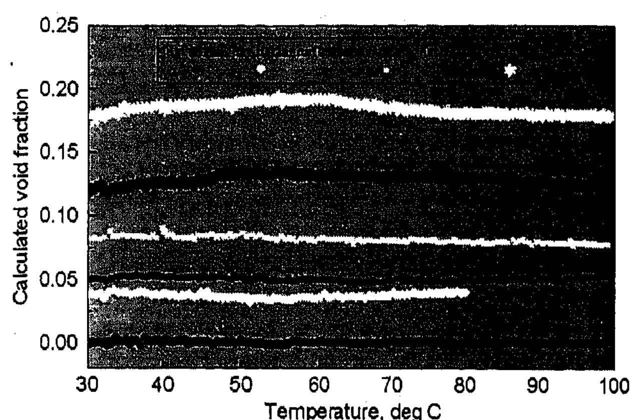

Fig 4: Calibration Data with Varying Amounts of Air

As expected, the void fraction based on these calculations remains constant (same as the initially created void fraction) throughout the experimental temperature range, subject to the experimental error. In the temperature compensation of conductivity, an error of up to ±0.5% can be expected. While accounting for liquid expansion and other unforeseen circumstances, the method is found accurate up to about ±0.75% over the entire temperature range from 20 - 100° C and initial air content of 2 - 16 % for which the experiments were conducted.

DEGAS BOTTLE TESTS IN LABORATORY

Initial tests for evaluating the performance of degas bottles have been conducted in the laboratory set up. A fixture for mounting the degas bottle was built and attached to the chassis on which other equipment rest. The height of degas bottle is adjustable, and is kept at a location so that the maximum liquid level in the degas bottle is at the same vertical level as the highest point in rest of the system. This arrangement ensures that overflow of degas bottle would be avoided at all times.

The pipelines upstream of one of the branches (3/8 inch) of the discharge end of the circulation loop were modified to include connections with the degas bottle. Isolation valves have been provided in the main line so that degas bottle can be brought into service whenever required; at other times, the main loop (without one conductivity sensor) can be operated in the usual manner. The complete schematic of the calibration rig with degas bottle attachments has been shown in Figure 2.

The laboratory tests have been conducted at ambient and near - ambient temperatures (<50° C). In a typical experiment, the degas bottle loop is isolated and the main system is filled with coolant completely, without any voids or air bubbles. The coolant is circulated and the no-void conductivity is established using the first sequence of the VI on the computer screen. As outlined in previous section, a known amount of liquid is drained while simultaneously substituting with ambient air. The heating tapes may be switched on, if desired, to get the data at elevated temperatures. The mixture in main loop is allowed to homogenize by re-circulation and the 'START' button on the computer screen is pressed to start data acquisition. The void fraction graph on computer screen, of course, indicates a constant void fraction equivalent to the artificially created void fraction in the main system.

To bring degas bottle in the service, it should be pre-filled with liquid level up to the 'maximum level', and with no air bubbles or voids in rest of the pipelines. Both the valves on the main system - inlet to the degas bottle, and the outlet from the degas bottle into main loop, are simultaneously opened. The liquid level in the inlet line momentarily drops, after which, the coolant - air mixture enters the degas bottle. The flow pattern of the coolant - air mixture can be clearly seen inside the degas bottle, especially if the mixture is very milky with air content exceeding 10% of the total system volume.

A very steep drop in the void fraction is observed for several seconds, as displayed in the graph on computer screen. This is followed by tapering of void fraction, ending with asymptotic behavior with nearly zero void fraction. Typical operating conditions consist of coolant flow rate of 40 gpm (0.0025 m^3/sec) with 2-5% flow through the degas bottle. The void fraction reaches zero in about 20 - 30 minutes. A typical graph, with an initial void fraction of about 6% is shown in Figure 5 and another with 14% initial void fraction is given in Figure 6. The horizontal portion of the graph shows the void fraction before connecting degas bottle to the system, showing a constant void fraction. As soon as the degas

bottle is connected, it starts removing the air from coolant. The slope of void fraction vs time is exceptionally high during the first 30-60 seconds, indicating a very high rate of air removal. The tapering down zone, followed by asymptotic behavior follows a pattern similar to an exponential decay curve. The void fraction reaches 0.5% slightly faster in case of lower air content but the rate of air removal is not remarkably different for the two cases.

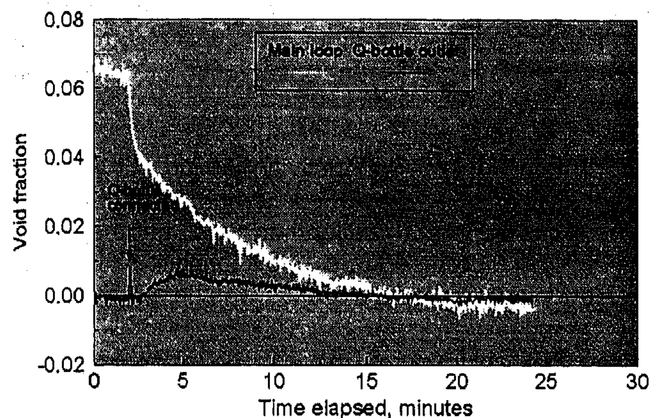

Fig 5: Air Removal from Degas Bottle for 6% Initial Void Fraction

The laboratory tests were conducted with the degas bottles of pick up truck, heavy diesel truck and a passenger car. The shape, size and geometry of baffles of these bottles are different but the working principle is same in all cases, with a residence time of 20 - 30 seconds. In each case, air in the system drops down to below 1% within 15-20 minutes.

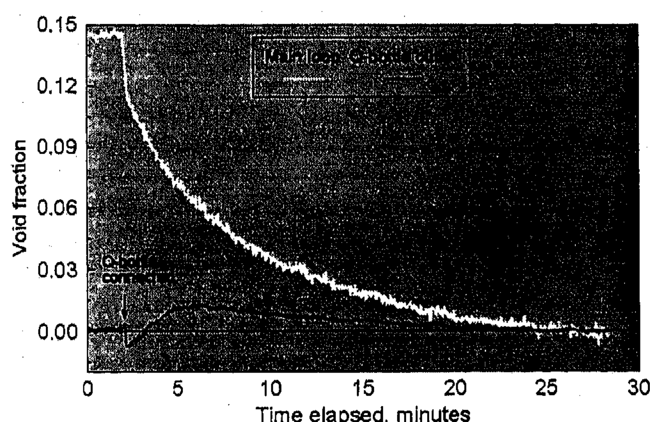

Fig 6: Air Removal from Degas Bottle for 14% Initial Void Fraction

After the coolant was left in the experimental rig for several weeks, the degas bottle test was repeated a few more times at varying flow rates. It was found that when the degas bottle flow rate was well below 1 gpm ($6.3x10^{-5}$ m^3/sec), the de-aeration took place in the normal way but when flow through the inlet nozzle was increased to greater than 1 gpm ($6.3x10^{-5}$ m^3/sec), degas bottle stopped functioning and in fact, started putting air back into the system. These characteristics are shown in Figure 7 which shows four clear zones of flow rates through the degas bottle. Initially, the flow was maintained at 1.1 gpm ($7x10^{-5}$ m^3/sec) for which the void fraction could not be brought below 0.06. When the flow was dropped to 0.55 gpm ($3.5x10^{-5}$ m^3/sec), the de-aeration followed the regular exponential decay trend and the complete removal of air was observed in 25 minutes. The flow rate was increased back to 1.1 gpm ($7x10^{-5}$ m^3/sec) at which time, the degas bottle started putting air back into the main loop till the void fraction was about 0.07. This step took roughly 20 minutes. When the flow rate was cut back to half again, degas bottle stared de-aerating again. During the entire run, the fractional flow through the degas bottle was maintained between 3.5 - 4% of the total flow.

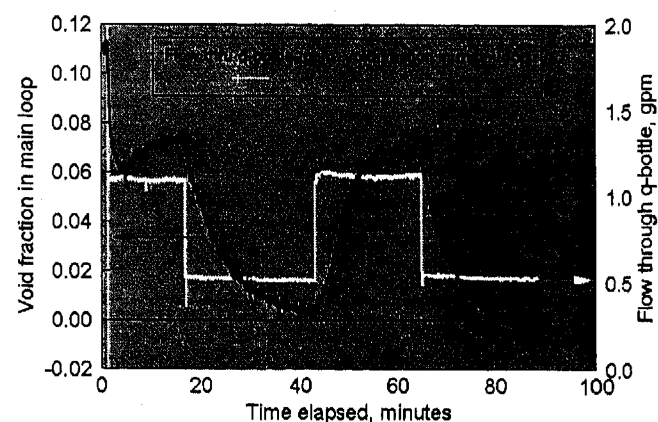

Fig 7: Degas Bottle Re-aeration with High Flow and Aged Coolant

It seems that the behavior of degas bottle is a complex function of maximum permissible flow as well as the aging of the coolant. When the coolant was changed, the results could not be reproduced. The long exposure of the coolant to the atmospheric oxygen may have been responsible for loosing the characteristics of the anti-foaming agents used as additives in coolant.

VEHICLE TESTS

Based on the success of the technique for monitoring void fraction in laboratory degas - bottle set up, additional tests were conducted on vehicles. In order to get the data based on wide operating conditions, tests were conducted on three different vehicles - 5.4 liter F250 pickup truck, 12 liter L9000 diesel truck and a 3 liter Taurus car. The data for the diesel truck were obtained in a chassis dynamometer set up whereas other two vehicle tests were conducted at fast idle conditions without putting any load. Data for both the trucks are presented here.

The de-aeration data are best obtained by monitoring the conductivity in a continuous flow loop and therefore, heater core loop was considered for all the

tests. Some data were also obtained at the degas bottle outlet and radiator inlet. A typical cooling system schematic is shown in Figure 8, showing the sensors at the inlet of heater core, where the coolant is hottest. The coolant flow through the conductivity sensor, where pressure, temperature and conductivity are monitored, and then the direction is reversed while installing the turbine flow meter. The outlet of flow meter is connected back to the heater hose. The additional instruments and hoses increase the cooling system capacity by about one liter, which roughly equals the additional amount of void artificially created at the time of each fill up.

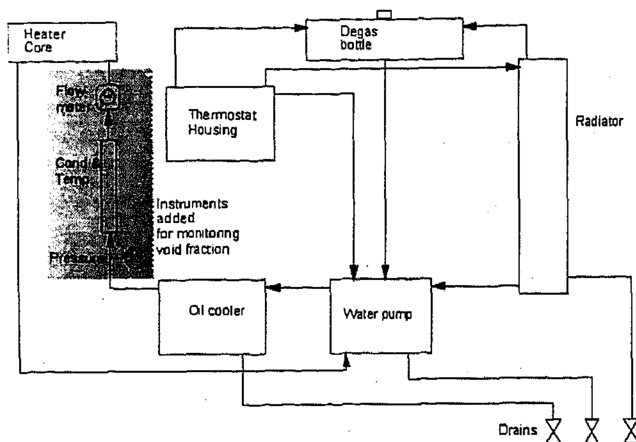

Fig 8: Cooling System Schematic

Following strategy for a cooling system de-aeration measurements was adopted for the vehicle testing:

(1) Install the instruments at the heater core

(2) Establish the exact capacity of the cooling system with incorporation of additional instruments and hoses. The cooling system is completely drained and measured amount of coolant added. Vehicle is started and a few minutes after thermostat opens up, shut down and then allowed to cool. The system is refilled with coolant and the cycle is repeated 2-3 times as necessary.

(3) Run the data acquisition system for completely filled cooling system for normalization.

(4) Run the de-aeration measurement tests at idle, typical operating and an intermediate rpm with a known volume of coolant which is deliberately under-filled.

(5) Repeat the tests at the above rpm's for different amounts of coolant so as to have different initial void fractions.

(6) As additional tests, run the vehicle at idle rpm and gradually raise the speed to speeds higher than typical operating speeds and observe the rate of air removal as a function of vehicle speed.

L9000 HEAVY DIESEL TRUCK - The de-aeration tests for L9000 diesel truck were made at APX International, 1120 John A Papalas Drive in Lincoln Park. The truck is equipped with a 12 liter engine from Detroit Diesel. All the measurements were made in the chassis - dynamometer set up wherein the vehicle was operated under closely monitored load to simulate the actual driving conditions. The set of instruments was installed at the heater core inlet. A sight glass was also provided at the radiator inlet for visual observation of the vehicle de-aeration.

To account for conductivity variation of water at different locations, samples of coolant and water from the site were carried over to calibration rig to get the actual conductivity - temperature relationship. Following conductivity - temperature equation was generated:

$$C = 835.92 + 31.714(T-20) + 0.20765(T-20)^2 - 0.00097753(T-20)^3 \quad (8)$$

The total capacity of the cooling system (including the degas bottle and additional pipelines / instruments) was found to be 36.1 liters and the runs on different days were conducted by under-filling the system by 2 to 5 liters, making sure that some liquid always existed in the degas bottle to avoid the possibility of re-entraining air back into the system. All the tests were conducted in the dynamometer room by running the truck under a known load and speed. A heavy duty fan installed in front of the truck was used for cooling the radiator and engine between two successive runs on the same day. The typical operating speed of this truck is at 1800 rpm, based on highway driving at 55 miles per hour, while the recommended maximum rpm is 2100.

The vehicle needed to be drained completely and refilled to desired capacity before every run. This was accomplished by draining coolant from the water pump, oil cooler and bottom of the radiator under gravity. Extended hoses and valves / pet cocks were provided for each line to facilitate easy drainage. When no more liquid flowed, compressed air was surged through a specially fabricated degas bottle cap which accepts ¼ inch compressed air line. Usually, compressed air at 10-20 psig (70000 - 140,000 N/m^2) was found to adequately drain the complete coolant in about 30 minutes. The drained coolant was always collected and measured to make sure that all coolant put in for the run was collected.

Figure 9 shows the temperature and de-aeration data at 1300 rpm. The truck was started by putting a load of 50 hp on each axle, simulating a speed of about 40 MPH which was maintained constant throughout the run. The temperature started rising within one minute of starting the truck and the thermostat started opening

within 7 minutes of the start up. The graph shows the temperature oscillations for about 2.5 minutes, going through 4 cycles. During this period, air removal rate is very high as observed on the computer screen as well as the sight glass at radiator inlet. Once the thermostat is fully open, the temperature continues to rise and is controlled by the radiator fan which kicks in at about 93 °C. The temperature oscillates between 83 and 93 °C, leaving the thermostat partially closed for a few seconds during each fan cycle, lasting about a minute each. Some air trapped in the cooling system shows up in the conductivity sensor and therefore, the graph shows continuous oscillations in the calculated void fractions. Rate of air removal tapers down during this period, showing the complete removal in over 30 minutes after the first opening of thermostat. Even if the vehicle is run for a long time, the characteristics of the void fraction curve do not change.

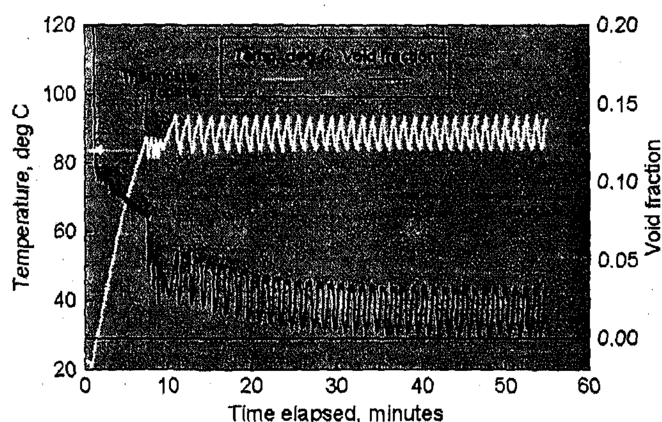

Fig 9: L9000 Heavy Diesel Truck De-aeration Data at 1300 rpm

The pressure and the flow rate at the heater core are shown in Figure 10. The pressure steeply rises till thermostat opens up, after which it cycles along with the thermostat opening and closing (decreases when thermostat closes after shutting off of radiator fan), with gradual overall drop in pressure. The flow rate remains fairly constant at 3 gallons per minute (0.00019 m^3/sec) with only minimal variations with the cycling of radiator fan.

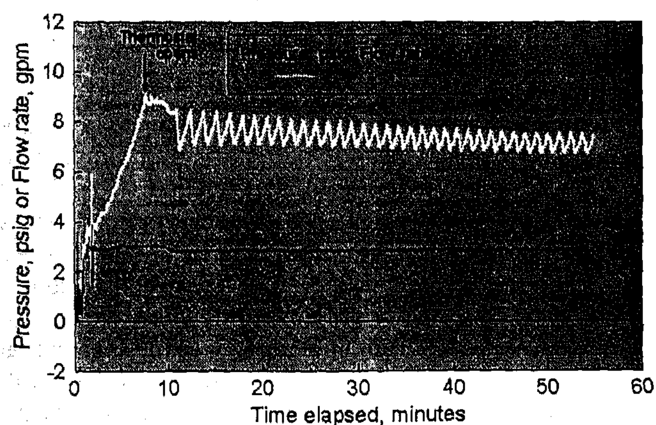

Fig 10: L9000 Heavy Diesel Truck Pressure and Flow Rate at 1300 rpm

It was noticed that the truck had to be operated with at least 1300 rpm (simulating a speed of 40 MPH) for reasonably good de-aeration. Figure 11 shows the temperature and void fraction data at 1000 rpm (based on 30 hp load on each axle, simulating a speed of 25 MPH). Although 10% void fraction had initially been created, it does not show in the graph because all air pockets are not removed by the flowing coolant. Thermostat takes longer to open (about 12 minutes) and the radiator fan cycling is much slower. Although the graph shows only small void fraction, all air had not been removed by the degas bottle, as evident from the fast approach of void fraction towards zero value.

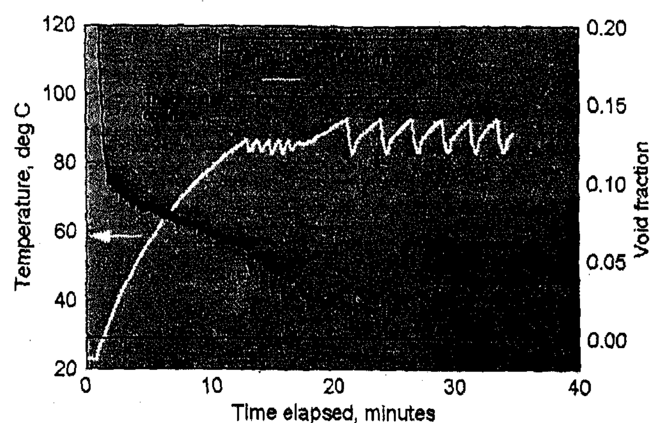

Fig 11: L9000 Heavy Diesel Truck De-aeration Data at 1000 rpm

In order to compare the de-aeration data at heater core loop and the radiator inlet, another conductivity sensor (2 inch diameter) was built and installed at the radiator inlet. Using the sight glass, it had been observed that the air is not uniformly distributed along the entire cross section. There is always more air at the top than the bottom part of the sight glass. Therefore, two sets of electrodes were used - one set was inserted from top and the other from bottom. The output of both was combined to get the data representative of the entire cross section. The comparison of void fraction observed at both the locations is shown in Figure 12 for one run at 1800 rpm. The data from the radiator sensor is meaningless before the opening of thermostat as well as immediately after opening of thermostat because of very large amount of air flow. The instruments could not detect a very rapid change in conductivity. However, the data is presented for the period after the thermostat had been open for a few minutes. Both the curves follow the void fraction cycling with the radiator fan, and are in phase. The de-aeration at the radiator inlet was slightly slower than the data at heater core. This confirms the fact that a small amount of air always resides in the cooling system and shows up only during the closing period of thermostat.

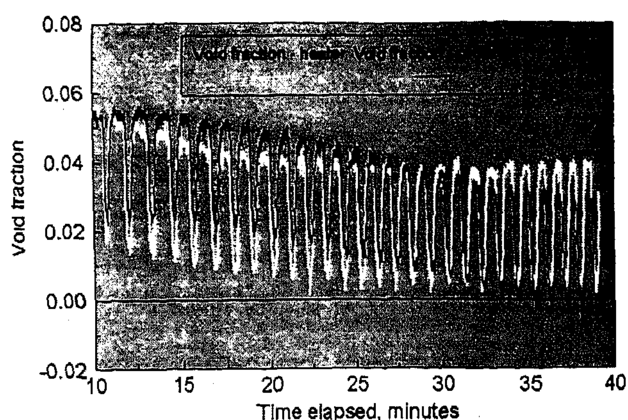

Fig 12: L9000 Heavy Diesel Truck De-aeration Data at 1800 rpm - Comparison of Void Fraction at Heater and Radiator

F250 PICK UP TRUCK - The tests on PN102 vehicle, an F250 pickup truck, .were conducted in the garage of Carron & Company at 26700 Princeton Avenue in Inkster. As explained above, instruments package was installed in the heater core loop. An additional set of instruments package was also tried at the degas bottle outlet for continuously monitoring the air removal efficiency of the degas bottle. However, the conductivity and flow sensors did not work because the flow was not continuous and suitable signals could not be generated with any reasonable confidence. The signal conditioning instruments, data acquisition system and the notebook computer rest on the passenger seat on a sheet metal tray. The conductivity of water and coolant mixture at this site was different than the values obtained at calibration rig, and therefore, a correction factor of 1.36 was applied for all on line calculations.

The total capacity of the cooling system was found to be 16.5 liters and the runs on different days were conducted by under-filling the system by 1 to 3 liters, making sure that some liquid always existed in the degas bottle to avoid the possibility of re-entraining air back into the system. All the tests were conducted on high idle speed in the garage without putting any load on the vehicle. A floor fan put directly in front of the radiator was used for controlling the temperature and for simulating the actual driving conditions.

The vehicle had to be drained completely and refilled to desired capacity before every run. This was accomplished by draining the engine drain block and bottom of the radiator under gravity. To facilitate easy drainage from engine, a pet cock was installed at the engine drain block. When no more liquid flowed, compressed air was surged through the degas bottle inlet (while clamping the line from top of the radiator which was connected to the degas bottle). The drained coolant was always collected and measured to make sure that all coolant put in for the run was collected and accounted.

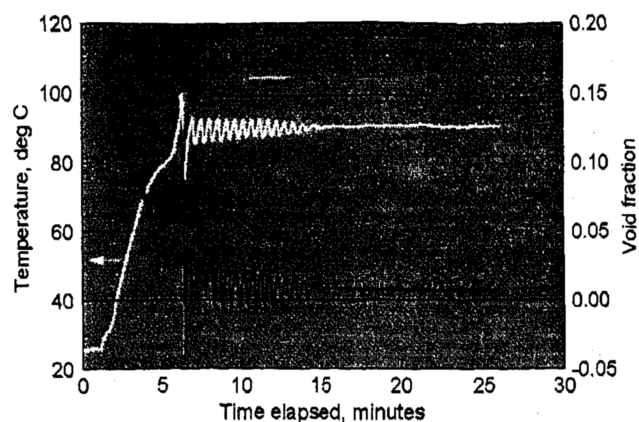

Fig 13: F250 Pickup Truck De-aeration Data at 2500 rpm

The data from a typical run are shown in Figure 13 wherein the temperature and calculated void fraction are plotted against time from the beginning of the data acquisition. For first minute, only the base conditions were recorded, at which time, the engine was started and quickly raised to desired rpm. The temperature in the heater core gradually rises and the thermostat opened up after about 5.5 minutes. Right at this moment, the degas bottle enters the coolant circulation loop and the void fraction starts dropping. For several minutes, the thermostat goes through the cycle of opening and closing (about 8.5 minutes for this graph) with an oscillation period of roughly 35 seconds between two consecutive cycles. The temperature subsequently becomes constant with thermostat in fully open position.

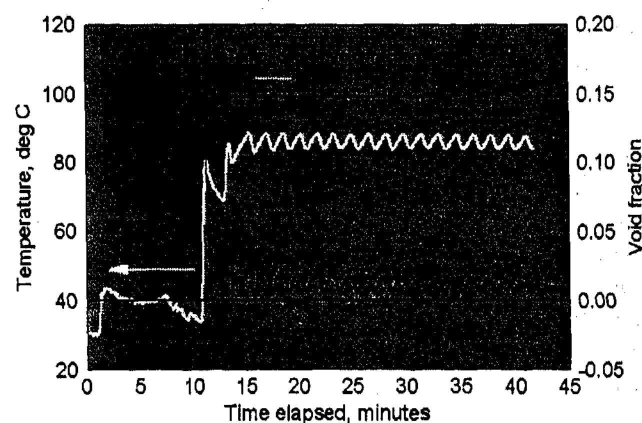

Fig 14: F250 Pickup Truck De-aeration Data at 700 rpm

In many instances, the temperature rise in heater core was not steady, rising marginally and jumping to about 85 °C as soon as thermostat opened. This could be attributed directly to the level of coolant in the degas bottle. When the cooling system was highly under-filled and / or the vehicle was operated at low rpm, the heater core temperature rise was never steady. Figure 14 shows the data at idle rpm, indicating that the thermostat opened up after 10 minutes of vehicle operation with temperature suddenly jumping to the operating temperature when the thermostat opened. A large amount of air was entrained in the system but could not

be picked up by the flowing coolant. Although the graph shows near zero void fraction, air still remained in the system. This is apparent based on high void fraction shown when the thermostat opened up. Further, even after 30 minutes of vehicle operation, the thermostat oscillations continued without any dampening effects in temperature. This shows that air entrained in the cooling system can not be removed at low rpm.

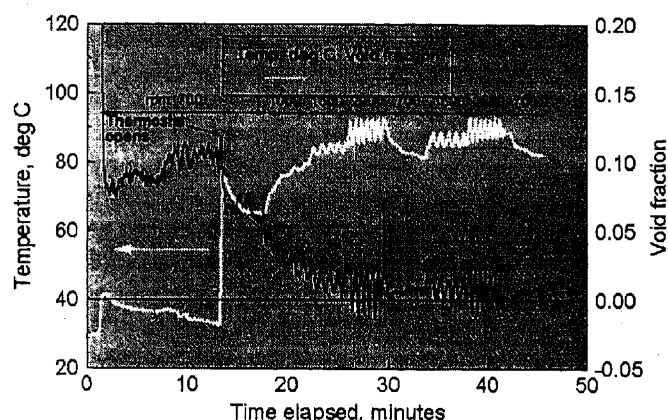

Fig 15: F250 Pickup Truck De-aeration Data with Varying Flow Rates Between 700 and 2900 rpm

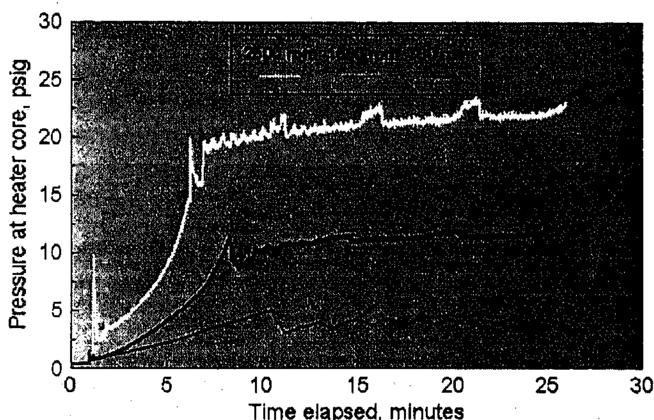

Fig 16: F250 Pickup Truck Pressure at Different rpm

The effect of engine rpm on the rate of de-aeration is illustrated in Figure 15. The vehicle was started at idle rpm and a few minutes after the thermostat opened, the speed was gradually increased to 2900 rpm. No de-aeration was observed at idle conditions while only a partial de-aeration took place at 1000 and 1600 rpm. Complete de-aeration was observed when the speed was further increased. Subsequent drop and increases in rpm had no effect on the level of de-aeration, though the oscillations of the thermostat followed the predicted behavior. The pressure in the heater core transducer was found to exceed 16 psig (110,000 N/m^2), the relief pressure set for the degas bottle cap. It is expected that the additional pressure in heater core should be about 3 psig (20,000 N/m^2) as compared to the pressure in the air space in degas bottle. Figure 16 shows the pressure in the heater core obtained on three different runs at speeds of 700, 1600 and 2500, with the same level of coolant. At lower rpm, pressure is below 12 psig (84,000 N/m^2), but at 2500 rpm, degas bottle cap is popping on periodically due to high pressure after opening of the thermostat.

CONCLUSIONS

- Electrical conductivity measurements provide a functional method for establishing the fractional amount of air in the flowing coolant, with an accuracy of ±0.5% absolute.
- The temperature - conductivity relationship of coolant - water mixture is quadratic in nature over the range of 20-120 °C, the typical operating range.
- The conductivity of different coolants and waters are not only different at ambient temperature, but may also have different temperature slopes. Therefore, the equation should be generated for each quality of coolant - water mixture, prior to actual vehicle tests.
- Laboratory tests have shown that degas bottle can remove up to 15% air within 10-20 minutes for typical operating conditions.
- The performance of degas bottle significantly deteriorates with high flow and aged coolant. If both these factors combine, the degas bottle starts aerating instead of removing the air.
- Vehicle tests have shown that at idle or near idle conditions, flowing coolant is not able to pick up the air; conductivity sensors may show de-aerated coolant while air pockets remain in the system. Tests showed that a good level of de-aeration could be achieved when the operating rpm was at least twice the idle rpm (1500 - 2000 rpm).
- The time required for complete de-aeration at intermediate to high rpm's was at least 20 minutes for diesel truck whereas the de-aeration in pick up truck was faster under comparable operating conditions. The slower rate of de-aeration in heavy truck may be due to much larger coolant volume but the circulation flow rate is not proportionately high.

Comparison of Aqueous Mixtures of Propylene-Glycol and Ethylene-Glycol Under Simulated Engine Cooling Conditions

C. Branchi, S. Bhowmick, and E. V. McAssey, Jr.

ABSTRACT

Test results have been obtained on the thermal performance of aqueous mixtures of propylene-glycol and ethylene-glycol for conditions simulating automotive engine operation. For the present study, thermal performance is defined as the test section surface temperature for a given set of operating conditions. In addition to testing over a wide range of surface heat fluxes up to 2.3 MW/m^2, data were also obtained at different mixture concentrations. For all cases considered, both coolant mixtures provided similar results.

INTRODUCTION

An extensive test program has been accomplished to evaluate the thermal performance of propylene-glycol and ethylene-glycol aqueous mixtures under conditions similar to those existing in modern internal combustion engines.

Because of environmental concerns, there has been an increased interest in replacing ethylene-glycol as the primary engine cooling fluid. Although ethylene-glycol/water mixtures have performed satisfactorily in internal combustion engines for a number of years, leaks from cooling systems annually cause a large number of human and domestic pet poisonings. Propylene-glycol appears to be an ideal replacement fluid. It is less toxic and possesses very similar heat transfer characteristics when compared to ethylene-glycol. However, differences do exist. Ethylene-glycol/water mixtures have a lower viscosity and higher thermal conductivity than propylene-glycol/water mixtures at the same concentration. At the normal cooling system operating pressure of 200 kPa, the saturation temperature of a 50/50 by volume mixture of propylene-glycol/water is approximately 3 °C lower than the equivalent mixture of ethylene-glycol/water.

In a modern automobile engine, the cooling system operates over the entire heat transfer spectrum from single phase convection to saturated flow boiling. The objective of the present study was to obtain experimental data on the heat transfer characteristics of both coolant mixtures over a wide range of flow-rates and surface heat fluxes. In addition, the effects of variations in concentrations from the normal 50/50 by volume value were also examined.

BACKGROUND

Although ethylene-glycol/water mixtures have been used as engine coolant for over fifty years, there is very little data available in the open literature.

In an automobile cooling system, the working fluid is generally a mixture of water and either ethylene-glycol or propylene-glycol. The normal mixture concentration is 50/50 by volume. Finlay et al. (1987) presented experimental results for an ethylene-glycol/water mixture covering an operating range appropriate to automotive engine conditions. Most of the data were obtained under constant pressure conditions using a copper test section. Some data were also obtained for other test section materials including cast iron and aluminum, and for constant flow-rate operation. These results showed reasonable agreement with analytical predictions based upon correlations at low surface heat fluxes. However, at higher fluxes under sub-cooled boiling conditions, the analytical model tended to under-predict the surface temperature. Gehres (1963) examined the performance of ethylene-glycol/water mixtures at different locations in the engine under various operating conditions Results showed that,

for severe driving conditions, nucleate boiling takes place on approximately 60 percent of the cylinder heat transfer surface area. High heat flux regions can experience surface heat fluxes exceeding 0.3 MW/m^2. In general, experimental data using glycol mixtures at typical automotive conditions of high inlet temperature (85 °C) and system pressures of two atmospheres are limited.

McAssey, Stinson, and Gollin (1995) presented test results comparing propylene-glycol/water and ethylene-glycol/water mixtures for a range of conditions similar to those existing in normal engine operation. Test data were obtained for test section inlet velocities up to 0.5 m/s and surface heat fluxes up to approximately 0.8 MW/m^2. All the test data were obtained for a 50/50 by volume mixture at a system pressure of 205 kPa and a test section inlet temperature of 85 °C. For this range of test conditions, the resulting data spanned the spectrum from single phase convection to saturated boiling. These investigators concluded that the overall performance for both coolant mixtures was very similar. At high velocities (approximately 0.5 m/s) under predominantly single phase conditions, the ethylene-glycol/water mixture yielded slightly lower surface temperatures. Conversely, at low velocity (approximately 0.1 m/s) where sub-cooled boiling occurred, the propylene-glycol/water mixture provided lower operating temperatures on the heated surface. This paper also presented comparisons between analytical predictions and experimental results. In general, the analytical results under-predicted the surface temperature when the difference between the surface temperature and fluid temperature exceeded 60 °C.

Bhowmick, Branchi, McAssey, and Gollin (1996) presented additional data on both fluid mixtures for a wider range of conditions. In this paper, the inlet velocity varied from approximately 0.4 m/s to 2.5 m/s and the surface heat fluxes reached a maximum of 1.8 MW/m^2. The concentrations of the mixtures were limited to 50/50 by volume, and the test conditions were the same as the previous paper. In addition, comparisons were presented between experimental results and analytical predictions. The experimental results showed that both mixtures had similar thermal performances. In general, the analytical results under-predicted the experimental results by a significant margin.

DESCRIPTION OF TEST FACILITY

FLOW LOOP - The flow loop consisted of a test section, pump, accumulator tank, rejection heat exchanger, and required piping. Figure 1 presents a schematic layout of the test loop. For this program, the loop was operated in the controlled flow mode. In this mode of operation, the test section is provided a constant volumetric flow-rate

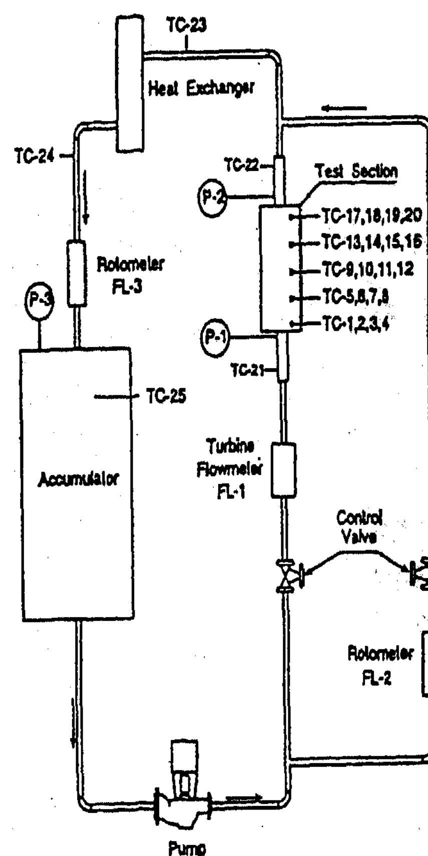

Figure 1 Schematic of Test Loop

under all operating conditions. Since most of the pressure drop occurs across the control valve, changes in the test section pressure drop due to heating have a small effect on the flow-rate to the test section. The bypass line around the test section was installed to allow operation on the constant head portion of the pump performance curve and to reduce the vapor content of the fluid entering the heat exchanger. The primary flow-rate instrument was a turbine flowmeter (FL-1) located upstream of the test section. Test section inlet pressure and temperature were measured by a pressure gauge (P-1) and a thermocouple (RTD-1) respectively. A similar arrangement (P-2 and RTD-2) located downstream of the test section was used to measure exit conditions.

The accumulator tank was used to maintain the system pressure. Pressure control was accomplished by means of adjusting the liquid level or the argon pressure. An argon blanket was maintained in the top of the accumulator tank and the pressure in this region was adjusted using an external argon supply. The tank also contained a heater which controlled the test section inlet temperature. The accumulator tank also produced a constant head source for the loop pump, which was a centrifugal pump capable of producing 0.3 m^3/min. at 400 kPa. A control valve located upstream of the test

section was used to provide the required flow to the test section. After leaving the test section, the bypass and test section flows combined before entering the heat exchanger.

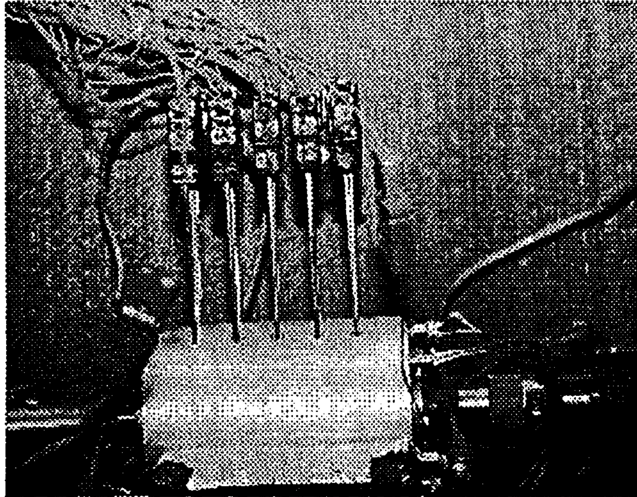

Figure 2 Test Section

TEST SECTION - The test section was constructed from a 114 mm diameter aluminum cylinder with a length of 165 mm. The horizontal flow channel consisted of a 9.53 mm diameter hole drilled along the center-line of the cylinder (see Fig. 2). The test section was heated by ten cartridge heaters located on a 97.9 mm diameter circle. Each heater was capable of producing 1,000 watts at 120 volts. By operating at slightly higher voltages, it was possible to dissipate approximately 11 kW in the test section.

The test section was connected to the flow loop by means of inlet and exit calming sections, which have the same inside diameter as the test section. The upstream calming length and the test section each had an L/D ratio of 17:1. This ratio was considered to be sufficient to provide fully developed flow to the heated length.

In order to minimize heat loss from the system, the entire flow loop and test section were insulated. The insulation on the test section consisted of over 200 mm of fiberglass insulation. Calculations of the adiabatic fluid exit temperature agree with the measured fluid exit temperature to within 2-3 °C.

The test section temperatures were measured by 20 E-type thermocouples mounted at five axial stations along the cylinder (see Fig. 2). Using two thermocouples on the same radial line, the surface temperature can be calculated as shown in Bhowmick et al. (1996). All thermocouple measurements were made in the same horizontal plane. This arrangement provided two essentially equal measurements at each axial location.

INSTRUMENTATION - The instrumentation for this program was chosen to determine various test parameters and test section temperatures. Test section flow-rates were measured with turbine flowmeters and rotometers. The rotometers were calibrated using a weigh tank with the mixtures at the required operating temperature of 85 °C. The turbine flowmeters were then calibrated against the rotometers. Initially the thermocouple calibration provided by the vendor was checked by calibrating each thermocouple in an environmental oven up to approximately 125 °C. Later in the test program, a high temperature thermocouple calibrator was used to calibrate each sensor over the complete operating range. Table 1 presents an estimate of the overall accuracy of the instruments used in these tests.

Table 1 Instrument Accuracy

Measurement	Type of Instrument	Accuracy
Temperature	E-type thermocouple	+/- 1.2 °C
Pressure	Pressure gauge	+/- 1% F.S.
Pressure Drop	Differential pressure transducer	+/- 0.25% F.S.
Test Section Flow-rate	Turbine flowmeter	+/- 0.50% of reading
Loop Flow-rate	Rotometer	+/- 0.75% F.S.
Test Section Fluid Temperature	E-type thermocouples	+/- 1.2 °C

RESULTS AND DISCUSSION

Test results were obtained over a range of test section inlet velocities from 0.44 m/s to 2.6 m/s. In addition, the surface heat flux varied from zero to 2.3 MW/m^2. For each test, the test section exit pressure was maintained at 205 kPa while the inlet temperature was set at 85 °C. Exit pressure was selected as the controlled parameter because it provided a more stable operating point. These conditions correspond to normal design operation of an engine.

The following procedure was used for each test:

1. The test section exit pressure, inlet temperature, and flow-rate were set.
2. The power to the test section heaters was increased in steps from zero to the maximum conditions. Generally, eight steps were used for each flow-rate.
3. For each power setting, the test conditions were maintained until steady state conditions had been achieved. Steady state was usually reached after 15-20 minutes of operation.

This procedure was followed for three coolant mixture concentrations, 50/50, 30/70, and 70/30 by volume for each type of fluid. Approximately, 400 tests were conducted in this program.

For this range of conditions, the full spectrum of heat transfer from single phase forced convection to saturated boiling was produced. Figure 3 presents the measured fluid exit temperatures at three inlet velocities for a 50/50 concentration of propylene-glycol/water and ethylene-glycol/water. At the lowest inlet velocity (0.445 m/s), both coolant mixtures' fluid temperatures reached saturation at approximately 1.2 MW/m^2 surface heat flux. At 50/50 concentration and these test conditions, propylene-glycol/water and ethylene-glycol/water have saturation temperatures of 127 °C and 130 °C respectively. At the maximum flux condition, adiabatic energy balance calculations indicated that approximately one half the channel experienced saturated boiling. Conversely, at the highest velocity, the exit fluid remained subcooled at approximately 100 °C. Local subcooled boiling will occur when the local surface temperature exceeds the onset of nucleate boiling (ONB) temperature. For the present test conditions, T_{ONB} is approximately 145 °C.

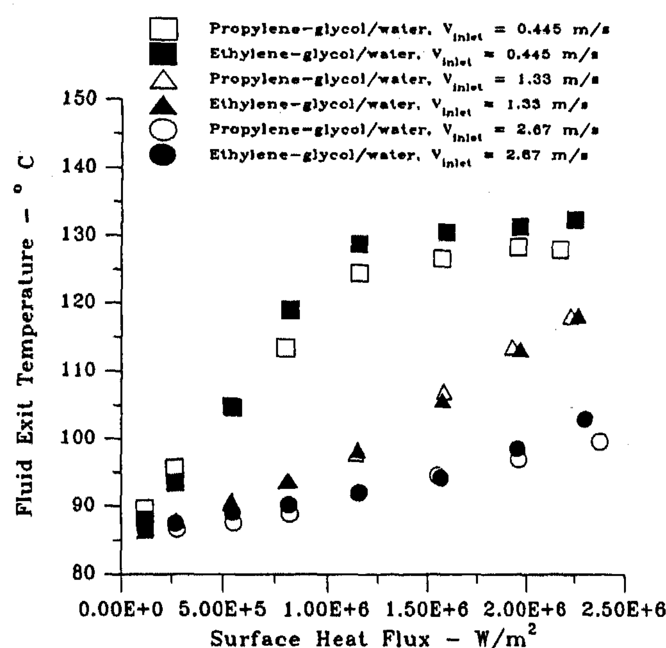

Figure 3 Comparison of fluid exit temperatures for 50/50 by volume propylene-glycol/water and ethylene-glycol/water mixtures. P_{system} = 205 kPa, T_{inlet} = 85° C

Figures 4, 5, and 6 present surface temperature results at the test section midsection (z/L = 0.5) as a function of surface heat flux for inlet velocities of 0.445 m/s, 1.33 m/s, and 2.67 m/s respectively. In these figures, data are presented for both propylene-glycol/water and ethylene-glycol/water. The data are drawn from two test sets performed approximately six months apart. The agreement between the data sets is quite good. The later data shows better agreement between the temperatures measured on each side

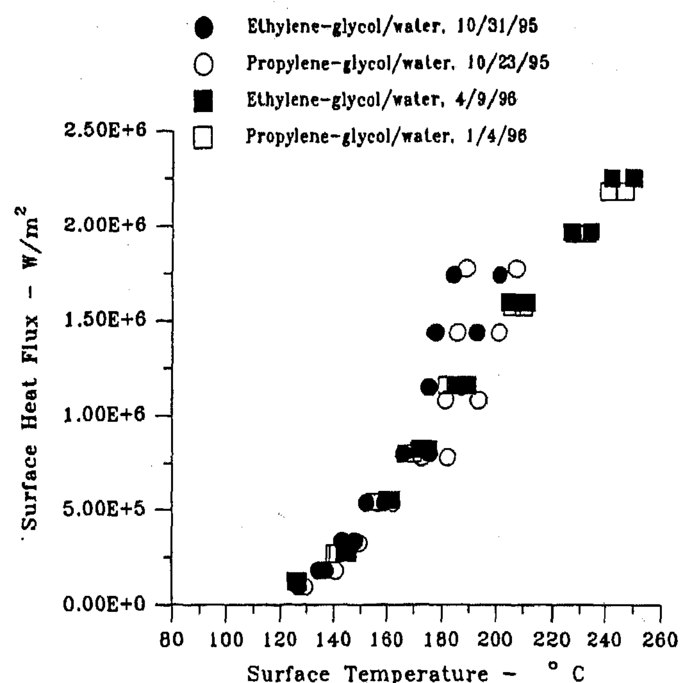

Figure 4 Comparison of propylene-glycol/water and ethylene-glycol/water at V_{inlet} = 0.445 m/s
z/L = 0.5, P_{system} = 205 kPa, T_{inlet} = 85° C

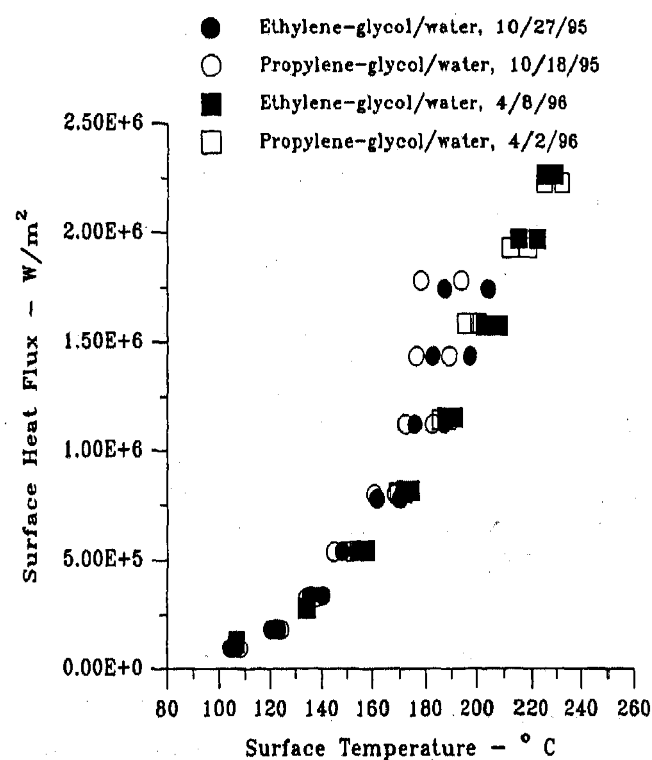

Figure 5 Comparison of propylene-glycol/water and ethylene-glycol/water at V_{inlet} = 1.33 m/s,
z/L = 0.5, P_{system} = 205 kPa, T_{inlet} = 85° C

of the flow channel. For the thermocouples used in the earlier data, the vendor-supplied calibration curves were

used. However, for the later data, each thermocouple was calibrated and matched. Both coolant fluids yielded very similar results over the range of heat fluxes and inlet velocities.

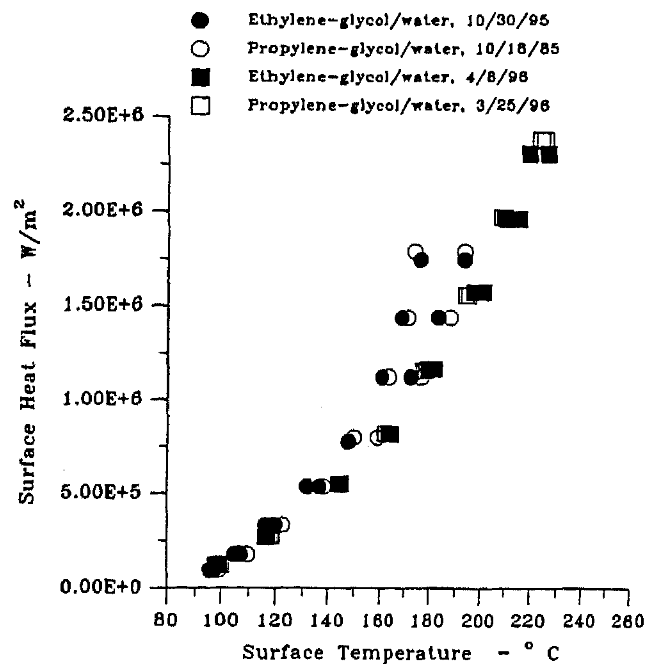

Figure 6 Comparison of propylene-glycol/water and ethylene-glycol/water at V_{inlet} = 2.67 m/s

z/L = 0.5, P_{system} = 205 kPa, T_{inlet} = 85° C

It is significant to note that over the entire range of test conditions, there was no evidence of heat transfer crisis. The data did not show the presence of critical heat flux, film boiling, or dryout. When local saturated boiling conditions were established, the local surface temperature increased more rapidly with heat flux. In Fig. 4, there is a change in slope above a surface heat flux of 1.5 MW/m². At this point in both fluids, saturated boiling is taking place and the heat transfer coefficient is slightly reduced. Conversely, in Fig. 6 for the highest inlet velocity, the coolant mixture local condition is well below saturation; however, the wall temperature is above the onset of nucleate boiling,and local subcooled boiling is present.

Table 2 Mixture Saturation Temperature

Concentration	Saturation temperature for Propylene-glycol/water	Saturation temperature for Ethylene-glycol/water
30/70 by volume	123.8 °C	124.4 °C
50/50 by volume	127.5 °C	130.3 °C
70/30 by volume	134.9 °C	138.9 °C

Figures 7, 8, and 9 present results showing the effect of coolant concentrations. In addition to the normal 50/50 by volume, tests were conducted with

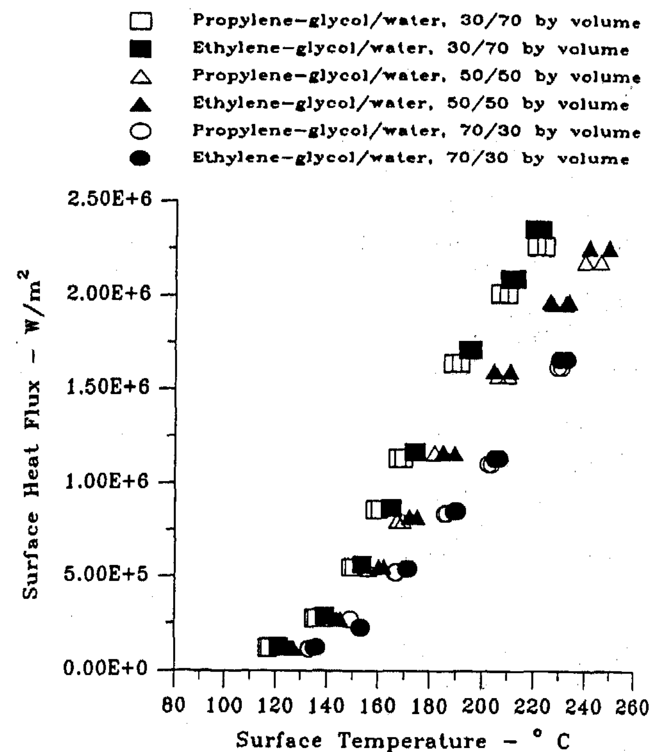

Figure 7 Concentration comparisons for ethylene-glycol/water and propylene-glycol/water at an inlet velocity = 0.445 m/s
T_{inlet} = 85° C, P_{system} = 205 kPa

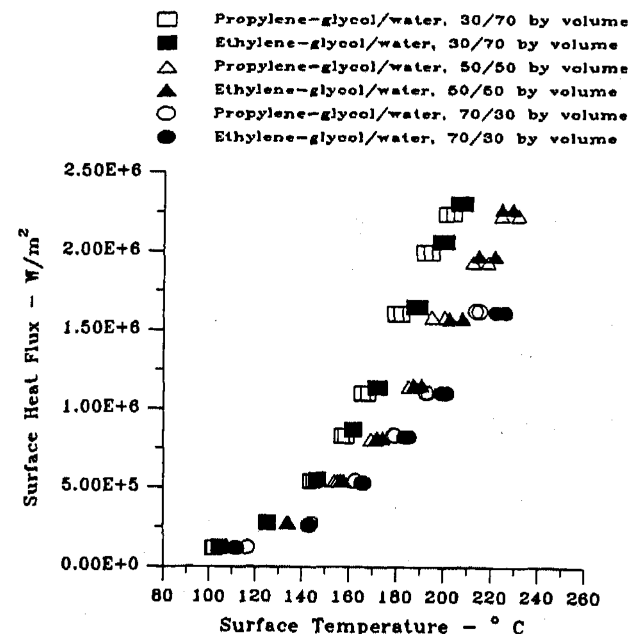

Figure 8 Concentration comparisons for ethylene-glycol/water and propylene-glycol/water at an inlet velocity = 1.33 m/s
T_{inlet} = 85° C, P_{system} = 205 kPa

70 % and 30 % coolant concentrations. Increasing the concentration of coolant raises the saturation temperature and reduces the effective heat transfer. Table 2 presents the mixture saturation temperature for each concentration tested.

For reference, the saturation temperature for 100 % water at the test pressure is 120 °C. From these

figures, it can be seen that the variation of wall temperature with concentration at the higher flux levels is approximately 40 °C for both coolant mixtures. Comparing the performance of propylene-glycol/water to ethylene-glycol/water, there is little or no difference as the concentration changes from 30 % glycol to 70 % glycol. At the higher velocities, the propylene-glycol mixture has a slightly lower surface temperature at the 30 % concentration; however, this difference (approximately 10 °C) is not considered significant.

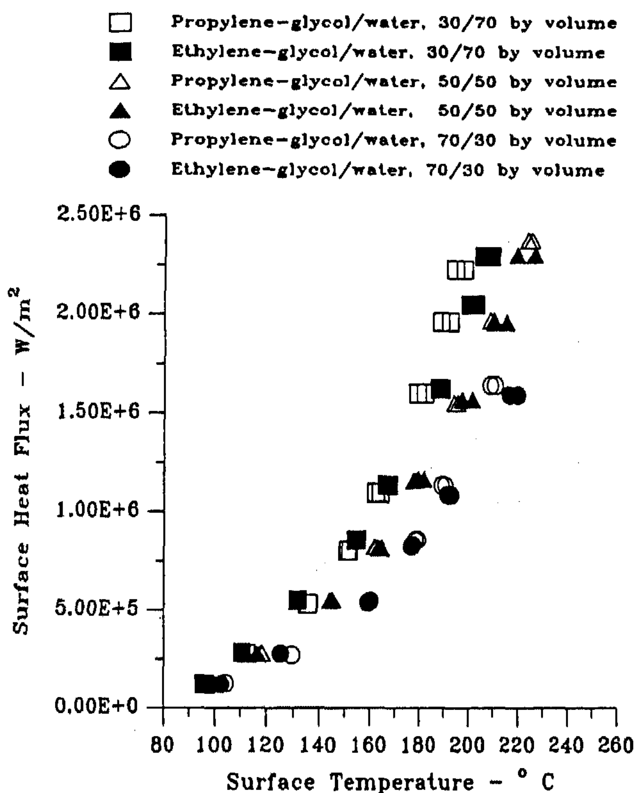

Figure 9 Concentration comparisons for ethylene-glycol/water and propylene-glycol/water at an inlet velocity = 2.67 m/s T_{inlet} = 85° C, P_{system} = 205 kPa

CONCLUSION

An experimental program has been conducted to examine the thermal performance of propylene-glycol/water and ethylene-glycol/water engine coolant mixtures over a wide range of heat fluxes and mixture concentrations.

The results of these experiments indicate that both coolant mixtures have similar performance with respect to surface temperatures.

For normal engine operating conditions of two atmospheres and 85 °C inlet temperature, two phase heat transfer exists over most of the heat flux range. At low inlet velocities, this two phase heat transfer involves both subcooled boiling and saturated boiling. Increasing the inlet velocity eliminates saturated boiling; however, even at the highest inlet velocity (2.67 m/s), subcooled boiling exists when the surface heat flux exceeds 0.6 MW/m². This result is particularly important because subcooled boiling can affect the hydrodynamics when alternate flow paths exist. This condition was not simulated in these tests.

Since boiling is an important aspect of heat transfer in engines with aqueous coolant mixtures, the effects of off design conditions such as lower system pressures and higher inlet temperatures are being considered in a separate test program.

The effect of surface finish is also under examination in tests planned using a cast iron test section.

Modelling of Car Dynamic Frontal Crush

Denis P. Wood and Stephen Mooney
Wood & Associates

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper examines the dynamic displacement-crushing force and dynamic displacement-absorbed energy behaviour of eight cars in full width barrier, 45% overlap rigid barrier and 30^0 angled barrier tests at 56, 50 and 56 kph respectively. This study shows the frontal crush behaviour of these cars can be divided into three regions or zones of constant force, these zones being associated with crushing of the front structure as far as the engine, the engine and rear front structure and the occupant compartment. The highest average crushing force is associated with crushing of the engine and rear front structure with lower average crushing forces required for the extreme front of the car and for the occupant compartment.

It is hypothesised that the energy absorbed-dynamic displacement behaviour in the full width barrier test represents the energy absorbed-mean displacement for all other crush configurations. This hypothesis is combined with the geometric crushing model for the car front (Wood 1993, 1995) to calculate the responses in the 45% overlap and the 30^0 angled barrier tests for one of the cars. A high degree of correlation is obtained. Further evaluation is needed to verify the hypothesis.

INTRODUCTION

This paper examines the frontal crushing behaviour of eight cars in full width and 30° angled barrier tests at 56 kph and in 45% overlap rigid barrier tests at 50 kph. The purpose is to obtain an insight into the overall crushing behaviour of car front structures and the manner in which this behaviour varies with depth of crush. The evaluation is carried out by examining the force-displacement and the absorbed energy-displacement responses of the cars. Also a model (Wood 1993, 1995) for frontal crush of cars is applied to obtain the energy absorbed responses in the 45% overlap and 30° angled barrier tests from the full width barrier response and these computed responses are compared with the actual responses obtained in the tests.

CARS EXAMINED

The details of the eight cars examined are detailed in Table 1. All are front wheel drive and with the exception of car 3 which has a longitudinal engine all are fitted with transverse engines.

Table 1 - Vehicle Data

Car	Curb Mass Kg	Length m	ds/L	de/L	db/L
1	860	3.96	0.033	0.081	0.220
2	809	3.96	0.045	0.091	0.250
3	1010	4.41	0.030	0.059	0.249
4	810	3.63	0.030	0.094	0.218
5	1090	4.56	0.026	0.103	0.208
6	990	4.41	0.035	0.084	0.236
7	745	3.70	0.052	0.086	0.238
8	1260	4.71	0.074	0.128	0.244

The ratios ds/L, de/L and db/L are the normalised distances from the fronts of the cars to the start of the two longitudinal members in each car, to the front of the engine and to the front of the bulkhead/firewall which divides the occupant compartment from the car front structure.

TEST RESULTS

DYNAMIC DISPLACEMENT RESPONSES

Figures 1 to 3 inclusive show the normalised crushing force-dynamic displacement responses of Car 4 in the full width, 45% overlap and 30° angled barrier tests. Figures 5 to 7 show the corresponding averaged responses for all eight cars. The full width barrier responses show that there is an initial peak force, the position of which corresponds with the location of the fronts of the longitudinal members and the initiation of their collapse.

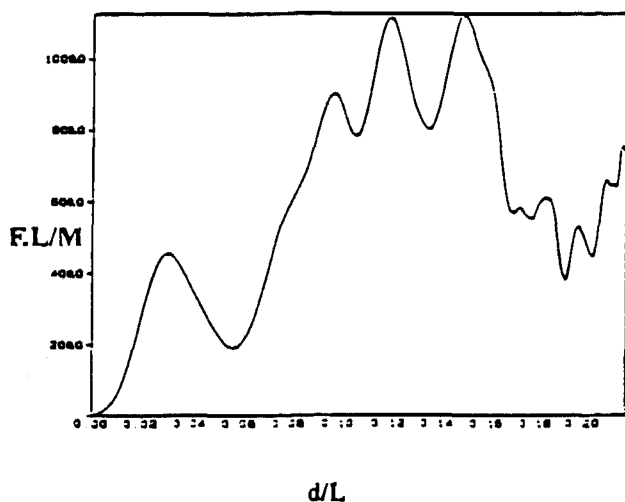

Figure 1 Full Width Rigid Barrier Response - Car 4

This is followed by a displacement over which there is a low force after which it climbs to a high force regime where the force oscillates about an average level before dropping to a lower force level.

The 45% overlap and 30° angled responses are similar but the initial low force region occurs over larger displacements before rising to a high force. This behaviour pattern was found for all cars with the exception of car 6 which did not show the reduction in force as maximum displacement was reached, the reason for which will be discussed later.

Figure 4 shows the absorbed energy-dynamic displacement response in the full width barrier test for car 4. Three distinct regions are immediately apparent. Each region can be represented by a straight line the slope of which is the average force in the respective region. The 45% overlap and 30° angled barrier responses for car 4 showed similar characteristics as did all the other cars in the full width, 45% overlap and 30° angled barrier tests (with the exception of car 6 which showed distinct regions 1 and 2 only).

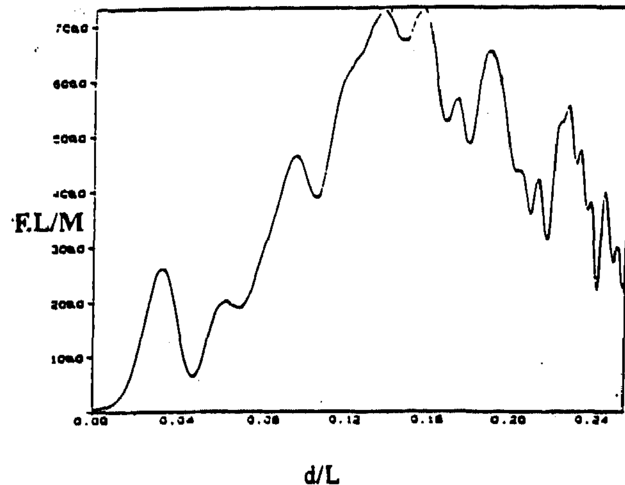

Figure 2 45% Overlap Response - Car 4

For car 4 in the full width barrier test the transition between regions 1 and 2 at a d/l of 0.087 is 93% of the

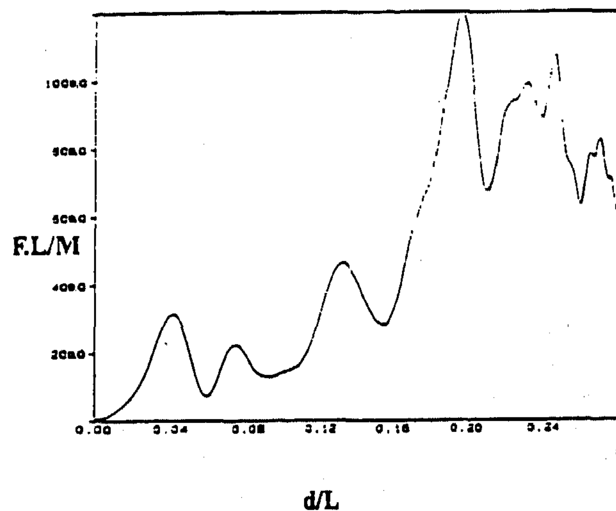

Figure 3 30° Angled Barrier Response - Car 4

distance to the front of the engine. The transition between regions 2 and 3 occurs at d/L of 0.164 which is 75% of the distance to the firewall/front bulkhead. Statistical analysis

for all eight cars shows that the position of the initial force peak corresponds with the location of the front of the longitudinal members and that the transition point between regions 1 and 2 in the full width barrier tests are, on average, 75% of the distance to the front of the engine and that the transition between regions 2 and 3 is at 75% of the distance to the firewall/front bulkhead.

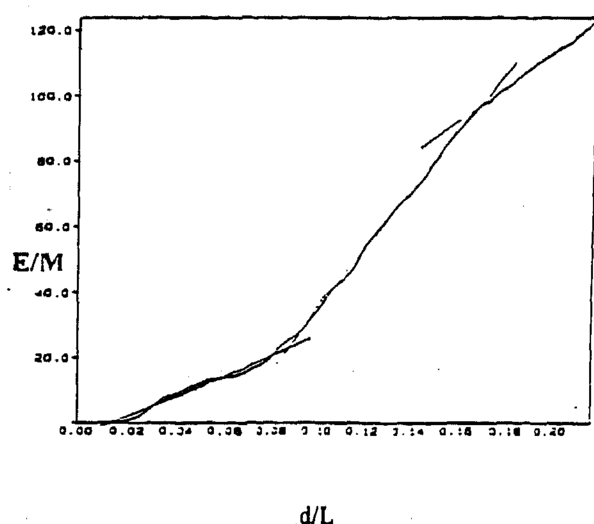

Figure 4 Full Width Absorbed Energy Response - Car 4

Jones et al (1990) shows that the depth of crushed material behind the crush face of tubes is such that the distance to the crush face is, at most, 75% of the total distance to the rear of the crushed material. When the depth of the crushed material immediately behind the crush face is taken into account and using the proportionality factor from Jones et al (1990) then for uniform full width crushing of the car front the transitions between regions 1 and 2 and between regions 2 and 3 correspond to the front of the engine and the firewall/front bulkhead respectively.
Therefore we can conclude that region 1 and the initial average force corresponds with crushing of the two longitudinals on their own with little contribution from the rest of the structure, that region 2 and the highest average crushing force is associated with crushing of the engine and rear front structure of the car front while region 3 and the lower average crushing force in this region is associated with crushing of the occupant compartment.

FULL WIDTH BARRIER AVERAGE FORCES

Table 2 shows the average forces in region 2 - the engine and rear front structures for each of the cars and the ratio of average forces between this region and regions 1 and 3 respectively. With the exception of car 6 which has a high region 1 force at 85.3% of region 2 the other seven cars have low region 1 forces which average 34% of their

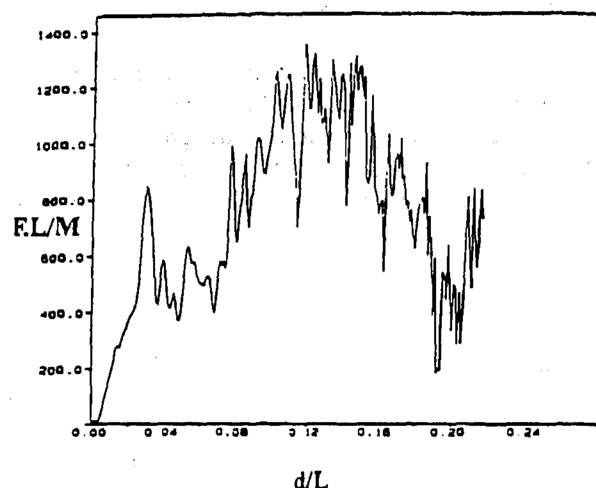

Figure 5 Average Full Width Response - All Cars

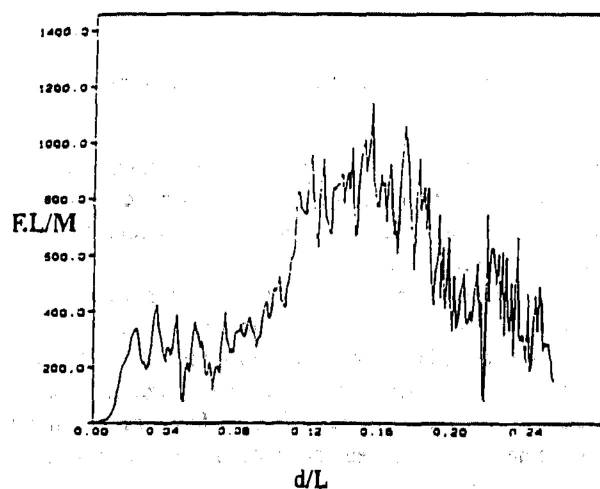

Figure 6 Average 45% Overlap Response - All Cars

region 2 values. All cars with the exception of car 6 showed evidence of a lower region 3 force. However the displacement in this region was sufficiently large for only four of the cars to compute the average force in region 3.

One explanation for the absence of evidence of a lower force region 3 for car 6 is that the crushing was not

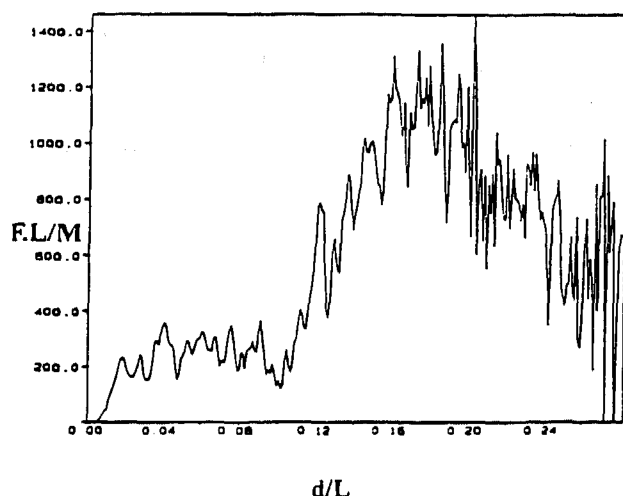

Figure 7 Average 30° Response - All Cars

sufficient to reach this region and involve the occupant compartment in the crushing process. The maximum crush in the full width test was 58% of the distance to the firewall/front bulkhead while it was 69% in the 45% overlap test i.e. both were less than the 75% crush face/crush depth ration from Jones et al (1990) necessary for the crushed material to reach the firewall/front bulkhead.

Table 2 Full Width Barrier Average Forces,kN.

Car	Region 2 Force,kN	Force1 / Force2	Force3 / Force2
1	227.3	43.6%	63.1%
2	187.1	48.7%	-
3	190.1	34.5%	-
4	204.2	33.0%	57.7%
5	519.2	15.5%	55.2%
6	294.1	85.3%	-
7	258.7	30.0%	43.6%
8	496.5	32.8%	-

Table 2 also shows that there is a high degree of variability in the average force required to crush the engine and rear front structure of the cars from a low of 187.1 kN to a high of 519.2 kN, a 2.8 to 1 force range. The mean force is 297.2 kN.

Turning to the 45% overlap and the 30° angled barrier tests Table 3 shows the ratios of the average forces in each of the three regions in these two tests by comparison with the full width barrier test.

Table 3 - All Cars, 45% Overlap & 30° Force Ratios.

Region/Test	45%	30°
Region 1/Region 1 Full Width	60.9%	53.6%
Region 2/Region 2 Full Width	78.0%	100%
Region 3/Region 3 Full Width	55.3%	95.2%

This data shows that the average forces in each region for the 45% overlap test are less than those in the full width barrier test. However in the 30° angled barrier test only the region 1 force is significantly less than for the full width test. In regions 2 and 3 the average forces in the 30° angled barrier tests are similar to those obtained in the full width barrier tests. An extended analysis is given in Wood (1996).

DYNAMIC DISPLACEMENT RESPONSES

DYNAMIC CRUSH MODEL

It is hypothesised that the absorbed energy-displacement characteristic of any individual car type in the full width barrier test represents the absorbed energy-average displacement characteristic for that car type in all frontal crush configurations. Wood (1993, 1995) has previously proposed that in frontal crushing the portion of the car not in direct contact with the barrier or opposing car i.e. the induced crush portion can also be regarded as crumpling rearward, see Figure 8, and that the average crush depth should be calculated over the deformed front profile in the manner shown in Figure 9.

APPLICATION OF CRUSH MODEL TO CAR 4

Figure 10 shows the absorbed energy per unit mass for car 4 as a function of dynamic displacement in the full width barrier test i.e. as a function of average dynamic displacement as per hypothesis. The relation between the dynamic displacement of the C.G. in the 45% overlap and 30° angled barrier tests and the corresponding average dynamic displacement is calculated on the basis of the car front deforming in a simple geometric manner, refer Wood (1993). For the 30° angled barrier tests the car front was considered to progressively increase in angle until 30° was reached after which the car maintained a 30° angle while

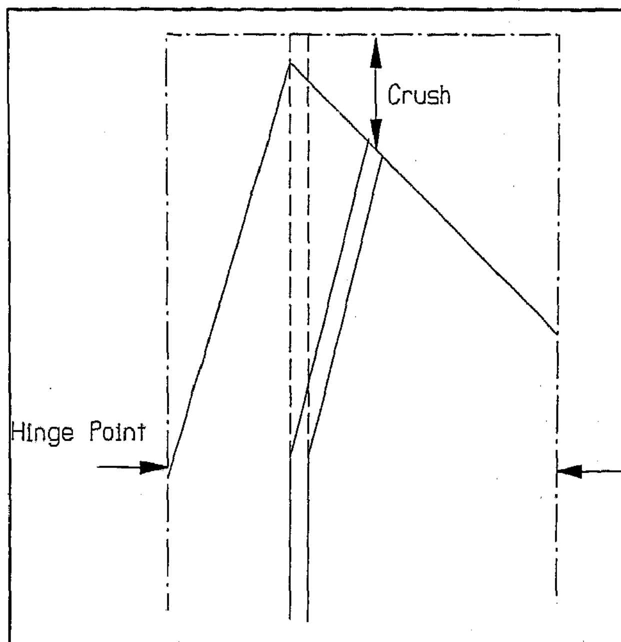

Figure 8 Crush Model

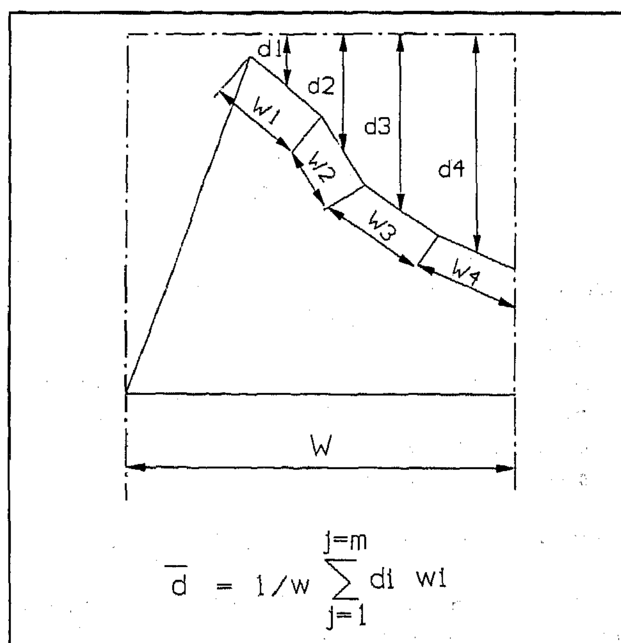

Figure 9 dbar Calculation Method

continuing to crush to maximum dynamic displacement.

The comparisons between the actual and calculated absorbed energy-dynamic displacement are shown in Figures 11 and 12 for the 45% overlap and 30° angled barrier tests respectively. There is a high degree of agreement between the actual and calculated responses in both tests. Towards maximum dynamic displacement there is some deviation between the computed and actual responses. However in the 30° angled barrier comparison the calculated response is less than the actual response whereas the reverse occurs in the 45% overlap comparison, i.e. the calculated response is greater than the actual response.

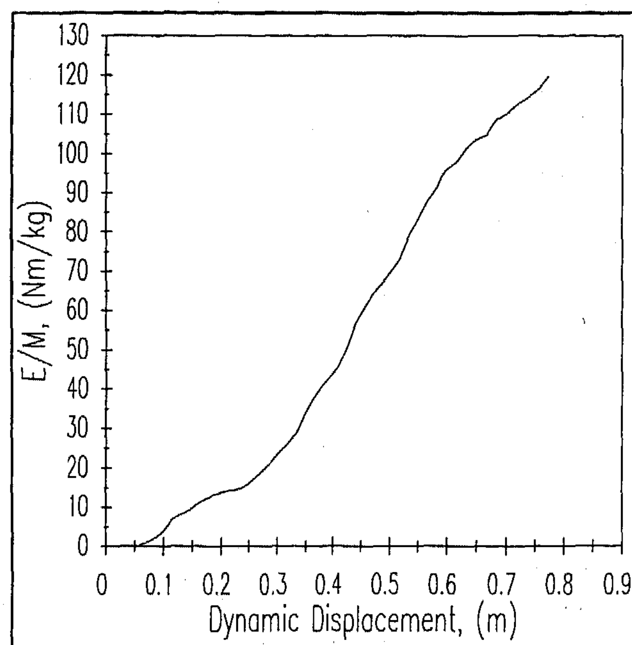

Figure 10 Car 4 Energy Absorbed -v- Displacement Full Width Barrier

DISCUSSION

Examination of the crush behaviour of eight cars in full width, 45% overlap and 30° angled barrier tests in terms of absorbed energy-dynamic displacement shows that the crushing can be divided into 3 regions or zones, each with a constant force. Comparison of the transition points between the regions or zones shows that the zones are associated with the immediate front of the car and the two longitudinal members, the engine and rear front of the car and the occupant compartment respectively. The data for the eight cars shows that the lowest force zone is the first i.e. the immediate car front and the plastic collapse of the longitudinal members, the highest force zone is the engine and the rear front structure while the occupant compartment has a lower crushing force level than the engine and rear front structure. The reason why collapse is progressive despite the occupant compartment having a lower crushing force than the engine cum rear front structure is due to dynamic inertia effects under impact conditions, Johnson (1970).

It is hypothesised that the absorbed energy-dynamic displacement behaviour in the full width barrier crushing

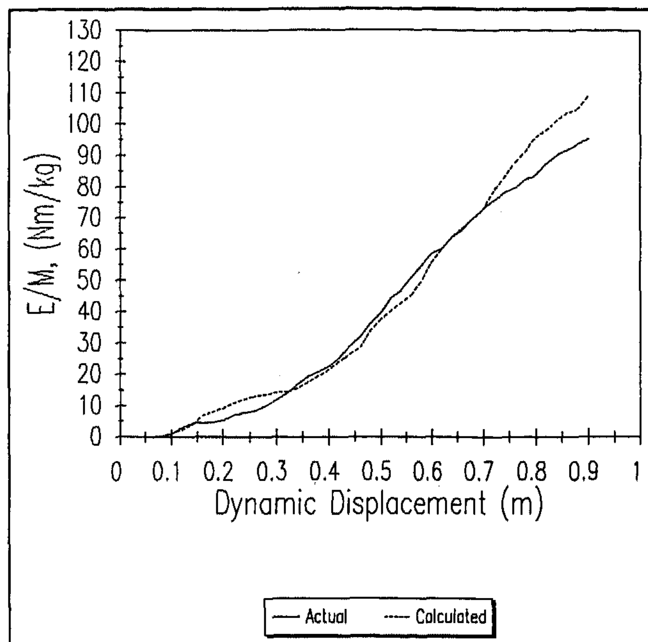

Figure 11 Car 4 Energy Absorbed -v- Displacement 45% Rigid Offset Barrier

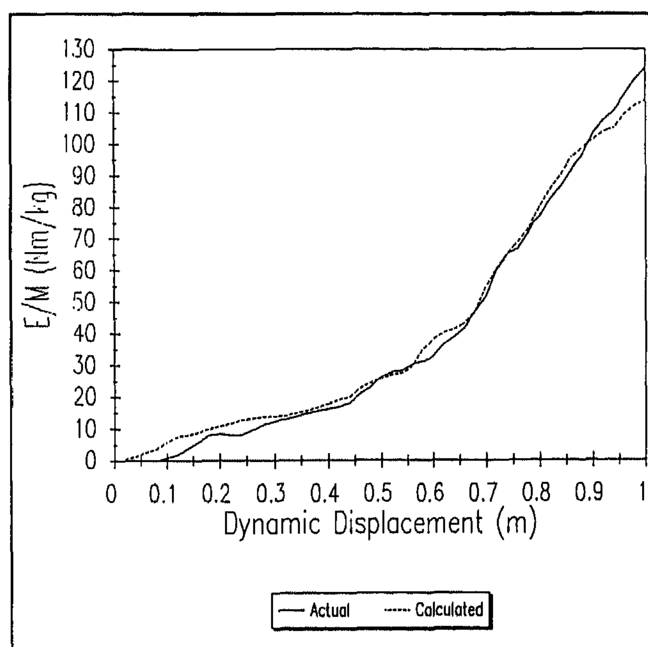

Figure 12 Car 4 Energy Absorbed -v- Displacement 30° Angled Barrier

represents the absorbed energy-average dynamic displacement in all other frontal crush configurations. Evaluation of the hypothesis combined with the geometric model, Wood (1993, 1995) for one car, car 4, shows a high degree of correlation between the actual and calculated dynamic responses in the 45% overlap and 30° angled barrier tests. Comparison of the hypothesis with the actual responses for other cars is needed to verify the model in the context of dynamic crush behaviour. The basic hypothesis of regarding the car front as crushing in a geometric manner and considering the full width barrier characteristic as being the characteristic for average crush have already been successfully applied to residual crush data for pole, offset and car to car collisions, refer Wood (1993, 1995).

APPLICATION TO ACCIDENT RECONSTRUCTION

Before this approach can be applied to the residual crush data obtained from crashed cars and to accident reconstruction a reliable method of correlating dynamic and residual crush for individual car types is required. Hight et al (1985) details residual and dynamic crush values for a number of cars. Wood (1992, 1995) derived a general correlation between normalised or non-dimensional residual and dynamic crush for the car population which can be used to estimate dynamic crush values from residual crush measurements when the data for a particular car type is not available. Previous analysis (Wood, unreported) showed that there was considerable variation in the residual/dynamic characteristics as between different car types.

The test data also indicates that care is needed in extrapolating the crush force response data to higher impact speeds. The full width barrier data indicates that the average full width barrier force during crushing of the occupant compartment varies between a low of 112.8 kN and a high of 286.6 kN. Also the full width barrier response data for numbers of car types is such that crushing of the occupant compartment is not sufficiently developed to allow average force levels for this region to be derived. Methods of using the 30° angled barrier and the 45% overlap test data to derive this force level is being examined. Consideration of high speed, 80/100 kph full width barrier tests of various car types in order to have sufficient data to reliably calculate speed from residual crush in high speed collisions is desirable in the light of the test data in this paper.

Reviewer's Discussion
by Philip V. Hight, P.E., Accident Research, Santa Barbara
Modelling of Car Dynamic Frontal Crush
Denis P. Wood, Stephen J. Mooney, Authors

This paper proposed a dynamic model of automobile crush using data from 90 degree barrier impacts at 50 and 56 km/h (30 and 35 mph). At this time a comparison for the other cars has not been accomplished. This study had divided the frontal crush into three zones of constant force. This would enable researchers to calculate responses in 45% overlap and 30 degree angled barrier. It is hoped by this reviewer that by the presentation that further analysis will be available for comparison concerning the other seven front wheel drive automobiles. A preliminary review indicates a high degree of variability in the average force required to crush the engine and rear front structure of the cars, nearly a 3 to 1 force range. The concept of the paper is interesting but it seems premature to evaluate the success of the hypotheses until after further cars have been analyzed. The basic hypotheses that the front of the car crushes in a geometric manner and can be applied to crush profiles from pole impacts may be disputed by other researchers. It appears probable that this concept can be applied to residual crush of offset and car to car collisions.

Passenger Vehicle Braking Performance with a Disabled Vacuum Power Booster

Wade Bartlett
Mechanical Forensics

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

When the vacuum-powered brake booster in a passenger vehicle becomes disabled, the brake force gain of the system is reduced significantly, and the brake pedal force required to lock the tires increases beyond the ability of some adults. In such cases, the maximum braking deceleration acheived by those individuals will be something less than the upper boundary as defined by available traction.

This paper's goal is to review the design of vacuum boosters, the literature concerning human ability to depress a brake pedal, and FMVSS 105 requirements which must be met by vehicle manufacturers, and to present performance data with and without the booster operational for four passenger vehicles. Furthermore, the application of this information to accident investigations involving disabled boosters will be discussed.

INTRODUCTION

The vacuum power booster (booster) is the most common form of power assistance unit now found in passenger vehicle brake systems. It derives motive force from an air pressure differential across a large surface area, and significantly reduces the force an operator must apply to the brake pedal to achieve satisfactory deceleration.

Vacuum booster systems are fairly reliable, but can fail. One study completed in 1977 concluded that approximately one failed booster per year per 11,700 vehicles could be anticipated.[1] Though passenger vehicle component reliability has improved since the 1970's, a finite number of failures can still be expected. If the booster becomes disabled, the operator must apply a much greater force to the brake pedal to achieve a given deceleration. If such a failure occurs unexpectedly, an accident could result.

It is the goal of this paper to outline the design and operation of vacuum booster systems and their possible failure modes, review the portion of the Federal Motor Vehicle Safety Standard 105 (FMVSS 105) which lists braking performance criteria new vehicles must meet in the event of a booster failure, and review of some of the literature concerning the brake pedal application forces of which drivers have been found capable. Results of brake performance testing for four passenger vehicles, with and without their boosters operational, will be presented, and the application of this information to accident investigations involving disabled boosters will be discussed.

Hydraulicly activated power boosters (hydro-boosters) are occasionally utilized in passenger vehicles, but often share a hydraulic pump and pressure accumulator with the power steering system, and incorporate a variety of plumbing arrangements which vary by manufacturer and vehicle model. These complications prevent the sort of general treatment possible for vacuum-powered systems which are simpler and less expensive to manufacture, and have enjoyed more widespread use. There is overlap in the performance and regulation of the two system types, but this paper will be devoted exclusively to consideration of the vacuum-type.

The inclusion of anti-lock braking systems (ABS) in passenger vehicles in recent years has had little effect on the design and operation of brake boosters. The pedal force required to engage the ABS is significantly increased with a disabled booster, but the ABS will operate normally if called upon.

This paper will not address issues related to surfaces having a low coefficient of friction, such as snow or ice. All testing was conducted in conditions where available traction was greater than the decelerations attempted. Deceleration resulting from tire forces can never exceed the traction available at the tire / road interface, regardless of brake system design, booster condition, or ABS operation.

BOOSTER DESIGN AND OPERATION

The purpose of a vacuum power booster is to reduce the brake pedal application force required to generate sufficient pressure in the hydraulic system to stop the vehicle at a particular rate of deceleration. Figure 1 shows how deceleration varies pedal with force for a typical passenger vehicle. Tire rolling resistance and other minor sources of drag provide a slight deceleration even without brake application, shown as the area adjacent to 1 in Figure 1. A modest pedal force is required to overcome internal resistances and various springs in the brake system. This system "kick-in point" is

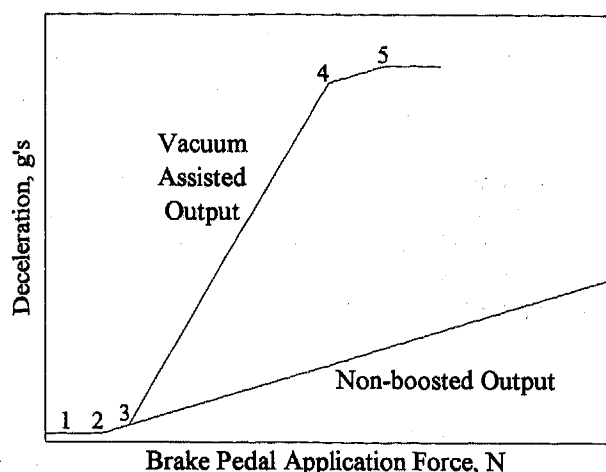

Figure 1: Vehicle deceleration as a function of brake pedal application force; 1 deceleration from minor drag sources, 2 brake system kick-in point, 3 booster crack point, 4 booster run-out point, 5 maximum deceleration.

shown as point 2 in Figure 1. Once the pedal force exceeds the kick-in force, deceleration increases in an essentially linear fashion in a manual (unboosted) brake system or in a booster-equipped system when the booster is not functional. It should be noted that the slope of the performance curve for a manual system will likely be steeper than that for a system with a disabled booster.

The incorporation of a booster adds two features to the curve. Some pedal motion is required to operate the valves controlling the admittance of air into the rear chamber, allowing the booster to begin to augment the pedal application force. This point, point 3 in Figure 1, is commonly referred to as the "crack point," so named because at this point the valves first "crack open." The crack point is quite low and may not be noticeable in full-vehicle test data. The second feature added by a booster is the "run-out point" or "knee point," shown as point 4 in Figure 1. This is the point at which the rear chamber has reached atmospheric pressure, and no additional force augmentation is available. The names are derived from the booster's having "run out" of additional boost, and from the shape of the performance curve. Beyond the run-out point, additional hydraulic pressure is generated at the same rate as for the "unassisted" case.

Point 5 in Figure 1 shows the plateau defined by the available traction. This plateau will drop off once wheel slip increases beyond the point at which peak traction occurs. A discussion of this phenomenon is beyond the scope of this paper. Further information about how traction varies with slip can be found in most handbooks which discuss tire performance, including those by Gillespie and Bosch.[2][3]

Physically, a vacuum booster is a canister, typically measuring 200 to 270 mm in diameter, and 40 to 70 mm in depth.[4] It contains at least two isolated chambers, one forward and one rear. When not in use, both chambers are exposed to the partial vacuum of the intake manifold.* When the operator presses on the brake pedal, the booster input shaft moves forward, isolating the rear chamber from the partial vacuum in the forward chamber, and allowing a controlled amount of air at atmospheric pressure to enter the rear chamber. This creates a pressure differential of up to approximately 85 kPa.[3][5] Typical actuation force gain in the booster is 4:1 to 5:1,[6] causing the assisted output to rise much more quickly than the unassisted output. Thus, the force applied to the master cylinder piston is 4 to 5 times greater than the force applied to the booster input shaft. A drawing of the principle components of a vacuum booster unit is shown in Figure 2. Some designs incorporate a second "tandem" diaphragm for additional boost where the unit diameter must be minimized.

The booster input rod operates directly on the master cylinder, regardless of the booster's operation; therefore, in the event of booster failure, the operator can still apply force to the master cylinder, though the pedal application force to lock the wheels may more than quadruple from about 160 N to over 800 N.

A booster fails to augment brake pedal application force when there ceases to be a pressure differential across the diaphragm. Such a loss of pressure differential can occur at a variety of onset rates, depending on the nature of the breach in vacuum system integrity. If the failure allows a significant amount of air at atmospheric pressure into the forward chamber (for example, if the check valve body breaks off or falls out of the booster housing) there may not be any residual capacity, resulting in a sudden loss of all power assist.

Other disablement modes may not be as sudden, as when the engine ceases to run or when the vacuum system between the engine and the check valve is breached. In these cases, the check valve should preserve a partial pressure differential for one or more power-assisted brake applications, depending on the severity of each application. Additional failure modes may only result in a slow degradation of power assist, as in a small tear in the diaphragm material.

Though FMVSS 105 does not explicitly discuss the reserve capacity of boosters, the Society of Automotive Engineers (SAE) has published Standard J1808, Vacuum Power Assist Brake Booster Test Procedure,[7] which offers a protocol to test the reserve capacity of a booster once disconnected from the vacuum source. Performance requirements are still under development as SAE standard J1902, at the time of this writing. The protocol, interestingly enough, tests the number of times that a booster supplies some

* The intake manifold vacuum is generally used; however, some types of engines, including diesels, do not develop enough partial vacuum to power a booster. In these cases, an auxiliary vacuum pump is required.

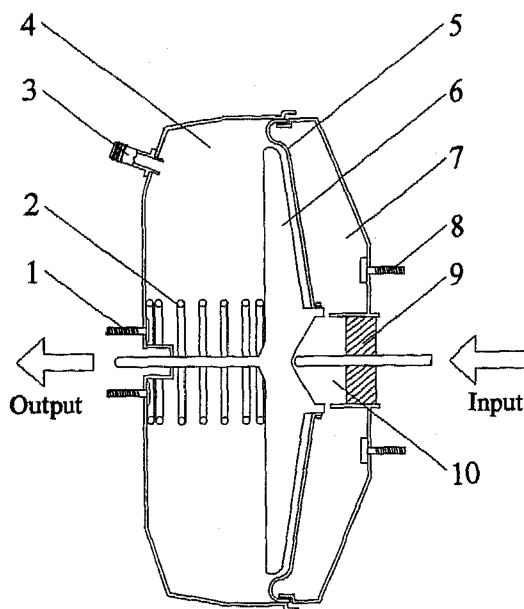

Figure 2: Simplified schematic of a typical vacuum power booster; 1 master cylinder mounting bolts, 2 return spring, 3 vacuum connection and check valve, 4 partial vacuum chamber, 5 diaphragm, 6 diaphragm plate, 7 rear chamber, 8 booster mounting bolts, 9 inlet air filter, 10 air control valve hardware location.

assistance during applications which only reach up to 25% to 30% of the knee point. This test does not imitate a panic stop.

When a booster becomes disabled the brake pedal remains high, and feels "hard" to the operator. Repeated pumping of the brake pedal, as many drivers have learned to do in case of brake troubles, exacerbates the problem by depleting whatever reserve vacuum remains in the front chamber.

In addition to component failure, a loss of pressure differential can be caused by incorrect assembly of the system, two recent examples of which caused vehicle manufacturers to issue vehicle recalls.[8][9]

Though not a factor in analyses involving diminished braking performance, additional booster failure modes exist which can cause the brakes to be applied, usually lightly, despite no application of the brake pedal.

FMVSS 105 REQUIREMENTS

Part 571 of the Code of Federal Regulations includes FMVSS 105, which outlines the requirements for hydraulic brake systems.[10] Though there are several testing options from which manufacturers can choose to meet the requirements for a disabled booster, a typical test is outlined in Section 7.10.2: With the booster depleted of all reserve capacity, a passenger vehicle must be capable of stopping from 96.6 kilometers per hour (kph) (60 miles per hour) at a deceleration rate of 2.13 meters per second per second (m/s^2) (7 feet per second per second), using a pedal application force of not more than 667 N (150 lb). The equivalent stopping distance is 168.9 m (554 feet), or a deceleration of 0.218 times that of gravity (0.218 g's).

An array of additional requirements address different situations. Most requirements involving fully functional brake systems (with or without the inclusion of some form of power boost system) allow pedal application forces up to 667 N (150 lb) to meet prescribed stopping distances.

OPERATOR CAPABILITY

The Human Factors Design Handbook [11] recommends an upper bound for brake pedal force of 267 N (60 lb.), though it states that "When power assist can be provided, this force can and should be considerably reduced." It has been this author's experience during testing for this paper, that control forces below 130 N were noticeably easier to modulate accurately than higher forces. Control forces above 550 N (125 pounds) were found very difficult to apply and modulate smoothly within 10% of a given desired value.

Radlinski and Price [12] measured the maximum average sustained pedal force which 105 women, ages 18 to 62, could apply over five seconds. The maximum force which could be applied by their female test subjects was measured first in a vehicle with a normal brake pedal height, then in the same vehicle with a reduced pedal height, then in a second vehicle with a normal pedal height. In the first vehicle, with the pedal at a normal height, the results ranged from 378 to 1,290 N (85 to 290 pounds), with a mean of 778 N (175 pounds). Twenty percent of the volunteers could not exceed an average sustained pedal force of 605 N (135 pounds). In a second vehicle, also with the brake pedal at its normal height, the same group of women generated average sustained brake pedal forces of between 400 N and 1,379 N (90 lb and 310 lb), with a mean of 863 N. In the first vehicle, when the brake pedal was lowered to simulate a partial system failure, the mean maximum pedal force measured was 587 N, significantly lower than the "normal pedal height" value of 778 N.

Test results reported in the Human Factors Design Handbook indicate that the distance between the seat and pedal plays an important role in operator capability, as does the relative height of the pedal to the seat.

Mortimer et al. [13] used a test buck with a rigid seat to measure the ability of 276 females to apply a brake pedal. When coached to press as hard as possible, the test subjects were able to apply forces from 270 N to more than 1,300 N (60 to 290 lbs), with a mean of 860 N (192 lbs) Five percent of those tested could not exceed 448 N (100 pounds), while twenty percent could not exceed 623 N (140 pounds). These data correlate well with Radlinski's findings.

Mortimer et al. additionally reported a range of 506 to well over 1,340 N (113 to well over 300 lbs) for males when

tested in the same fashion. The fiftieth percentile male was capable of pedal forces in excess of 1300 N (290 lbs). The fifth percentile value for males was 823 N (185 pounds).

Eaton and Dittmeyer [14] tested the pedal-force application ability of female operators when faced with an unexpected increase in control force required to stop the vehicle. They determined that a fifth percentile female was capable of applying up to 448 N, which is the same value reported by Mortimer et al.

The above data indicate that males are more likely to be *capable* of exerting enough brake pedal force to achieve maximum braking; however, the actual performance of every driver, whether male or female, is dependent on their response to an unfamiliar situation.

This author has investigated three cases where the booster became disabled in a male-operated vehicle. In two of those cases there was no warning and the failure occurred as they entered intersections. Both drivers described their vehicle's problem as "brake failure," reporting that they had "no brakes." Both of these operators reported that they responded to the "hard" pedal by pumping it, which in one case effectively exhausted any partial vacuum remaining in the booster, and in the other case had no effect, as the failure was in the diaphragm itself. In the third case, the operator knew of the failure prior to attempting to stop, and was able to apply enough pedal force to control the vehicle, but reported that he feared the forces required would damage the seatback or the steering wheel.

VEHICLE TESTING

Two sets of tests were performed on a 1995 Saturn SL2, a four-door sedan. For all tests, a Valentine Research G-Analyst [15] was used to measure and record the accelerations generated during each stop. The G-analyst's internal parameters were set to those described in the instructions as being appropriate for a slightly sporty sedan. The highest acceleration value maintained for at least 0.5 seconds was recorded. A 4 kN load cell was affixed to the brake pedal, to measure pedal application force. The digital readout was placed such that it could be viewed easily by the operator during testing. The vehicle was accelerated to about 40 kph and shifted into neutral before brake application.

During the first set of tests, the brake pedal application force was applied manually by the operator, with the steadiest possible pedal force, while for the second set of tests an air piston mounted between the steering wheel and load cell was used. The piston was activated using a compressed air tank carried in the vehicle.

Figure 3 shows the braking performance of the Saturn with and without the vacuum booster functional. All data are included, illustrating that the results of the two pedal application methods were not significantly different.

Some of the features described in Figure 1 can be seen

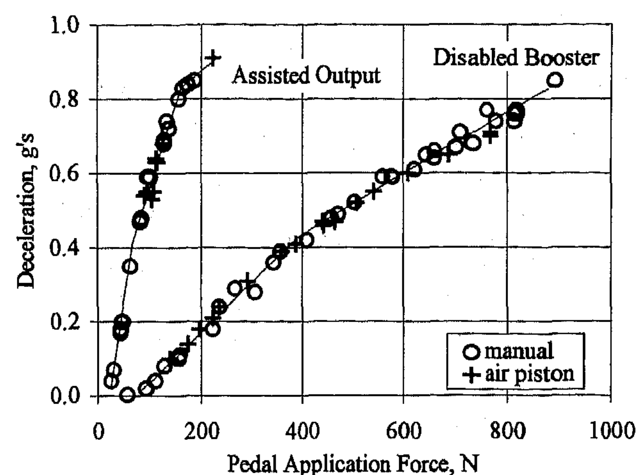

Figure 3: Deceleration of a 1995 Saturn SL2 with and without the vacuum booster functional.

in Figure 3, including the run-out point, at approximately 0.84 g's on the "Assisted Output" curve. At the low end of the curves, the two main features, the kick-in point and the crack point, become blurred, and cannot be discerned accurately.

The curves in Figure 3 show an additional knee near 0.4 g's, which is a result of the inclusion of a proportioning valve in the vehicle's braking system. Among other things, proportioning valves modify rear wheel brake pressure after a predetermined input pressure to optimize the front-to-rear brake balance. This balance is a compromise which attempts to account for dynamic variations which result from braking on surfaces offering different traction and for variations in vehicle load. The slope-change is a function of valve design, and can be seen in some whole-vehicle test results more clearly than others, as will be shown below. A vehicle's proportioning valve may be combined with other valves in a single body, commonly known as a combination valve. Such valves are included in the brake system of virtually every modern passenger vehicle. Most vehicle handbooks offer a more detailed explanation of the purpose and operation of these valves.

Hyung Dae Kim and Younchul Rhim [16] offered a model to predict deceleration as a function of pedal force, which incorporated all the major elements of modern passenger vehicle braking systems. Although they showed an excellent correlation between their predictions and test results, the model required a significant amount of information which is not typically available to an accident reconstructionist, including exact performance characteristics for the proportioning valve and vacuum booster, caliper piston diameter, drum diameter, friction material parameters, pedal mechanical advantage, master cylinder diameter, etc. Though the model is not helpful to this analysis, testing which they conducted to support their work is. They tested the braking performance of two vehicles,

one of which they tested a second time with a variety of components altered or replaced. Figures 4, 5, and 6 present their findings, comparing braking performance with and without the booster operational as a function of pedal force.

Note that the effects of the proportioning valve are not as visible in Figures 4 and 5 as in the earlier example.

A summary of the data presented in Figures 3, 4, 5, and 6 is shown in Figure 7, along with markers to indicate the pedal force application ability reported by Mortimer, et al for both male and female operators. Despite the variations between vehicles, the four "Assisted Output" performance curves are similar, as are the "Disabled Booster" curves.

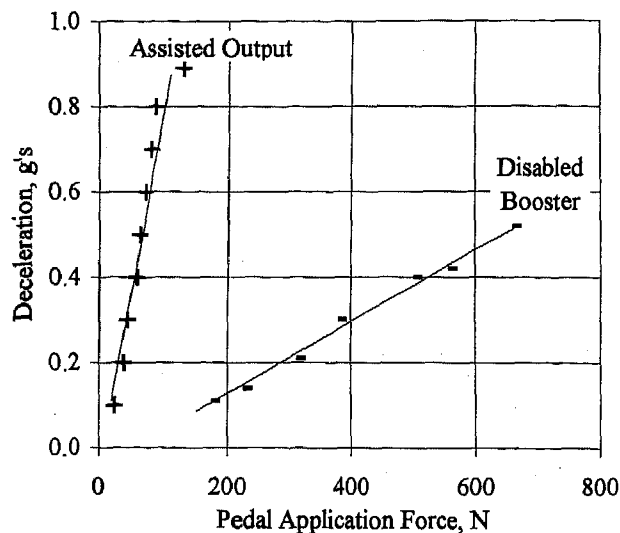

Figure 4: Deceleration with and without the vacuum booster functional, as reported in [16], "Test 1."

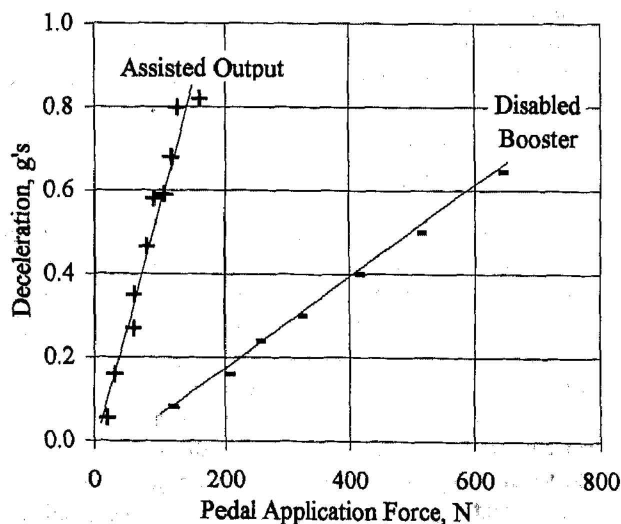

Figure 5: Deceleration with and without the vacuum booster functional, as reported in [16], "Test 2A."

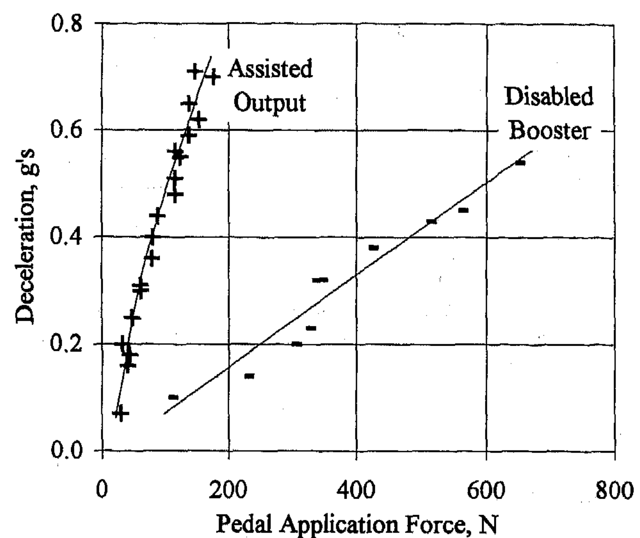

Figure 6: Deceleration with and without the vacuum booster functional, as reported in [16], "Test 2B."

DISCUSSION OF TEST PROCEDURE

The benefits of using the pneumatic piston, instead of manually applying the brakes, included a narrower data spread, and more accurate control over advance selection of the pedal application force. The piston was found to offer very little stiction, and the analog air tank pressure gage was found to be fairly accurate. Using the air pressure and the piston working area, it was possible to calculate the pedal application force within a few percent of that recorded by the loadcell. This method is sufficiently accurate for braking evaluation as it relates to accident reconstruction, and does not require an in-line loadcell.

Use of the pneumatic piston did, however, limit steerability during testing, and applied a significant force (up to 800 N) to the lower portion of the steering wheel ring. This did not result in any permanent damage to the test vehicle's steering wheel or steering column, but it did deflect the lower edge of the steering wheel ring by more than 4 cm. An alternative means of securing the piston should be sought when the possibility of interior damage must be avoided.

Despite the difficulty in modulating high pedal application forces, as noted earlier, the manual results compare favorably with the pneumatic piston results. The loadcell's digital display was not as informative as an analog device would have been, being essentially incapable of offering information concerning the rate at which the force was changing. A compact "pedal effort gage," incorporationg an analog dial and intended for repair facility brake system diagnostic testing is marketed by Kent-Moore Automotive Group.[17] It is anticipated that such a tool would provide

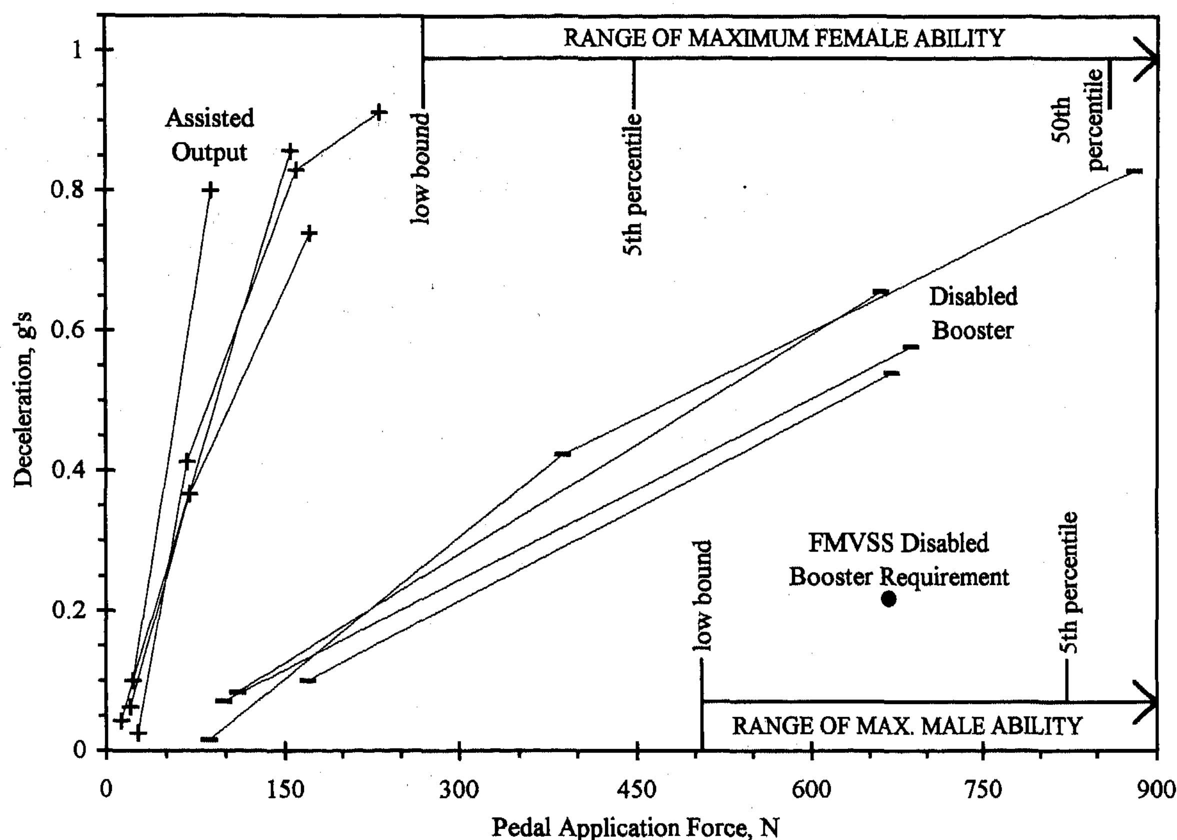

Figure 7: Composite plot of four vehicles' braking performance with and without the vacuum power booster disabled (as presented in Figures 3, 4, 5, and 6), showing ranges for male and female pedal application abilities, as reported by Mortimer, et al.[16]

sufficient accuracy for testing related to accident reconstruction, given other variables in such analyses. The added information supplied by the analog gage would probably improve the accuracy of manual testing, as compared to the use of a digital readout.

DISCUSSION OF RESULTS

The variability between operator capabilities and the variety of vehicle designs precludes determination of deceleration values a particular operator may have effected preceding an accident while faced with a failed vacuum power booster, without conducting specific testing. A female operator may be capable of generating maximum braking (ie, locking the wheels), but may also be only capable of generating sufficient brake pedal force to acheive 0.2 g's, depending on her own capabilities and on the particular design of the vehicle, as shown in Figure 7. A fiftieth percentile male operator is almost certain to be capable of generating sufficient brake pedal force to acheive maximum braking, while a male at the low end of the scale may only be capable of generating 0.4 g's.

Using statistical methods, Mortimer, et al offered a means of evaluating the likelihood that a person of a particular percentile ability would be capable of generating the pedal force required to slow their vehicle at the rate they desired. A statistical approach, however, was not the goal of this study.

In order to evaluate the possible brake pedal forces effected by a particular operator immediately prior to an accident, their ability to depress a brake pedal must be directly measured. Research noted earlier showed that the ability of operators to depress the brake pedal varies noticeably between vehicles and also with pedal height and seat location, thus the following recommendations are made: An operator's ability should be tested in an exemplar vehicle of the same interior geometry as the one they were operating during the accident. The seat should be in the same location. The booster should be depleted, so that the pedal height will be the same as at the time of the accident. If a force gage is mounted on top of the brake pedal, its height should also be considered.

The most accurate means of assessing the effect of the loss of power assistance on a vehicle's braking characteristics is to conduct direct testing.

With the two portions of the driver-vehicle system tested independently, the decelerations which could have been effected by a driver can be evaluated with some confidence. This process does not, however, take into account the possible effects the stress an impending accident may have on an operator, which must be considered, nor does it account for operator perception and reaction time. Further complicating an analysis of such accidents, some operators respond to a booster failure by pumping the brake pedal, which does not increase the brake line pressure significantly, but does expend precious seconds. The amount of time spent in inappropriate responses must be evaluated on a case-by-case basis.

Gillespie noted that only 20% of brake applications during normal driving resulted in decelerations greater than 0.2 g's, which would indicate that the control forces employed are generally below 50 N (referring to Figure 7). Based on the data presented in Figures 3 through 7, it can be deduced that if the booster became disabled, 80% of pedal applications would initally generate decelerations only barely more than those resulting from minor losses and rolling resistance. Many drivers would call an event of this nature "total brake failure."

In many driving situations (stopping in traffic for a red light, for instance), the availability of additional braking capacity, given unusual brake pedal force application, is of no benefit to an operator. Anticipating "normal" braking capacity to be available, operators may not have enough distance to stop prior to impact to perceive the problem and react to it, even if they are capable of applying sufficient pedal force under controlled test conditions to generate "normal" decelerations.

As noted above, in addition to the time required for an operator to perceive the problem and react to it, there is the very real possibility that an operator will respond with a course of action which is not the most desireable. Two such courses of action are pumping the brake pedal and simply "freezing," and failing to apply a significantly higher pedal force. Such failure to respond to an unfamiliar hazard with any action at all is not uncommon.

Since many drivers have the ability to generate braking decelerations well in excess of the 0.2 g's often effected during normal driving, even with a disabled booster, the time required to perceive the problem and press more firmly on the pedal will be an important factor. Stops from low speeds will tend to be more problematic, as the operator may only anticipate requiring two seconds to stop, thus a typical perception/reaction time of 1.2 seconds will place them very near the location at which they intended to stop. The longer time anticipated by drivers to stop from higher speeds allows more opportunity to take advantage of the additional braking capacity which is available, given higher pedal application forces.

CONCLUSIONS

Depending on the vehicle and driver combination, it is possible that an operator, particularly a female, will be incapable of generating sufficient pedal force to lock the wheels, regardless of how much warning and distance they are allowed.

Is is not possible to state, without specific operator and vehicle testing, what deceleration a particular person would be capable of in a particular vehicle, when faced with a failed power assistance unit. If an operator applies a "normal" amount of brake pedal force, the braking deceleration will be about 15 to 25 % of that acheived with the booster functional.

Direct testing of the driver and the vehicle is recommended in order to make accurate estimates of maximum possible braking performance in a particular situation.

Even with direct testing, the investigator must consider the operator's actual response to the perceived problem when evaluating stopping distances and times.

Passenger Vehicle Braking Performance With a Failed Power Booster
Wade Bartlett, Author

Bartlett assesses the physical force requirements for various decelerations for a specific but typical late model vehicle with and without the vacuum power booster operating. He compares this with the range of ability for male and female drivers, based on publications by others. He notes that for a specific incident it is not possible to know the braking effort a particular person might be able a generate if the power assist unit failed. Depending on the vehicle and driver combination he finds that an operator might be incapable of generating sufficient pedal force to lock the wheels. This paper provides a straight forward and succinct presentation which will be a valuable starting point for anyone undertaking tests and analyses to reconstruct the effects of a brake booster failure.

Reviewer's Discussion
by J. Rolly Kinney
Passenger Vehicle Braking Performance with a Failed Vacuum Power Booster
Wade Bartlett, Author

The paper suggests a significant portion of the driver population probably cannot activate the maximum vehicle braking capability when driving passenger cars with un-boosted or disabled booster systems. Those drivers probably achieve a maximum performance level similar to heavy trucks and inexperienced motorcyclists, so they are not exceptional in the traffic mix but are mismatched to the likely performance of passengers cars. When a booster is abruptly disabled a more serious mismatch probably occurs between the driver's expectations and the car response.

The author suggests some accidents may occur because drivers believe a disabled booster means the brake system failed and do not attempt to apply a larger foot force. A similar driver reaction sometimes occurs when the brake pedal stroke increases because one part of the dual brake system fails. Driver failure to use the remaining capability in both type incidents probably is best moderated by improved driver training practices that include actual operation with the booster disabled and with one part of the dual system disabled.

SMAC-97 - Refinement of the Collision Algorithm

Brian G. McHenry and Raymond R. McHenry
McHenry Consultants, Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The Simulation Model of Automobile Collisions (SMAC) computer program, developed in the early 1970's, includes a complex collision algorithm for monitoring, detecting and modeling the collision interactions of motor vehicles. A detailed review of some aspects of the logic, rationale and, in particular, limitations of the original SMAC collision algorithm is presented.

This paper presents refinements in the definition of the collision interface, the definition of collision type, the vehicle proximity and collision detection logic, and the form of supplementary impulsive constraints on relative motions.

The effects of the modifications of the SMAC algorithm on reconstruction results are presented in the form of direct comparisons of results obtained with the original and modified algorithms.

INTRODUCTION

The SMAC program was initially developed in the 1970's when all development of computer code was performed on time-share mainframe computer systems. The capabilities of computers at that time were limited by the maximum amount of available memory (e.g., limit on program size) and users were charged for computer use based on memory and CPU utilization. The costs associated with the development and execution of the SMAC program were relatively high (e.g., [1][1] ,circa 1971,p 48, "The range of costs,...,has been approximately $25.00 per application run" for the SMAC program).

These limitations during the original development of the SMAC program guided the selection of many of the simplifying assumptions of the mathematical model.

Since the early 80's and particularly by the mid 1990's, the prevalence of powerful mini-computers and more recently extremely powerful and inexpensive Pentium PC's, creates an availability of virtually unlimited and inexpensive computer resources. This has inspired a detailed re-evaluation and refinement of computer codes, particularly those developed in the 1970's. The general approach to the reported refinements of the SMAC computer program has been to reconsider the initial simplifying assumptions based both on the availability of additional full-scale test results and the virtually unlimited computer resources.

The reported research identifies and discusses artifacts and/or shortcomings of the original SMAC and the EDSMAC computer programs that have been encountered by the authors in relation to applications (SMAC) and evaluation of applications (EDSMAC) to actual accident cases.

It should be noted that any references to the original SMAC [2] computer program are also generally applicable to the EDSMAC [3] computer program. The original SMAC program and the widely distributed EDSMAC clone are essentially identical. No analytical refinements have been made by the distributors of EDSMAC which produce any significant changes in the results.

BACKGROUND

In the early 1970's, NHTSA sponsored a research project to develop a computer program that would achieve improved uniformity, as well as improvements in accuracy and detail, in the interpretation of physical evidence in highway accidents. The resulting prototype computer program was the Simulation Model of Automobile Collisions (SMAC) [1,2,4,5]. At the completion of the NHTSA sponsored research at Calspan in 1974, a preliminary version of the SMAC program was delivered to the NHTSA and it has subsequently been distributed as the NHTSA SMAC computer program.

Subsequent follow-up contracts for research and development of the SMAC program sponsored by NHTSA went to other organizations [6,7,8]. Further research and development on the SMAC program was also continued independently at Calspan [9] and additional corporate-sponsored research to support criticism of the SMAC program [10,11] was also performed.

[1] Numbers in brackets [] indicate references at end of paper

There were no significant changes by NHTSA into the 1974 NHTSA SMAC at the completion of the NHTSA follow-up contracts.

In 1986, Day and Hargens created EDSMAC[12], a PC version of the 1974 NHTSA SMAC program converted to the BASIC programming language. Subsequent reports related to the EDSMAC program [3,13,14] reveal that except for very minor modifications, the EDSMAC program is essentially the same as the original 1974 NHTSA SMAC program. Related development efforts by the distributors of the EDSMAC program have been directed towards a mini-computer based high-end graphics environment [14,15,16,17,18].

In 1988, a number of suggestions for further refinement and extensions of the SMAC program were presented [19]. In 1989, some suggestions for avoiding misapplication of computer programs, including the EDSMAC program [20] were presented.

The widespread distribution of the EDSMAC program has dramatically increased its utilization for the reconstruction of individual accidents (e.g., accidents that are involved in litigation). This creates a situation where in many instances, either through misuse, misapplication or due to shortcomings in the original NHTSA SMAC (and therefore EDSMAC), there have been applications of the program which include significant effects of artifacts of the original programming logic.

The current reported research defines some important refinements of the SMAC program, particularly with respect to the collision modeling algorithm. This paper also extends the suggestions in [19] and [20] to assist users in avoiding possible misapplication of the SMAC program. Note that any references to the "original" SMAC program refer to the 1974 NHTSA SMAC program and therefore to the EDSMAC program.

This paper constitutes a continuation of the research presented in [19] and more recently in [21]. Specific refinements to the original SMAC program collision modeling routines discussed herein are as follows:

1. Definition of the collision interface.
2. Collision type specification.
3. Supplementary impulsive constraints on relative motion.
4. Vehicle proximity and collision detection logic.

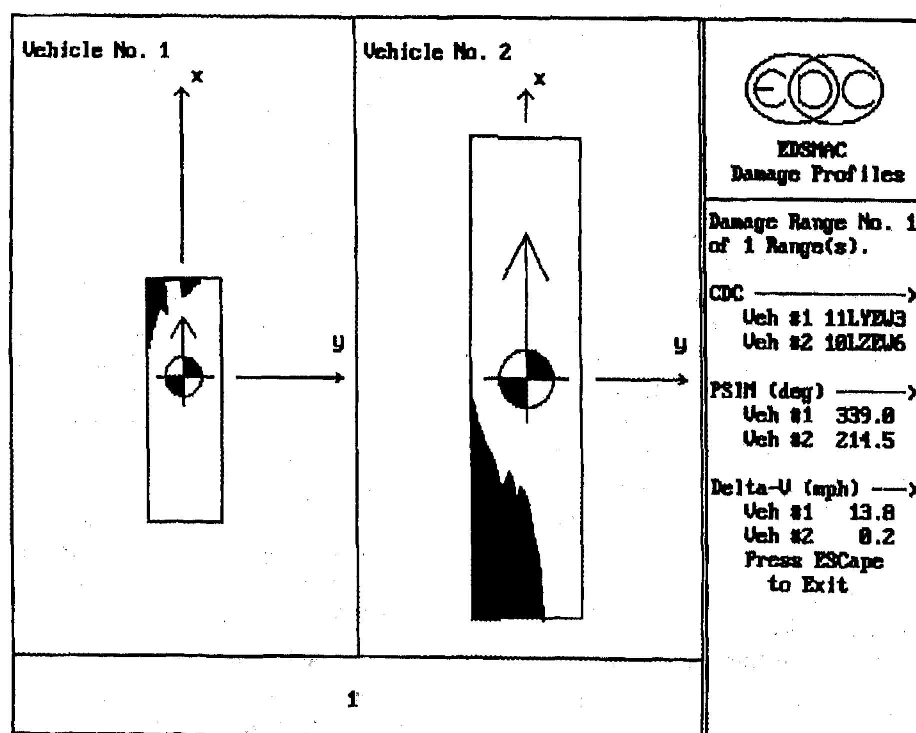

Figure 1 EDSMAC damage display for bus/auto impact simulation with 90 degree vector artifact demonstrated [22]

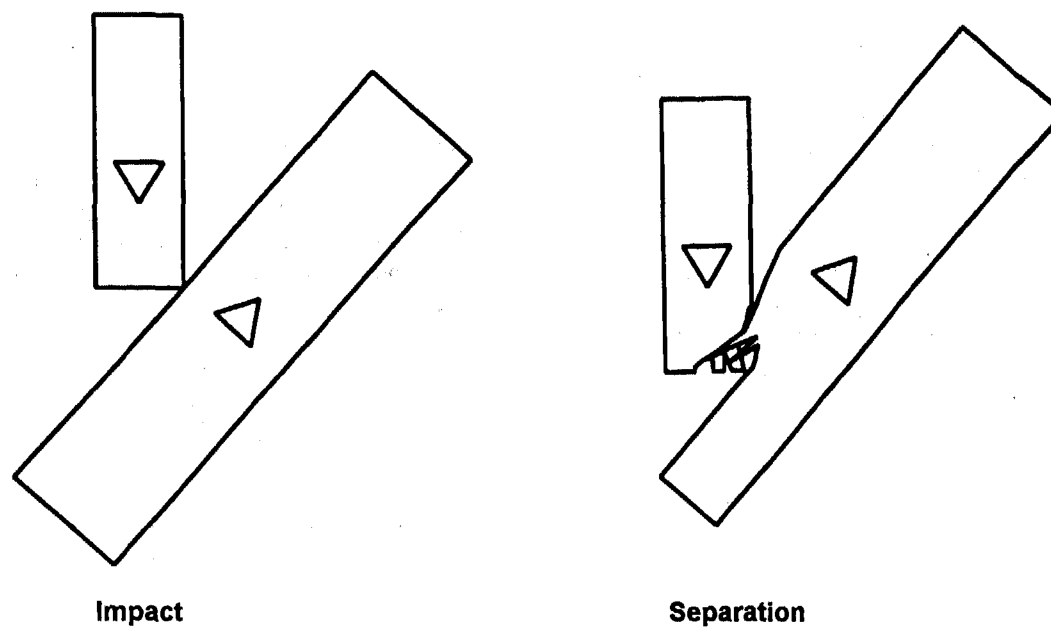

Figure 2 Original SMAC(EDSMAC) bus/auto impact simulation at 0.140 sec after initial impact with 90 degree vector artifact demonstrated.

DEFINITION OF THE COLLISION INTERFACE

Problems encountered in applications of the original version of the SMAC (and EDSMAC) programs in oblique impacts particularly when a long vehicle is struck on the side at a position away from the center of gravity (e.g., **Figure 1** and **Figure 2**) originate in limitations imposed by the selected original form of analytical definition of the vehicle peripheries.

In particular, radial vectors with origin at the center of gravity are used to define the peripheries of the two vehicles (e.g., **Figure 3**). During a collision, the lengths of the radial vectors in contacted regions are adjusted by an iterative procedure which seeks an equilibrium dynamic pressure on the collision partners. The dynamic pressures at individual peripheral points are assumed to be proportional to their displaced distances from the undeformed periphery.

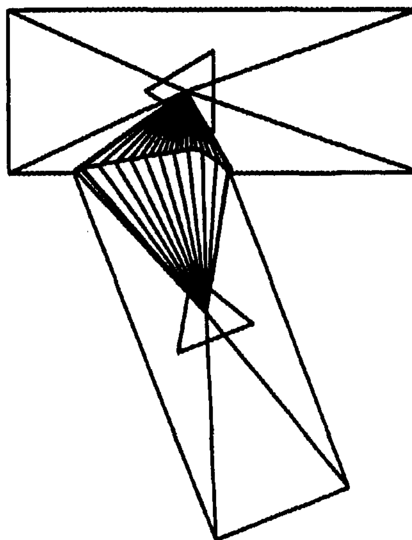

Figure 3 Mathematical representation of the SMAC periphery by radial vectors.

In the cited problem configuration, some of the radial vectors of the two interacting vehicles approach the condition of being perpendicular to each other and, as a consequence, the iterative adjustment procedure for the lengths of radial vectors cannot find a proper solution. The inter-vehicle pressure associated with these vector points cannot find an equilibrium. As a result, an unrealistic equilibrium interface is produced that includes a series of jagged notches (e.g., **Figure 1** and **Figure 2**). A close-up illustration of the phenomenon is included in **Figure 4** and a close up detail including display of the radial vectors is included in **Figure 5**. The error flag normally associated with the problem in the SMAC program is "PRESI (or PRESIJ) tends negative". In the original program the error flag sets the associated pressure to 0.0 and attempts to continue program execution. The setting of the zero pressure creates the jagged interface wherein only some of the vectors are "active". Other vectors have the error and, therefore, they are undeformed or partially deformed from the periphery. The original SMAC included a program stop if a sufficient number of PRESI/PRESJ type errors occurred in an individual simulation run.

The perpendicular vector problem is most obvious in the original SMAC with longer vehicles as a result of the large distance of the contact region from the origin. Individual vectors on the long vehicle are required to define a larger area of the vehicle periphery than that in a more typical impact configuration. This tends to amplify the near perpendicular vector problem where one radial vector on the long vehicle may affect several on the other vehicle.

An initial approach that was investigated for a generalized fix to the phenomenon was an increase in the number of vectors and, thereby, the detail included in the collision routine. In the original SMAC program the capabilities of the collision routine were limited due to computer memory storage considerations. The specific limitations were the maximum number of interacting vectors (100) and the maximum number of iterations the program could utilize to attempt to find equilibrium in inter-vehicle pressure (100). In consideration of the capabilities and capacities of modern day (1990's) computers, the capabilities have been increased to permit the use of 1 degree vectors and smaller values for the acceptable error in inter-vehicle pressure. Users of SMAC should never make use of an angle greater than 3 degrees between radial vectors. The use of 1 degree increments reduces the problems associated with near 90 degree vectors by decreasing the area of coverage of individual vectors for longer vehicles. It also provides a generalized increase in the detailed equilibrium interface of the collision routine for normal simulations. However, the described changes did not solve the problem with perpendicular vectors.

The indicated problem is resolved in the revised SMAC program by means of locating the origin of the radial vectors of the collision interface at a position on the vehicle other than the center of gravity. In this manner, the origin of the vectors defining the vehicle periphery can be moved longitudinally to be near the location of the collision contact (e.g., see **Figure 6** and **Figure 7**) and/or moved laterally away from the initial contact location (e.g., see **Figure 8** and **Figure 9**).

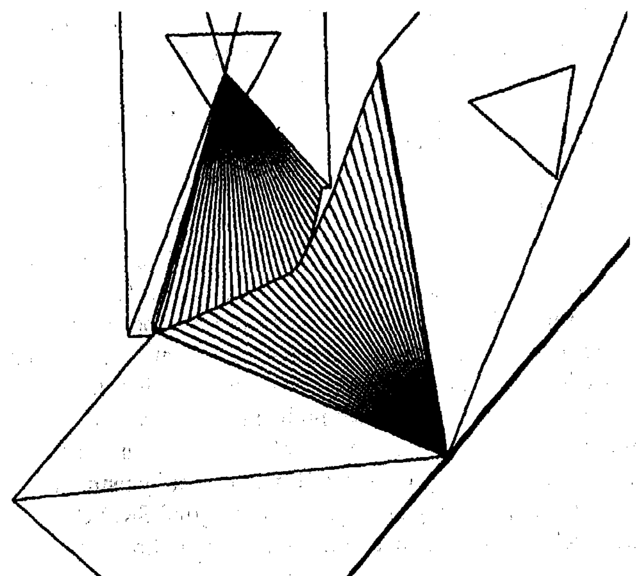

Figure 9 Close-up detail, including radial vectors

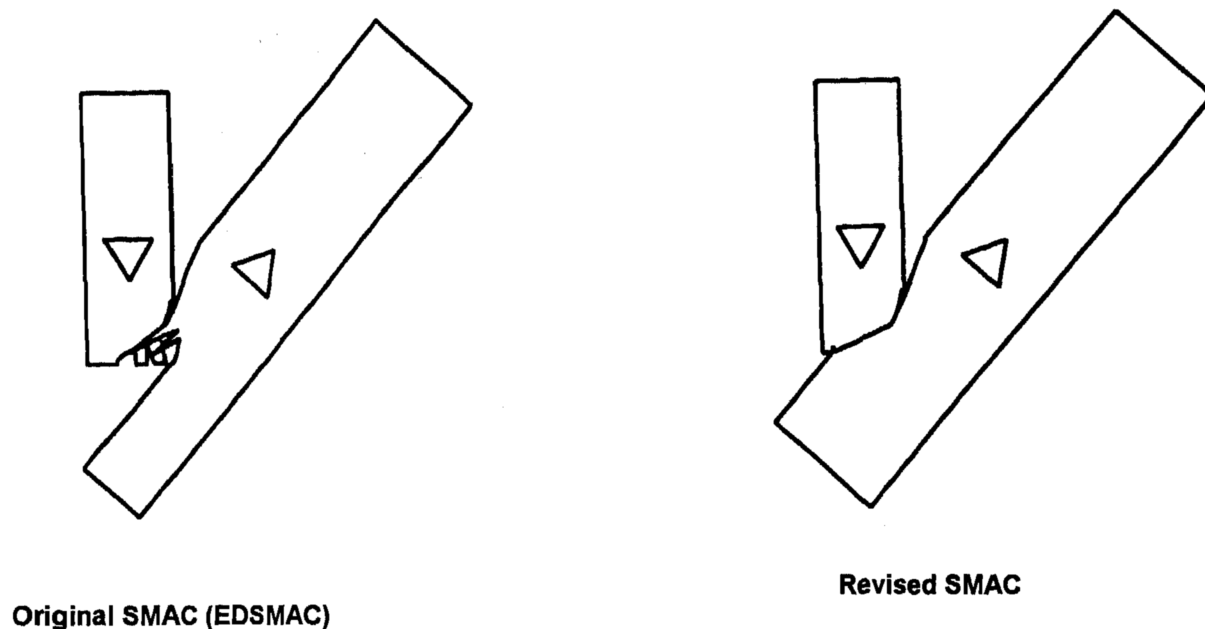

Figure 10 Comparison of predicted damage of original SMAC (EDSMAC) and revised SMAC (0.14 sec after initial impact)

A comparison of the effects of moving the origin of the collision interface from the CG is displayed in **Figure 10**. The results of the car/bus impact presented in **Figure 1** also indicate an incorrect value for the impact speed-change of the automobile. The EDSMAC program indicated an impact speed-change of 13.8 MPH for the automobile, whereas the correct value is 31.5 MPH (The impact velocities were 43 mph for the automobile and 15 mph for the bus).

The long vehicle example dramatically demonstrates problems which can occur with perpendicular vectors. Users of the original SMAC (EDSMAC) should also be aware that to a lesser degree, dependent on the impact configuration and severity level, normal length vehicles may occasionally encounter perpendicular vector problems. The problem is dramatically demonstrated on a smaller scale when users attempt to simulate a pole or small tree impact by using a small rectangular or square object. The original SMAC (EDSMAC) program is not valid for the simulation of pole and/or small tree impacts. The fundamental problem of pole impact simulations with the original SMAC(EDSMAC) (i.e., non-homogeneous crush properties for small contact areas) is increased by the perpendicular vector problem when the pole and/or small tree impact location is offset from the vehicle center of gravity. A separate research report will include discussion of revisions to SMAC to accommodate pole and/or small tree impacts[23]

The original form of SMAC can also produce application problems in reconstructions in which the equilibrium interface approaches the center of gravity of one of the vehicles. Therefore, lateral movement of the origin of the collision interface vectors may be required for simulations of severe side impacts where the collision interface can approach and/or exceed the ½ width of the vehicle. In the original SMAC (and EDSMAC) program these types of collisions normally produce either a program error or an effective softening of the crush characteristics (e.g., [11]).

The present discussion should not be interpreted as an indication that valid results can be obtained at very high severity levels. Rather, the related modifications of SMAC are aimed at minimizing the effects of artifacts, in the computer implementation of the analytical relationships, on the predicted results. Evaluations of the ranges of validity of a mathematical technique should not, of course, be obscured by the presence of significant effects of artifacts.

Research is underway to establish a generalized fix to automatically locate the origin of the collision interface vectors on the basis of impact configuration and severity. An automatic adjustment of the origin is considered to be highly desirable from the viewpoint of eliminating any possibility of related deviations from uniform interpretations of evidence. In the existing revised version of the SMAC program an option is presently included to permit the user to move the origin, where appropriate.

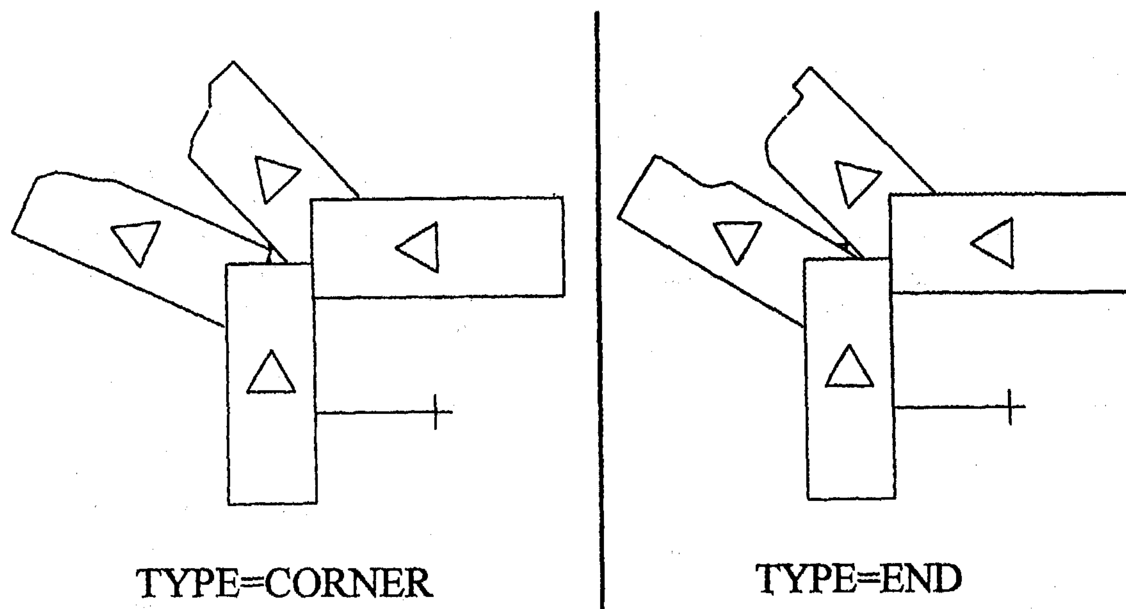

Figure 11 Demonstration of effects of 1" change in Y of vehicle produces different definition for type of impact configuration and therefore different damage profiles.

COLLISION TYPE SPECIFICATION

In the original SMAC (EDSMAC) program, the collision interface handles three types of impact configuration: End, Side, and Corner. Logic in the program calculates the extent of collision contact overlap at the instant of contact and determines which of the three types of configuration logic to use for calculation of the collision forces. Occasionally the program may exhibit a disproportionate sensitivity to minor changes in a particular impact configuration which is near a "logic" transition point. Minor changes in the impact configuration can cause the program to switch between the different types of collision force logic (e.g., Figure 11). Research is underway to update the logic associated with determination of the impact type as part of a general fix of the collision logic to avoid this phenomenon. To avoid sensitivity problems a manual override of the automatic logic is suggested and has been provided in the revised SMAC program. The manual override of the impact configuration logic eliminates the sensitivity and provides for a manual check of the effects of changing the designated impact configuration type.

SUPPLEMENTARY IMPULSIVE CONSTRAINTS ON RELATIVE MOTION

There are some impact configurations for which the simple combination of compressive forces and coulomb friction of the original SMAC program are inadequate. The actual structural interactions between colliding vehicles can include significant tensile forces and/or moment constraints on relative rotation in addition to the primary compressive interaction. Also, significant alternative load paths can occur which do not produce sheet metal crush. In such cases, supplementary impulsive constraints on relative motions can be applied without detracting from the principles of conservation of linear and angular momentum in relation to trajectory analyses. In other words, such impulsive constraints on relative motions of the two vehicles continue to conserve the linear and angular momentum of the two-body system with regard to interactions between the two vehicles. Any benefits derived in the form of improvements in the match of the position and heading at rest of vehicle#1 will have equal and opposite effects on the predicted position and heading at rest of vehicle#2. If both simulated vehicles can be brought into acceptable matches of their positions and headings at rest by means of such supplemental impulsive constraints on relative motions, the required pre-impact linear and angular momentum of the two vehicle system will be unaffected and the approximation of initial speeds and impact speed-changes can proceed as usual.

It should be noted that supplementary impulsive constraints on relative motions can have the effect both in reconstructed accidents and in actual collision evidence of disturbing the relationship between sheet metal crush and the corresponding ΔV. For example, in a small-overlap offset frontal collision, interlocking front wheels can support large interaction forces with only a limited extent of sheet metal crush. Also, a pocketing sideswipe can include a major load path (e.g., wheel/axle/suspension) that does not produce corresponding crushing of sheet metal.

It is therefore necessary for the reconstructionist to evaluate the role of alternative load paths when interpreting sheet metal crush. In those cases where alternative load paths play a major part in the vehicle interactions it is necessary to place greater emphasis on scene evidence as opposed to sheet metal crush and, in the case of SMAC applications, to make use of supplementary impulsive constraints.

To work around the indicated form of shortcoming of the original SMAC program some of the RICSAC reconstructions performed by Jones [24] and some users of EDSMAC made use of a value of the inter-vehicle friction coefficient substantially greater than 1.0 attempting to compensate for the lack of tensile forces and/or moment constraints on relative rotation. The problem with the high friction approach is two-fold.

First, the inter-vehicle friction coefficient of the SMAC collision model is based on coulomb friction which is independent of the sliding velocity and has a coefficient value less than or equal to 1.0. During the collision, as relative sliding of the surfaces occurs, the magnitude of the inter-vehicle friction force depends on the existence and magnitude of the collision normal force. Supplemental tensile forces and/or moment constraints occur in vehicles as the vehicles begin the separation phase when the normal force may be very small or zero. After the primary collision, as a result of the impact configuration, the vehicle contact area and/or the vehicle component contacted, intermeshed components of the two vehicles can offer additional resistance to separation in the absence of the normal forces required for coulomb friction. Using a value for the inter-vehicle friction coefficient greater than the recommended range (normal value 0.55, recommended range 0.3-1.0) may unrealistically and/or adversely affect the primary impact phase, since the additional forces and moments produced by the elevated friction can act to redirect the forces and moments during the primary impact.

A secondary problem which may occur with original SMAC (EDSMAC) use of a high value of inter-vehicle friction can occur in the post-processing program which may not be able to "match" the accelerations to the damage region. As a result invalid ΔV values and clock direction may be reported. An EDSMAC application summary page (used by an expert witness as an exhibit to deposition testimony) which contains invalid ΔV values for the collision partners was produced by the use of a value for the inter-vehicle friction coefficient of 2.0 and is shown in **Figure 12.** (Note that $m_1\Delta V_1 \neq m_2\Delta V_2$. In the original SMAC a supplementary page included diagnostics which report all of the speed changes calculated in a given run to permit a check of the values reported by the post-processing routine. This auxiliary page appears to have been omitted in the EDSMAC program.).

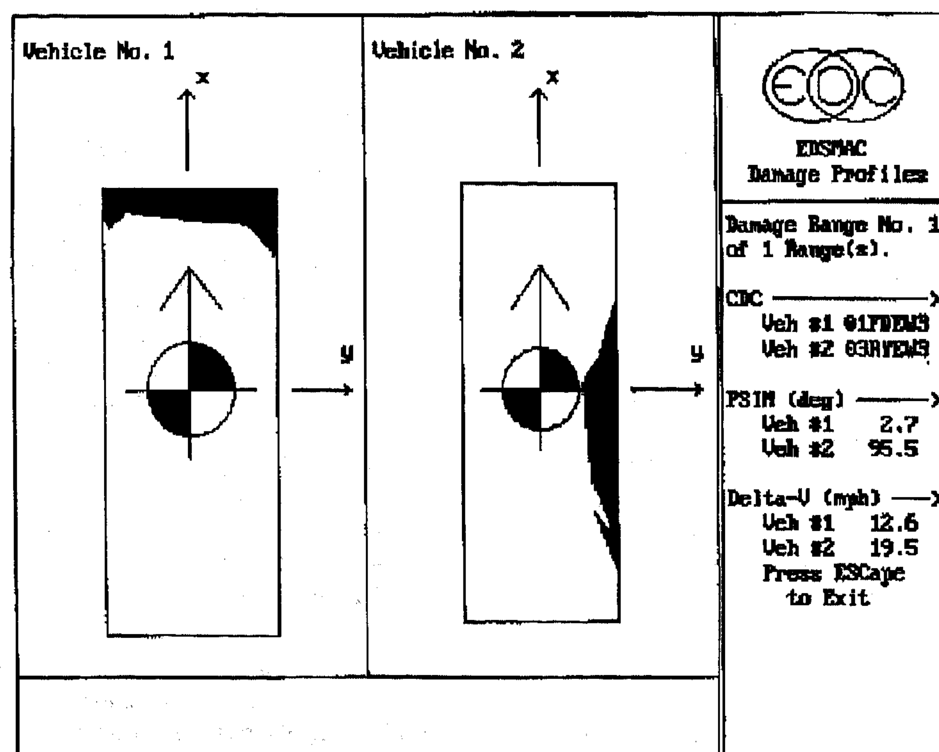

Figure 12 Example usage of invalid inter-vehicle friction coefficient of 2.0 which produces invalid results (Weight1=3226 lb., Weight2=3953 lb.) Therefore $m_1\Delta V_1 \neq m_2\Delta V_2$.)

Revisions to the SMAC program to model supplementary impulsive constraints include the impulsive-constraint "SNAG" option as previously presented in [19]. In **Figure 13** the original SMAC program does not adequately simulate an impact on the LR wheel of vehicle #1. The impact on the LR wheel in the investigated accident produced a 180 CCW rotation of vehicle #2 due to a momentary snagging of the LR wheel of vehicle #1 on the front of vehicle #2. In **Figure 14** two different impulsive constraints ("SNAG") are applied to the vehicles in the area of the left rear wheel of vehicle #1. The results indicate that applying a 1000 lb.-sec impulse is adequate to spin vehicle #2 180 degrees and, thereby, it constitutes a reasonable approximation of the magnitude of the actual snagging of the vehicle structures.

Efforts are being directed toward the development of automatic calls for impulsive constraints and for standardized related input values on the basis of the impact configuration and the closing speed. Prior to completion of that development the timing and the magnitudes of any impulsive constraints should be reported along with corresponding reconstruction results.

VEHICLE PROXIMITY AND COLLISION DETECTION LOGIC

In the SMAC program, each vehicle is represented by a rectangular box with the length and width dimensions of the simulated vehicle. Collision detection is accomplished by continually checking the corners of each vehicle "box" to determine if it is within the periphery of the other vehicle "box". Once a corner point is found to be in contact, the program begins calling the collision routine to use the collision model radial vectors to scan for interference and contacts and to calculate the associated collision forces. The program also changes the integration time increment to the user specified collision integration interval (DTCOLL, normally 0.001 seconds). The end of the collision event is assumed when a fixed number of time increments have passed wherein the accelerations for each vehicle is below 1 g-unit. The program flags the system into a separation mode and utilizes the separation time increment (DTCOLT, normally 0.005 seconds). In the original form of the SMAC program, the separation time increment was utilized for a fixed number of increments (originally 100). It was the intent of the separation time increment to catch side-slaps, etc. while the program was still in a relatively small time increment. If the fixed number of DTCOLT time increments are passed without any accelerations greater than 1 g-unit then the program shifts to the trajectory time increment (DTTRAJ, normally 0.01 seconds) for the remainder of the simulation run.

Problems have been found with applications of the EDSMAC program where the program missed the accelerations associated with "side-slap" impacts. The reasons for the problems with the EDSMAC program have been found to be mainly due to the choice of time increment size.

The recommended time increment sizes for use of the SMAC (or EDSMAC) program are as follows:

DTTRAJ, Trajectory time increment, not to exceed 0.01 seconds.

DTCOLT, Separation time increment, not to exceed 0.005 seconds

DTCOLL, Collision time increment, not to exceed 0.001 seconds.

These time increments should be assumed to be absolute maximums. With the speed of modern day Pentium computers, a complete SMAC ten second simulation run of an impact and spinout can be performed in less than 10 seconds of real time with all time increments set to 0.001 seconds. EDSMAC documents recommend the use of 0.01 for the DTCOLT separation time increment, 0.05 for the DTTRAJ trajectory time increment, 0.001 for the DTCOLL collision time increment **[25]**. These suggested times must have been based on suggested times for mainframe applications from 1974 contained in **[26]**.

A problem with larger time-increments is the fact that they may reduce the accuracy of the predicted results. Also, when simulating a collision which may include a side-slap secondary collision, the program may miss the forces and moments associated with the side-slap event. After a primary collision event, once the SMAC (EDSMAC) program has changed to the EDSMAC recommended large DTCOLT or DTTRAJ time increments, the occurrence of a sideslap may not be detected or detected so late that the sideslap event is over and no associated accelerations are developed in the simulation due to the sideslap. The logic in the original SMAC (EDSMAC) associated with sideslap detection does not return to the DTCOLL small time-increment until the acceleration on either of the vehicles exceed 1 g-unit.

The following illustrates what occurred in an application of the EDSMAC program (used by an expert witness as an exhibit to deposition testimony). The impact configuration is displayed in **Figure 15** and the EDSMAC output damage page is contained in **Figure 16.** The damage display contains sideslap "damage" for which the accelerations associated with the sideslap "damage" were not simulated. The time history of the acceleration which 'misses' the side-slap is contained in **Figure 17** while the time-history of the corrected simulation is contained **Figure 18.** The differences which may occur between the incorrect simulation (which missed the accelerations associated with the sideslap) and the corrected simulation (which included the sideslap) are significant differences in the total amount of rotation and direction of travel to rest.

Revisions to the SMAC program have been implemented to make the post-impact interval where the program stays in DTCOLT a fixed *duration* of 0.30 seconds rather than a fixed number of time steps. In this manner, when the user sets the DTCOLT increment to 0.001 the program will continue to scan for greater than the 100 time steps . It is recommended that in accidents which include a sideslap collision that users use a DTCOLT of 0.001 seconds.

SUMMARY

With the rapidly changing capabilities and capacities of modern day computers, computer programs in general and accident reconstruction computer programs in particular require continuing efforts to check and refine results while critically evaluating the underlying simplifying assumptions. This paper has presented some areas of needed refinement in the original SMAC collision algorithm.

Reviewer's Discussion
by Gary W. Cooper
SMAC-97 Refinement of the collision Algorithm
Brian McHenry, Raymond R. McHenry, Authors

The authors describe some of the limitations of the original SMAC algorithm. The paper focuses on limitations in four collision modeling routines in the SMAC program. The authors discuss the reasons that limitations existed in the original program, how the limitations manifest themselves in simulations, and then describe programming "fixes" for these limitations. The authors point out there have been no significant changes in the original 1974 NHTSA SMAC algorithm and many of the limitations (simplifying assumptions) were directly related to the cost and capabilities of the computers used at the time the program was developed. However, with the powerful PC's that now exist the simplifying assumptions are no longer required and the program should be refined. The authors do an excellent job of describing the limitations, how the limitations impact a simulation, and the way to resolve the limitation through improving the algorithm. Everyone should agree that any refinements that better model the "real world" should be incorporated in programs to enhance mathematical models used to simulate collisions.

SMAC-97 Refinement of the Collision Algorithm
Brian G McHenry, Raymond R. McHenry, Authors

The authors have done a good job in summarizing the history of the SMAC algorithm and have pointed out many of the simplifying assumptions that are a part of the original SMAC program. It seems that the most significant refinement presented is in positioning the origin of the radial vectors used to model the impact and deformation of the vehicles. The refinement presented here is a logical step in improving the behavior of the SMAC algorithm, but the only clear advantage presented is in collisions where the damage on one of the vehicles is a long distance from the center of mass. It seems that the refinement will also aid in all the collisions studied, but a validation study must be completed before these advantages are quantified. The other three refinements are also of interest and should be studied carefully by analysis. Overall this paper is summary of refinements that are possible. Intuitively, the refinements make sense and should improve the overall behavior of the SMAC algorithm. A detailed validation study needs to be completed so the overall improvements can be presented.

CRASH-97 - Refinement of the Trajectory Solution Procedure

Brian G. McHenry and Raymond R. McHenry
McHenry Consultants, Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The *trajectory solution procedures* of the original CRASH program included both the SPIN routine and an exploratory *trajectory simulation option* to approximate and refine the linear and angular velocities at separation. The resulting separation speeds were then used to determine the impact speeds by means of application of the principle of conservation of linear momentum.

This paper presents a detailed review of the logic, rationale and limitations of the trajectory solution procedures of the original CRASH program and discusses a number of refinements including: incorporation of the principle of conservation of angular momentum, approximations of the effects of changes during collision in the positions and orientations of the two vehicles and of the effects of external forces and moments that act on the two-body system during the collision, and adaptations of optimization techniques for error reduction and convergence in iterative solutions.

The overall effects of the refinements to the CRASH trajectory algorithm on reconstruction results are illustrated by direct comparisons of results with SMAC reconstructions of full scale collision tests.

INTRODUCTION

The original form of the CRASH **[1, 2, 3, 4]**[1] computer program, which culminated in the CRASH3 version, was not intended to be a detailed, highly accurate reconstruction program. Rather, it was developed to serve as a simple preprocesser for the SMAC program. While the results of CRASH3 applications can be useful in providing approximate measures of accident severity for use in statistical studies, where the average error is most important, it has been demonstrated in validation tests to produce results which when compared to those of full-scale crash tests can include individual errors as great as 45%**[4]**. The possible error levels of the CRASH3 computer program are also generally applicable to the EDCRASH **[5, 6, 7]** computer program, since the CRASH3 program and the widely distributed EDCRASH clone are essentially identical. No significant analytical refinements have been made to the trajectory solution or trajectory simulation procedures of EDCRASH. The EDCRASH program, while claiming to be "within -6 to +7 percent of the combined impact speeds at a 95 percent level of confidence"**[6]** is subject to errors in individual speeds as great as 43.5% (Table 2, case 12, vehicle No. 1 **[6]**). Any "improvement" of the EDCRASH results over CRASH3 is mainly due to the "optimization" of the inputs to EDCRASH (to produce better correlation with known results) and modification of the error reporting techniques **[6]**.

This paper presents refinements to the trajectory procedure of the CRASH3 program, herein referred to as the '***refined CRASH3***' program. Refinements to the CRASH3 trajectory routine include the approximation of separation speeds through automatic iteration of the trajectory *simulation option*, inclusion of angular momentum equations, and inclusion of an approximation of the effects of the external forces (i.e., tire forces) which occur during the collision, in the CRASH3 trajectory *solution procedure*. Also to be presented is a discussion of the adaptation of optimization techniques for error reduction and convergence in the iterative solutions.

One of the problems associated with the development and refinement of any accident reconstruction technique and therefore with our research related to CRASH3 is that of demonstrating correlation with full-scale tests. The RICSAC tests **[8, 9, 10]** were specifically designed to serve as standards for such comparisons. Unfortunately, during review and utilization of the results (e.g., **[11, 12, 13]**), and particularly in prior studies which included evaluating the correlation of computer codes with RICSAC (e.g.,**[6, 14, 15, 16, 17]**) there have been various levels of interpretation and acceptance of the measured results. As a part of many of the cited projects, questions have been raised as to the validity of some of the reported RICSAC test results.

Since there has been no consensus on the interpretation of some of the results of the RICSAC tests, an intensive independent effort has been applied toward

[1] Numbers in brackets [] indicate references at end of paper

achieving proper and generally acceptable interpretations of the RICSAC test data. That research is being performed as part of a separate project reported in [18].

To permit a continuation of refinements of the CRASH3 computer code, which required comprehensive comparisons for validation, the approach reported herein has been to make use of the SMAC [19,20] computer program to generate "test results" data. The SMAC program has been demonstrated to correlate well with full-scale test results [10] [17]. It has been generally accepted that, in the absence of significant external forces, the SMAC program correctly conserves linear and angular momentum of the two-body system. For example, **Figure 1** and **Figure 2** demonstrate comparisons of the linear and angular momentum and kinetic energy for two different RICSAC test configurations simulated on test track friction (mu=0.87) and on a frictionless surface (mu=0.0).

In the SMAC program the simulated vehicles are set up to run into each other at impact locations, orientations and speeds which are identical with those of the corresponding RICSAC tests. The response data generated by SMAC includes ΔV values for the centers of gravity, including effects of vehicle rotation and external forces, separation velocities and positions of rest. Use of the SMAC results for preliminary comparisons of the effects of refinements of computer codes avoids the complications which can occur when utilizing "raw" full-scale test data due to sensor locations and test measurement variations. The SMAC program also provides a means of refining imprecise definitions in the reported test data for such items as the effective drag at the individual wheels (e.g., driveline drag for automatic or manual transmissions in gear, rubbing of damaged sheet metal on rotating wheels) and steer angles. The refinement of the items can be achieved with SMAC on the basis of matching the positions and headings at rest between SMAC and the full-scale test results.

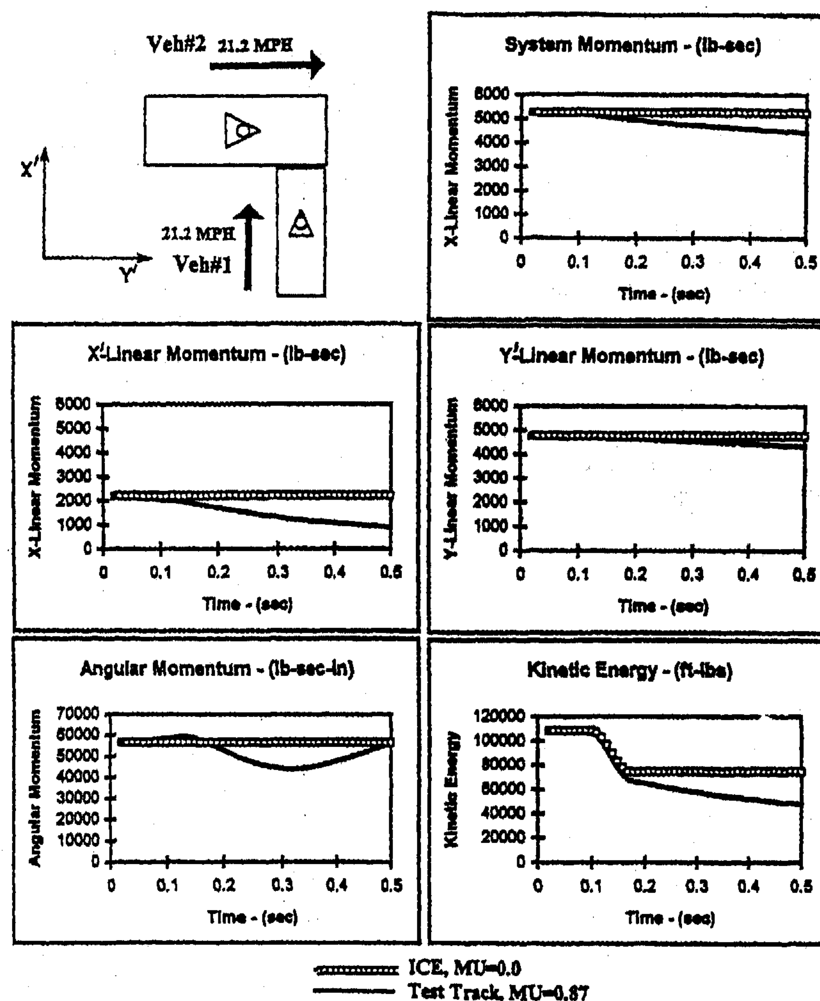

Figure 1: RICSAC Test 9: Comparison of SMAC generated System Momentum and Kinetic Energy time-histories for Test Track Friction and No Friction (note: impact at 0.10 sec, separation at 0.208 sec) (Veh#1 1975 Honda Civic,2270 lbs., Veh#2, 1974 Ford Torino, 4930 lbs.)

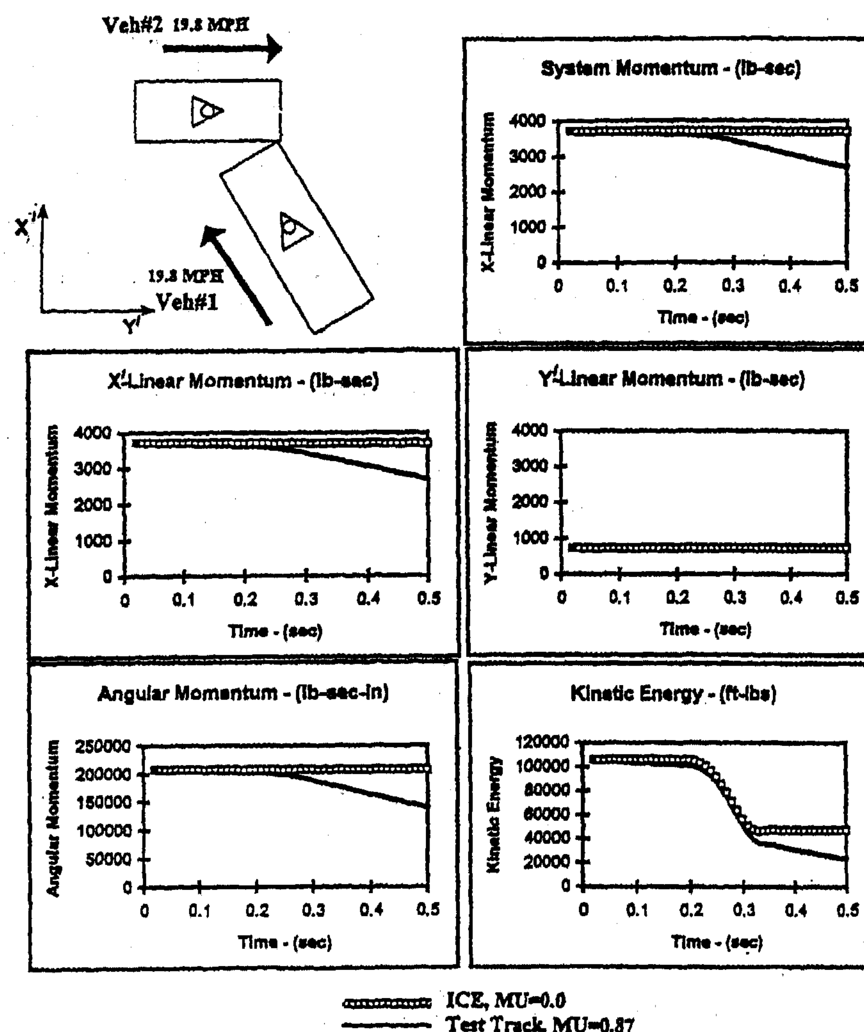

Figure 2: RICSAC Test 1- Comparison of SMAC generated System Momentum and Kinetic Energy time-histories for Test Track Friction and No Friction (note: impact at 0.18 sec, separation at 0.343 sec) (Veh#1 1974 Chevrolet Chevelle, 4650 lbs., Veh#2 1974 Ford Pinto, 3110 lbs.)

The inputs used in the present study for the SMAC runs were very similar to those that have been used in relation to SMAC validation [**10, 17**]. However, some of the cited prior SMAC inputs were found to be questionable (e.g., in some, the drag factor and steer angles at individual wheels were arbitrarily varied over time) or clearly erroneous (e.g., some had incorrect weights, tire cornering stiffness, intervehicle friction coefficient, etc.). The adjustment procedure for the SMAC inputs in the present research project was to initially check and correct any erroneous inputs and then to calculate a constant value for the wheel steer and drag factors based on the values reported in [**10, 17**]. The SMAC reconstructions were then re-run to determine the correlation of the SMAC "test results" with the full-scale test positions and orientations at rest. Minor refinements were then made, as required, to the constant values for the wheel steer angles and drag factors to achieve an approximate match of the SMAC reconstructed "test results" vehicle positions of rest with the RICSAC measured positions of rest [**21**].

Table 1 is a summary of the SMAC reconstructions of the RICSAC full-scale tests. This summary of the RICSAC tests represents a "best information" set of mathematically correct SMAC reconstructions for the individual RICSAC full-scale crash test conditions and results. The "best information" for the reconstruction results was derived from a review of the full-scale test reports [**8, 9, 22**], and a review of the reported results by Smith and Noga [**11**] to guide the SMAC reconstructions. Test numbers 1 through 12 were run at Calspan [**8, 9**]. Test number 14 is Test 3 run at Texas Transportation Institute [**22, also see 23**].

While the wheel drag factors and steer can be varied over time in the SMAC program, "validation" datasets should be representative of what can be achieved in real world applications. For normal reconstructions a constant value is generally required since detailed time-history information is not available. The intent of the refinements to the SMAC input datasets performed for this project was to create without undue delay a representative collection of mathematically

correct "test results" for comparison with CRASH predicted results. A more comprehensive review and refinement of the SMAC inputs will be performed as a part of the research reported in [**18**].

A set of input datasets for CRASH3 were then prepared which were derived from the SMAC "test results". The inputs for CRASH3 consisted of the SMAC impact and rest positions and headings, the SMAC steer angles and drag factors and the SMAC vehicle specifications (weights and dimensions) (see **Appendix 2** for the CRASH3 input datasets used). No further adjustments or refinements were made to the CRASH3 or SMAC input datasets as part of this project.

These inputs were then run with the CRASH3/EDCRASH programs and the results are depicted in **Figure 3** and **Figure 4.** These figures represent the starting point for the ***refined CRASH3*** research project and they demonstrate the general inability of the CRASH3/EDCRASH programs to consistently reconstruct the mathematically correct SMAC predicted "test results".

Table 1: Summary of RICSAC Tests Impact conditions and SMAC ΔV reconstructions

RICSAC	RICSAC TEST Impact Speed		SMAC Delta-V	
Test No.	Veh 1	Veh 2	Veh 1	Veh 2
1	19.8	19.8	14	20
2	31.5	31.5	21	30
3	21	0	10	15
4	38.7	0	16	25

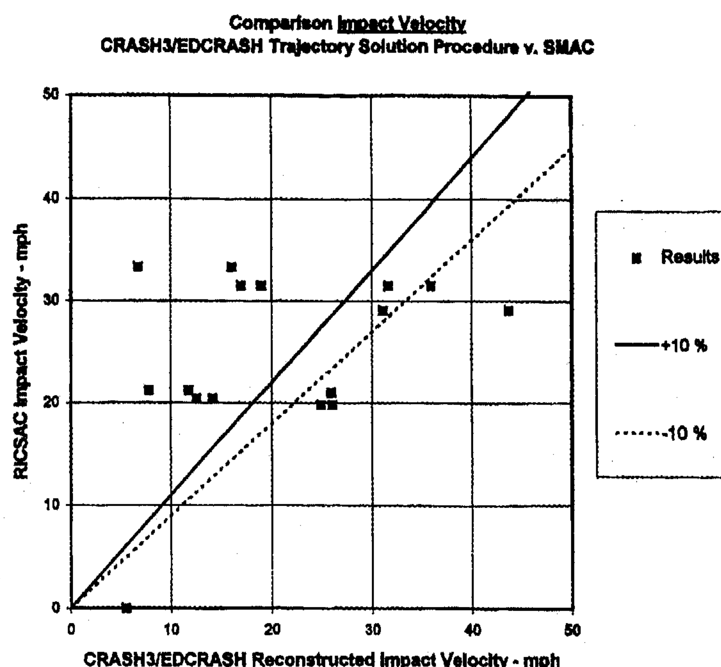

Figure 4 Initial comparison of reconstructed <u>Impact Velocity</u> of CRASH3/EDCRASH Trajectory Solution vs. RICSAC Test Results

BACKGROUND

When vehicles separate after a collision, they move to rest positions against resistance forces produced primarily by tire-ground friction. Analysis of the total energy dissipated as the vehicles travel from separation to their positions of rest and determination of their corresponding linear and angular velocities at separation constitute the essence of a *trajectory-based* reconstruction of a collision. The principles of conservation of linear and/or angular momentum are applied to the directions and magnitudes of the system momentum at separation to determine the velocities which must have existed prior to the collision.

In simple spinout motions, the actual paths traveled from separation to rest can be approximated, with reasonable accuracy, by straight lines between the separation and rest positions. The separation velocities can then be estimated on the basis of the total work done by each vehicle against tire-terrain friction forces between separation and rest. The rate of energy dissipation by tire forces is dependent on the heading direction of the vehicle in relation to its direction of motion, the rate of yawing rotation, and the extent of rotational resistance at the individual tires. For example, in a broadside slide, all tires produce full-friction resistance forces. In forward or backward motion, only those tires with applied brakes, damage effects, large steer angles or driveline braking produce significant drag forces. For the case of linear motion combined with angular rotation about a vertical axis (i.e., yawing rotation) a vehicle alternates between the two conditions of resistance of motion.

The CRASH3 program includes a simplified analytical procedure for approximating the linear and angular velocities of a vehicle subsequent to a collision. The developed procedure is referred to as SPIN2. A subcontract to refine SPIN2 undertaken in 1979 [24] (see **Appendix 1** for a discussion of SPIN2) led to the conclusion in **[24]**:

"To achieve a general improvement in the reliability and accuracy of approximations of the angular and linear velocities at separation, a step-by-step time history form of trajectory solution should be implemented."

The CRASH3 program also includes an exploratory *trajectory simulation* option solution procedure based on the SMAC trajectory model. The optional *trajectory simulation* procedure (USMAC) includes routines from the trajectory portion of the SMAC program to permit time-history simulations in CRASH of the spinouts of the individual vehicles from separation to rest.

The USMAC *trajectory simulation* model is a three degree of freedom (X, Y, PSI) mathematical representation of planar motion. The tire side force calculations are based upon a nondimensional side force function whereby the small-angle properties of the tires "saturate" at larger angles. The "friction circle" concept is used to approximate the interactions between side and circumferential (braking or tractive) tire forces. The "friction circle"

concept is based on the assumption that the maximum value of the resultant tire friction force is independent of its direction relative to the wheel plane.

The purpose of the USMAC routine in CRASH3 was to serve as a check of the SPIN2 approximations of separation speeds. An optional iterative procedure was also included in the CRASH3 *trajectory simulation option* to automatically adjust the SPIN2 separation velocities in an attempt to reduce errors in the predicted vs. actual final rest positions. The initial form of the trajectory iteration routine was implemented merely to demonstrate feasibility and was not thoroughly tested and evaluated. The costs of a CRASH run increased ten-fold by the use of the exploratory iterative trajectory solution procedure (USMAC) (e.g., **[25]** , circa. 1976, p1.,"The computer costs ... of the CRASH program ...range from approximately $1.00 to $10.00 per case. The upper end of the indicated cost range corresponds to a run in which the option for testing and refining the trajectory analysis portion of the calculation has been exercised"). There was no further NHTSA sponsored development of the original exploratory implementation of the USMAC routine.

By the mid 1990's, with the prevalence of extremely powerful and inexpensive Pentium PC's, and therefore the availability of virtually unlimited computer resources, consideration was given to internal research by McHenry Consultants, Inc. to further develop the *trajectory simulation* routine of the CRASH3 program. The objective in our refinements of the CRASH3 accident reconstruction procedures has been to simplify the input requirements of the program while providing a significantly improved correlation of the reconstruction results with known test results. A secondary consideration in the form of the refinement has been to limit the total computational time for convergence on a solution to a reasonable amount of time.

Effective refinements of the *trajectory simulation* procedure can substantially increase the usefulness of the simple "closed-form" CRASH3 accident reconstruction procedure by producing a general refinement of the *trajectory solution* procedure. The CRASH3 *trajectory solution* procedure requires a minimum amount of input information about the accident scene and vehicles. An effective improvement of the *trajectory solution* procedure can be expected to substantially improve the correlation or "validation" of the CRASH3 model when comparing the reconstruction results with full-scale test results. A 1989 study **[6]** concluded that the original form of the CRASH3/EDCRASH *trajectory simulation* option can actually degrade the *trajectory solution* results of the CRASH3 program.

A secondary task required in order to further refine and enhance the *trajectory solution* procedure of the CRASH3 program was a reactivation and refinement of the angular momentum solution procedure. The original CRASH program included conservation of linear momentum in the trajectory based solution to determine the impact speeds based on the separation velocities. A contract performed on CRASH2 to implement an angular momentum solution achieved mixed results **[26]**. A major hurdle for any procedure which includes an angular momentum solution is the need to approximate movement of the vehicles during the collision. In the CRASH2 formulation the impact and separation positions and headings were assumed to be identical. The research in **[26]** revealed that the accuracy of an angular momentum solution procedure for accident reconstruction which includes the assumption of no movement between impact and separation will produce unacceptable error levels (>>20%) in many cases.

Other analytical accident reconstruction techniques which include provision for an angular momentum solution procedure and/or which are based on conventional momentum analyses, include the somewhat subjective input requirement that either a vehicle-to-vehicle contact "point" **[27]**, or a "point of maximum engagement" **[28]** or an "impact center" **[29]** be specified. The additional input is required to compensate for the cited solution procedure's lack of an independent determination of separation positions and orientations.

The requirement that the user specify either an arbitrary impact contact "point" or an arbitrary "point of maximum engagement" detracts from the objectivity of the reconstruction techniques.

Figure 5 and **Figure 6** show representative changes in positions and orientations during the contact phase of collisions.

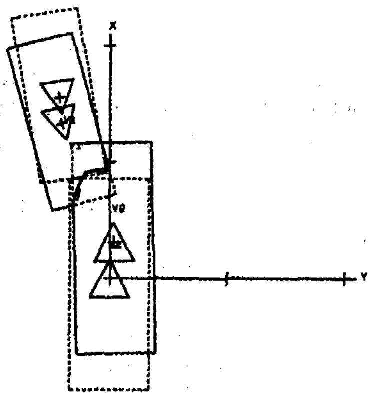

Figure 5 Impact and Separation Positions and Orientations for RICSAC Test #12

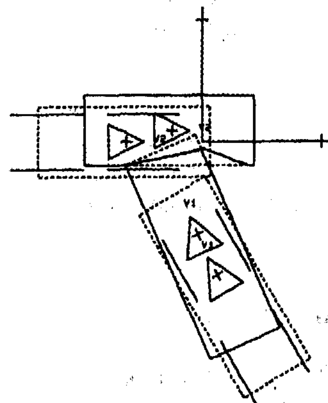

Figure 6 Impact and Separation Positions and Orientations for RICSAC Test #1

The subjective choice of a "point" can produce a large variation in the predicted results. During "validation," when the results are known, the user has some guidance in choice of the subjective "point." In real-world applications, where the answer is not known, the determination and arbitrary specification of a "point" can and will produce a wide range of predicted results. The normal input requirements of accident reconstruction programs of damage dimensions and approximate impact configurations should provide more than adequate information for any accident reconstruction program to independently achieve the function of any contact "point" or "point of maximum engagement" without user intervention. The movement of the vehicles between impact and separation can be initially approximated, for example, by moving the vehicles in their initial directions of motion to positions where the damage regions match. The procedure to determine a separation position should be automated to prevent subjective variations between users in the positions of match and therefore the results.

Other assumptions of the cited techniques **[27,28,29]** which may detract from the validity of their impact models for objective application to accident reconstruction are:

1. During the impact no consideration is given for ***tire-to-ground "external" forces***
2. The ***impact duration*** and time for exchange of momentum is assumed to be infinitesimally small.

TIRE-TO-GROUND "EXTERNAL" FORCES: The effects of tire-ground forces must be considered in a motor vehicle collision reconstruction. During the early development of the SMAC program **[19, 20]** tests were performed to determine the effects of external tire forces on the collision solution procedure. It was concluded that "The conventional assumptions that the effects of vehicle deformations and of tire forces can be neglected in analytical reconstructions of collisions can lead to significant errors. This is particularly true for intersection-type collisions at low to moderate vehicle speeds, in which prolonged or multiple contacts and significant movements of the involved vehicles occur" and that "therefore it is essential in a general procedure for reconstruction calculations that both the collision and tire forces be considered simultaneously."

IMPACT DURATION: The duration of a motor vehicle collision cannot be assumed to be infinitesimally small. Normally the exchange of momentum requires 50 to 125 milliseconds. Significant changes in positions and orientations can occur during the collision which can produce changes in the collision moments acting on the collision partners. Any accident reconstruction

solution procedure which contains the assumption of an instantaneous exchange of momentum should be carefully evaluated.

The importance of the inclusion of external forces in collision analysis and use of a finite time increment for the impact duration has also been reiterated more recently by Fonda [30].

RESEARCH APPROACH

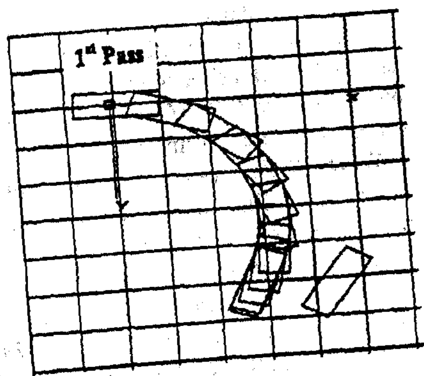
The refinement of the trajectory solution procedure of CRASH3 required the following two basic tasks:

1. **Refinement of the trajectory *simulation option*** to improve the prediction of separation velocities.
2. **Refinement of the trajectory *solution procedure*** to include implementation of an angular momentum solution procedure and to include provisions for vehicle movement and external forces during the collision.

REFINEMENT OF THE TRAJECTORY *SIMULATION OPTION*

The refinement of the trajectory *simulation option* of CRASH3 began with determination of what constitutes the minimal information required for a trajectory based reconstruction. The minimum information required for a trajectory based reconstruction is contained in **Table 2**.

Table 2: Minimum Information Required for a trajectory based reconstruction:



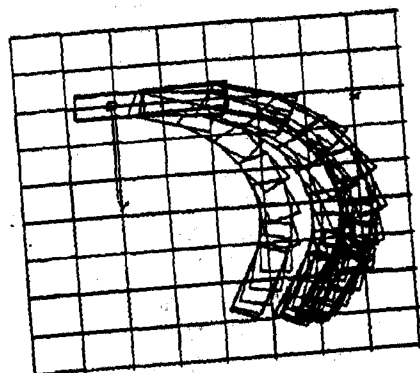
1. Impact and rest positions and headings.
2. Approximations of wheel steer and drag.
3. Vehicle specifications (weights, dimensions).

The CRASH3 program includes optional inputs for points on curve, end of rotation position and other inputs which were intended to permit use of such information when it is clearly indicated by physical evidence. However, the cited options have frequently been applied as arbitrary, subjective inputs. One intention in the reported improvement of the trajectory simulation routine has been to eliminate the need for any supplemental, sometimes subjective, inputs and to thereby create a reconstruction technique which will provide *uniform interpretations of physical evidence.* The use of sometimes arbitrary points-on-curves and end-of-rotation positions as inputs can detract from an objective analysis.

One major advantage of the present refinement of the trajectory simulation procedure for CRASH3 over the original development was the availability of essentially unlimited computer resources. The number of iterations of the trajectory algorithm for a given reconstruction is virtually unlimited on a PC. The only limitation is clock time and the feasibility of attaining a solution in a reasonable amount of time. There are no computer resource charges for execution of a simulation on a PC. Also, on a Pentium-60 or faster CPU, a 10 sec trajectory simulation of a vehicle spinout requires much less than 1 sec of real time. Therefore large numbers of iterations can be performed, if required. In the CRASH3 form of the trajectory simulation, computer resource concerns dictated an arbitrary limitation on iterations of 5 per run and in many instances, five iterations required more than 10 minutes real clock time to execute in a time-share computer environment [31].

The next phase in the refinement of the trajectory *simulation option* for CRASH3 was to determine how to create an iterative scheme which could converge on the separation speeds required to travel a given distance in a given direction and to match the extent of rotation. The only items of information to be provided to the routine were those listed in **Table 2**. The routine would then determine the required separation speed, course angle and angular velocity.

Figure 7 and **Figure 8** show representative results of iterative adjustments of the separation velocities by revised CRASH3 that produce convergence towards matching the positions and headings at rest.



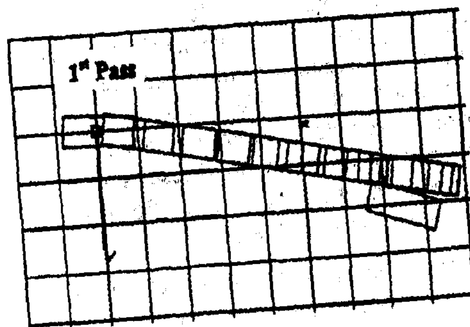


Figure 7 Sample of Revised CRASH3 Iterative Trajectory Simulation for RICSAC Test#4, Veh#1

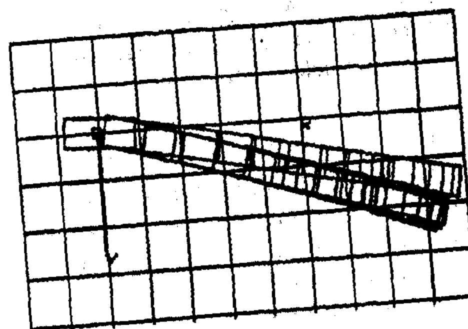

Figure 8 Sample of Revised CRASH3 Iterative Trajectory Simulation for RICSAC Test#7, Veh#1

Many different optimization and error minimization routines were investigated for convergence and optimization to a solution [32,33,34, 35]. A fundamental problem with the use of many of the investigated control algorithms was the inherent requirement that the functions must be continuous and/or linear. The spinout trajectory of a vehicle can be a highly non-linear event. Minor variations in starting conditions (i.e., speed, course angle, angular velocity) can produce major changes in the resulting rest positions (X, Y, PSI) and discontinuities in the calculated error evaluation terms. For example, during the various "step" changes in the decelerations of the linear and angular velocities as a vehicle travels from separation to rest, at any instant when the velocity vector aligns with the longitudinal axis the vehicle may "shoot off" tangentially in what has been described as a "dog-leg" type of trajectory. Traditional function minimization techniques tested as part of this research which normally require the evaluation of some form of derivatives (e.g., Cramer's rule, Newton's method) or include the assumption of a linear function (Powell's method, Broyden's method) were found to fail in many instances where step changes were produced in the "function" by minor alterations of the variables.

The choice of error terms and the relative magnitudes of the various calculated error terms can also cause iterative and optimization routines to fail. Within the reported research program error terms were developed which achieve a successful minimization of errors between predicted and actual positions of rest.

Problems encountered during the early formulation and comparisons of the revised CRASH trajectory simulation iteration procedure results (project USMAC2) with reported full-scale crash test results of RICSAC [8,9,10] revealed the need for an independent and separate task of evaluating the reported RICSAC test results. Most of the problems with comparisons were related to the values of separation conditions reported by Jones [10]. The reported values included some interpretation by Jones of the full-scale test results. In the full-scale

tests, the separation velocities were not directly measured and required some additional calculations which included interpretation of accelerometer information for accelerometers not located at the vehicle centers of gravity. Also, the accelerometers in some of the tests were located in or very near to the crush zone and/or on possible flexible components of the vehicle. Therefore a separate task was undertaken to check the reported results of RICSAC independent of any validation efforts for a particular computer program **[18]**.

The inputs for the ***refined CRASH3*** for the present project were derived from SMAC "test result" reconstructions (previously discussed in the introduction) and are contained in **Appendix 2**. The inputs consisted of the SMAC impact and rest positions and headings, the wheel steer angle and drag factors and the vehicle specifications (weights and dimensions).

A refined version of the original SPIN2 routine was utilized to determine starting values. The revised trajectory simulation routine, USMAC2, was then used to simulate the trajectory of each of the vehicles to positions of rest. Based on comparisons of the cited error terms, automatic adjustments were made to the separation conditions and the simulation was re-run. Once an acceptable "match" of the rest position and heading was achieved, the iterative procedure was stopped.

Table 3 contains SMAC generated separation conditions for the RICSAC full scale tests. The separation velocities are a direct output from the SMAC program and represent the first instance after the primary collision where the acceleration drops below 1 g-unit. **Table 4** contains a preliminary comparison of the USMAC2 with the SMAC generated separation conditions. Note that the comparison dataset does not include application of the angular momentum solution or external forces (these items are discussed in more detail below).

A review of the results reveal that most of the USMAC2 predicted separation speeds compare favorably with the SMAC "test result" generated separation speeds. However, some of the comparisons do not appear to agree very well. The reason for the differences is related to the assumptions regarding the time to separation. As a part of the ***refined CRASH*** trajectory solution procedure, a separation position is calculated. The calculation of a separation position requires assumption of a time to separation as well as reliance on the ***refined CRASH*** calculated impact speed. In order to provide for uniform interpretation in the ***refined CRASH*** results, a common assumption was made for the time to separation in the calculation procedure for the separation position and orientation. As more full scale tests become available (e.g., possibly the JARI crash test database which contains some 35 tests that are referenced in **[29]**) possible refinements of the technique will include modifications of the time to separation, etc. based on the impact configuration (e.g., a 90 degree side impact would be expected to have a longer time to separation than an offset frontal).

Another source of some discrepancy of the comparisons is related to the occurrence of secondary "side-slap" interactions. In tests 9 and 10 both the full-scale tests and SMAC reconstructions included secondary "side-slap" collisions. In test 10, a "side-slap" with magnitude greater than 5 mph on vehicle 1 occurred after the initial impact. The "side-slap" changed the magnitude and direction of the separation conditions. In test 9, subsequent to the initial contact the vehicles "side-slap" interacted at a lesser magnitude but for a longer time which produced re-direction of the initial separation velocities. The listed separation speeds in **Table 4** are the initial impact separation conditions which are different than the speeds and orientations after the occurrence of a "side-slap" collision.

The development of the trajectory *solution procedure*, discussed below, revealed that the cited comparison of SMAC and CRASH separation results, while not all within ±10%, were adequate when used with the refinements to the *trajectory solution* procedures to produce acceptable impact and ΔV predictions within ±10% of the corresponding SMAC results.

REFINEMENT OF THE TRAJECTORY *SOLUTION PROCEDURE*

The primary task required to refine the trajectory *solution procedure* of CRASH3 was to implement an angular momentum solution. The implementation of the procedure required determination of separation positions and orientations. A secondary consideration was the implementation of effects of external tire forces during the impact phase.

The problems of approximation of positions and headings at separation are compounded by the fact that neither the impact nor the separation velocities are known. The ***refined CRASH*** trajectory *solution procedure* therefore had to be modified to include an iterative solution procedure.

A basic outline of the procedure used to determine the impact speeds for a combination linear and angular momentum solution was as follows:

1. The separation velocities are approximated on the basis of the vehicle travel from impact to rest.
2. The separation velocities are used with an application of conservation of linear momentum for an initial approximation of the impact velocities.
3. The separation positions and headings are approximated using the initial approximations of the impact and separation velocities.
4. With approximation of the separation positions and headings, the following steps are repeated to converge on a solution:

    4.1. The separation velocities are refined based on the vehicle travel from *separation* to rest.

    4.2. The refined separation velocity is used with an application of conservation of both linear and angular momentum for a refined approximation of the impact velocities.

An iterative procedure was developed to guide the iteration of step 4, until an "acceptable" solution was achieved. The task became both a choice of iterative schemes and determination of what constituted an "acceptable solution." It was hoped that once the solutions for the angular and linear solutions matched, an acceptable solution would result.

However, during the testing of various iteration schemes, the question became which solution procedure, linear or angular, should guide the iterative process. Some impact configurations are more suited to a linear momentum solution procedure and some are more suited to an angular momentum solution procedure. Also available to the CRASH program algorithm is a damage analysis procedure which can provide an additional discriminator to guide the iterative process. However, although included in initial testing, adequate approximations of the separation positions and orientations where achieved without the use of damage information.

Coincident with the investigation of iterative solution procedures was the implementation of terms to approximate the effects of external forces. Terms were developed and included in the momentum equations to approximate the forces and moments produced by the tire forces during the collision. The implementation included investigation of approximate values for the finite duration of the collision.

The successful inclusion of effects of external tire-forces and of a finite time for the collision momentum exchange in the ***refined CRASH*** solution procedure benefited from the outstanding resources afforded by modern day Pentium computers. Rather than being forced to perform iterations of individual runs for comparison tests of the effects of individual input variables, the whole collection of test cases could be iterated by control algorithms to quickly evaluate the effects of the assumptions on all of the validation comparison runs. A "suite" of tests was easily set up and the various variables tested. Some of the many assumptions and approximations tested and refined in this manner included:

- The approximation technique used for determining the separation positions and orientations.
- The approximate duration of the time to separation.
- The magnitude and duration of the forces and moments used to approximate the effects of external tire-forces during the collision.
- The various error evaluation terms and weighting functions used to guide the iteration and achieve an "acceptable" match.

RESULTS

A comparison of the ***refined CRASH3*** trajectory solution procedure with the time-forward SMAC simulation program for 13 of the RICSAC tests is presented in **Table 5** and in graphical form for ΔV in **Figure 9** and Impact Velocity in **Figure 10.** The results demonstrate that the "closed-form" ***refined CRASH*** program can reconstruct "open-form" SMAC generated "test results" within less than ±10% of the impact speeds and impact speed-changes.

When comparisons are made between a calculated value and a measured or "true" value, the magnitude of the error expressed as a percentage of the comparison with the "true" value of an estimated quantity appears to be the most meaningful engineering measure of accuracy. However, in the case of a very small or zero "true" value, the use of the actual magnitude of the error is more meaningful than a percentage. If it is assumed that ±1.0 MPH is an acceptable error range about a very small "true" value, then the transition from the actual magnitude of error to a percentage error can arbitrarily be made, for example, at a "true" value of 10 MPH. The error should be reported in both formats for "true" values in excess of 10 MPH. For lesser magnitudes, only the actual magnitude should be displayed (e.g., **Table 5,** note that "true" value for **Table 5** is the SMAC simulated "test result" reported in **Table 1.** The table gives a correlation of the predicted results of ***refined CRASH3*** with the "true" SMAC "test results")

In the validation of EDSMAC contained in [6] the authors used the combined speeds of the two colliding vehicles (i.e., the closing speed of the collision) as a basis for calculating the error in the reconstructed impact speed. This technique was used to avoid the case where one vehicle was initially at rest and therefore had a "true" value of zero for its impact speed. The technique used appears to serve no useful purpose other than making the error appear smaller.

The SMAC "open-form" simulation is a widely used program that has been demonstrated to be a generally valid and accurate model of motor vehicle collisions. The primary drawback of the SMAC program is that it requires initial estimates and multiple iterations by the user to converge on an "acceptable" solution. Variations of what constitutes an "acceptable" solution for the SMAC simulation program are to some extent dependent on the individual users.

The ***refined CRASH3*** procedure achieves essentially the same results as the "open-form" SMAC computer program. The ***refined CRASH3*** "closed-form" approach eliminates differences in results for a given reconstruction that are produced by variations in the capabilities and perseverance of individual SMAC users.

CONCLUSIONS AND RECOMMENDATIONS

With regard to measures of reconstruction accuracy by means of comparison of reconstruction results with reliable test data, the distinction must be recognized between applications to statistical samples of cases and an application to an individual case.

In a large number of applications, the intercept and slope of the linear regression fit for actual measured data plotted against reconstruction estimates may be compared with the intercept of zero and slope of 1.00 corresponding to perfect correlation (e.g., see **Figure 9, Figure 10**). In this manner, measures of the average error may be obtained.

In an application to an individual accident, the maximum error in a comparison of reconstruction estimates with reliable test data constitutes the most significant measure of accuracy since it indicates the error that is possible with good data in any given application.

Subsequent to the research related to a review of the RICSAC tests **[18]**, the ***refined CRASH3*** program will be compared directly with the refined RICSAC full-scale test results.

Further development of the ***refined CRASH*** program, which will follow the completion of work related to RICSAC **[18]** and the availability of additional full scale crash test results, should further improve the results of ***refined CRASH*** to be generally consistent with those of the SMAC simulation program. The preference for the CRASH program, particularly for case studies, is that it does not require any iterations by the user and, therefore, there should be little or no variation in reconstruction results obtained by different users.

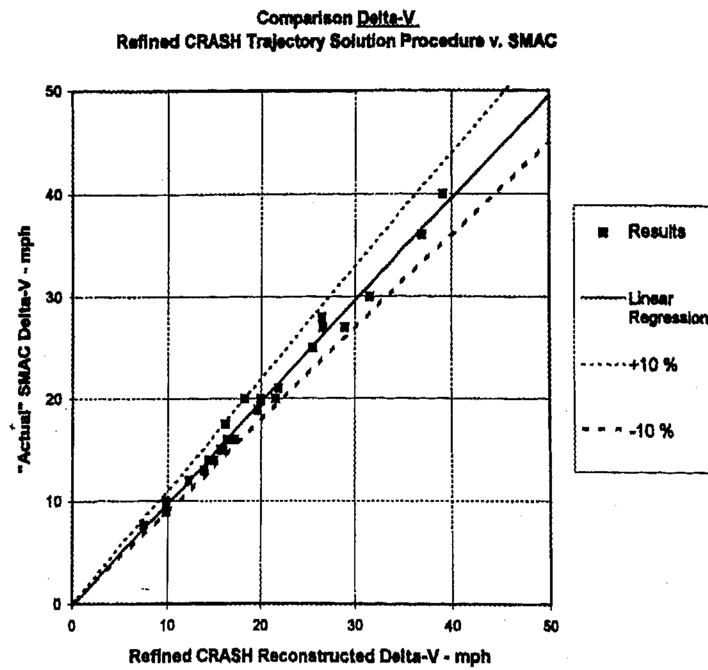

Figure 9 Comparison of reconstructed ΔV of *refined CRASH3* Trajectory Solution vs. SMAC

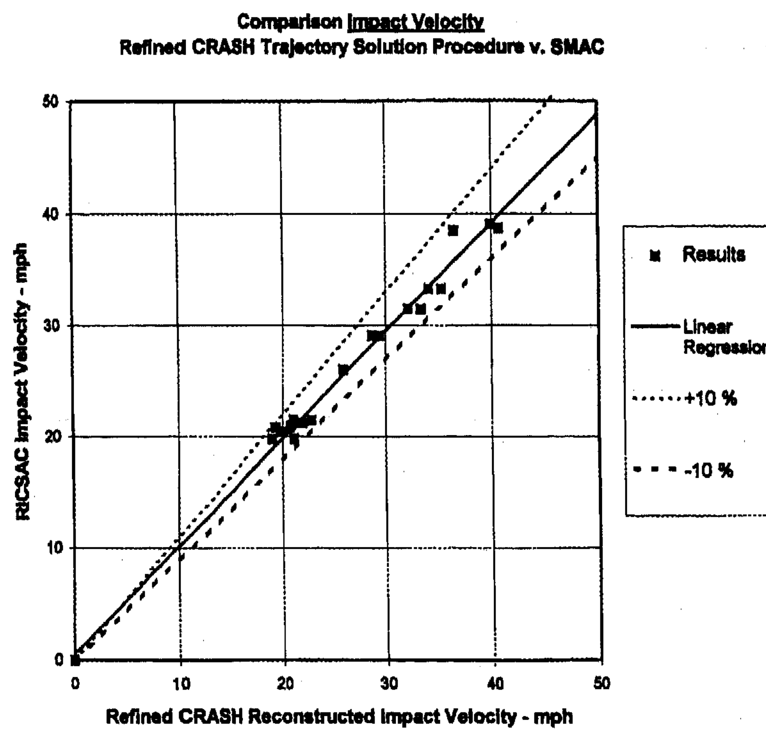

Figure 10 Comparison of reconstructed Impact Velocity of *refined CRASH3* Trajectory Solution vs. RICSAC Test Data

A secondary investigation is underway to determine internal tests and corresponding instructions that may be used to guide users if and when "bad" data are input. Since the results reported herein represent correlation of the predicted CRASH results with mathematically correct SMAC generated "test results", they indicate the 'best' correlation possible for the analytical technique. The next task is to test the procedure with "real world" data where problems may arise due to invalid or inconsistent inputs.

An auxiliary procedure developed during this project was a set of modifications for SMAC which automatically generates "evidence" for input to the ***refined CRASH3*** program. This routine provides a capability for further testing of the compatibility of results produced by the two programs. In tests performed to date, the ***refined CRASH3*** routine has consistently produced reconstruction results for the general case which are within ±15% of the speed inputs to the SMAC program and the corresponding impact speed-changes reconstructed by SMAC. Further testing and evaluation of the described routine and of the compatibility of the SMAC and CRASH program results will continue.

The final development of the ***refined CRASH3*** accident reconstruction procedure will incorporate previously defined refinements to the damage analysis procedure **[36,37]**. The utilization of damage information should assist in the analysis of real-world data and should dramatically improve the ability of the ***refined CRASH3*** to accurately reconstruct motor vehicle collisions while maintaining the original intent of the CRASH program to provide for *"uniform interpretation of accident evidence"*.

APPENDIX 1: DISCUSSION OF SPIN2

The SPIN2 procedure of the original CRASH program uses as a starting point the relationships developed by Marquard [**38**]. The Marquard procedure takes into account the fact that the linear and angular (i.e., yaw rotation) displacements of a four-wheeled vehicle subsequent to a collision each occur under conditions of intermittent deceleration when the wheels are free to rotate. By approximating the linear and angular deceleration rates of a vehicle with either (1) all wheels freely rotating or (2) all wheels locked during different phases of spinout motion, Marquard developed approximate relationships between the total linear and angular displacements during the travel from separation to rest and the corresponding linear and angular velocities of a vehicle at separation from its collision partner, for the two cited cases of rotational resistance.

In the CRASH program [1], the SPIN2 routine was developed to extend the relatively simple Marquard relationships to include the cases of partial braking and/or damage-locked individual wheels. Evaluations of the resulting, modified relationships by means of trial applications to spinout trajectories generated with SMAC [20] revealed several shortcomings of the initial SPIN2 relationships. First, a residual linear velocity frequently exists at the end of the rotational (i.e., yawing) motion. Next, the general shapes of plots of linear and angular velocity vs. time changed substantially as functions of the ratio of linear and angular velocity at separation from the collision. Finally, the transitions between the different deceleration rates of linear and angular motions were found to occur gradually rather than abruptly. Slope changes in the plots of linear and angular velocity vs. time were found to generally occur in the form of rounded "corners" in the curves.

To improve the accuracy of approximations of separation velocities, provisions for the introduction of a residual linear velocity at the end of the rotational motion and the development of empirical coefficients, in the form of polynomial functions of the ratio of linear to angular velocity at separation, were incorporated in the SPIN2 analytical relationships of the CRASH program. Since the separation velocity ratio is initially unknown, a solution procedure was

developed whereby several trial values of the ratio, based on an approximate equation, were used to test multiple solutions.

The cited analytical developments, reported in [2], involved only limited efforts which were aimed primarily at demonstrating the feasibility of the CRASH concept. Polynomial functions to generate empirical coefficients were developed, on the basis of 18 single-vehicle SMAC runs with relatively high linear and angular velocities for starting (i.e., separation) conditions. In the more common, real-life accident case, a relatively small rotation (i.e., yawing) velocity may exist at separation. In such a case the initial direction of the velocity vector with respect to the longitudinal axis of the vehicle will obviously affect the sequence and the duration of the linear and angular deceleration rates of the vehicle.

In consideration of known shortcomings of the SPIN2 aspect of the CRASH program, a subcontract to refine SPIN2 was undertaken in 1979 [24]. A representative sample of actual accident cases was selected from the NCSS [39] files for use in the study. A total of 50 cases were selected and then reconstructed with the SMAC computer program. For each of the SMAC reconstructions, separation information was used to formulate a basis for a refinement of the SPIN2 empirical coefficients.

A careful examination of the time-history plots of linear and angular velocities for all of the cases in the sample revealed a significant number of cases in which the SMAC-predicted behaviour deviated from the analytical assumptions upon which the SPIN2 routine is based. Attempts were undertaken within the research project to discriminate characteristics of separation conditions. Unfortunately, only partial success was achieved in the attempts to accommodate deviations by means of the use of logic and discriminators. As a result, a realistic appraisal of residual scatter in the empirical fits led to the conclusion in [24]:

"To achieve a general improvement in the reliability and accuracy of approximations of the angular and linear velocities at separation, a step-by-step time history form of trajectory solution should be implemented."

Subseqent work which has been performed on investigation and refinement of the SPIN empirical coefficients [30, 40, 41] and the corresponding modifications to CRASH is subject to the effects of 'scatter'. Any proposed refinements of the SPIN empirical coefficients and any reconstruction techniques which are based on the refinements of the SPIN empirical approach will ultimately fail in some applications to individual case reconstructions due to the possibililty that the particular case being investigated may be characteristic of a "scatter" point. The research cited in this paper strongly supports the conclusion from 1981 that implementation of a trajectory solution procedure should utilize an iterative time-history simulation.

APPENDIX 2: CRASH INPUTS

The following are the inputs for the ***refined CRASH3*** reconstructions used for comparison with the SMAC program. Note that most inputs (where applicable) are from the SMAC reconstructions.

The following questions are all answered the same and therefore not repeated for the inputs for the ***refined CRASH3*** test preliminary RICSAC test runs:

6. REST & IMPACT?.....................YES
9. ANY SLIP ANGLES?...................NO
11. SUSTAINED CONTACT?.................NO
13. SKIDDING STOP BEFORE REST?.........NO
15. CURVED PATH?.......................NO
18. MORE THAN 360 DEG? ....NO
20. SKIDDING STOP BEFORE REST?.........NO
22. CURVED PATH?.......................NO
25. MORE THAN 360 DEG? ....NO
26. TIRE-GROUND FRICTION............... .870
27. ROLLING RESISTANCE OPTION..........1
32. TRAJECTORY SIMULATION?.............YES
35. TERRAIN BOUNDARY?..................NO
38. DAMAGE DIMENSIONS?.................NO

In the input listings, the input specs were input to the ***refined CRASH3*** program in the following form:

SMAC: 4: A1,B1,TRW1,FMASS1,IZ1,XF1,XR1,YS1
SMAC: 5: A2,B2,TRW2,FMASS2,IZ2,XF2,XR2,YS2
SMAC 6: CSTF1, CSTF2, CSTF3, CSTF4
SMAC 7: CSTF5, CSTF6, CSTF7, CSTF8

where:

A,B = distances from CG to front/rear axles
TRW = track width
FMASS1 = vehicle mass, lb-sec**2/in
IZ1 = Total vehicle yaw moment of inertia, lb-sec-in
XF = distance from CG to front end
XR = distance from CG to rear end
YS = ½ width of vehicle
CSTF = cornering stiffness, lb/rad

The individual inputs are as follows:

CRASH 97 Refinement of the Trajectory Solution Procedure
Brian G. McHenry, Raymond R McHenry, Authors

The paper is a part of a long term continuous effort by McHenry Consultants, Inc. to develop improvements in the CRASH and SMAC family of programs. The basic intent is to modify CRASH by incorporating a post impact trajectory to rest iterative solution analysis methodology similar to the process currently utilized within SMAC. The objective is to remove at times misused assumptions and data selection questions from the hands of a user, and to replace the process with a more refined analysis process. The methodology is a reasonable extension to the CRASH and SMAC family of programs, and shows promise to potentially improve the CRASH based results. The primary question is how does this improved program version become available to the accident reconstruction community as a whole, because unless such improvements are made widely available they will be of a limited value.

CRASH-97 Refinement of the Trajectory Solution Procedure
Brian G. McHenry, Raymond R McHenry, Authors

This paper outlines helpful technical concepts that can improve the accuracy of the momentum collision model and the trajectory model contained in CRASH3 and possibly other algorithms that reconstruct an incident by beginning with the rest conditions and computing back in the event sequence to the impact conditions. However, the authors conclude the trajectory cannot be reconstructed with sufficient accuracy and reliability for some collision types and that the best generalized estimate for separation conditions is obtained by a trial and error simulation of the trajectory, for which they have developed an efficient iteration algorithm. That conclusion suggests reconstruction of some collision types is unreliable and that trajectory simulation should be used when improved accuracy for all type collisions is desired.

They also conclude that momentum reconstruction collision models must include angular momentum, tire forces, and movement during engagement in order to reasonably match the SMAC collision simulation model, which itself reasonably matches RICSAC results. Those who reconstruct collisions should incorporate those elements if they desire accurate results for all collision types.

For a real world collision the accuracy of the separation conditions established by any algorithm would be dependent on the wheel drag and steering angle values assumed. This paper did not discuss that aspect of the accuracy issue which probably cannot be evaluated until either the AIRP Trajectory Algorithm Comparison task group produces applicable results or until the refinements in this paper are applied in a blind analysis to instrumented tests.

The data shown in this paper demonstrate improved accuracy for the RICSAC test configurations but the rationale and values for some of the algorithm variable assumptions are not stated. Hopefully, the authors will detail those values and rationale in future presentations when their development is complete.

A Comparison of Moment of Inertia Estimation Techniques for Vehicle Dynamics Simulation

Duane D. MacInnis, William E. Cliff, and Kurt W. Ising
MacInnis Engineering Associates

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The moments of inertia, in yaw, pitch, and roll, as well as the center of gravity height are necessary to successfully model the 3D dynamic behavior of vehicles before, during and after collision. A number of vehicle parameter estimation techniques have been developed and are currently in use in North America and Europe. Many parameters have been measured by NHTSA and others. The estimation techniques are compared to the available measured values, and recommendations are made for best estimating the parameters when measured values are not available. The sensitivity of 3D vehicle collision dynamics and trajectory simulation to variance in the moment of inertia is demonstrated.

INTRODUCTION

Early 2D collision and spin-out models required only the mass and the yaw moment of inertia. Modeling the 3D dynamic behavior of a vehicle requires a minimum of the vehicle geometry, the center of gravity height and the triaxial moments of inertia. Because moments of inertia are difficult to measure for a given vehicle, there is a need for estimation techniques that use easily obtained vehicle measurements.

More complex models will require data concerning the sprung and unsprung vehicle parameters, as well as more detailed suspension and tire modeling data. The work of this paper is limited to discussion of the whole vehicle roll, pitch, and yaw moments of inertia relative to the total vehicle centroidal axes, and the height of the whole vehicle center of gravity.

This paper briefly addresses the theory, and presents a number of estimation techniques that are available in the literature. The values measured by Garrott of the NHTSA are compared to the values determined by the estimation techniques in five different vehicle categories. Correction factors were applied to each of the estimation equations to eliminate the average error. The adjusted equations were ranked by standard deviation, and the best equations, the ones with the smallest standard deviation, were chosen and presented. The nomenclature used is described in Appendix A.

THEORY

In simple linear Newtonian mechanics, the mass of a vehicle is assumed to be concentrated at the center of gravity location. This assumption may be appropriate for the simplest dynamic models, pure central collisions, or for very coarse estimation purposes. When the vehicles are involved in eccentric collisions with rotation, as is the most common case, then the simple models are inadequate, and the distribution of the vehicle's mass about the centroid must be considered.

The resistance of an object to rotation is a function of the mass of the object, and the location of the mass with respect to the center of rotation, and is known as its moment of inertia, I.

An idealized motor vehicle can be considered a solid homogeneous slab as shown in Figure 1.

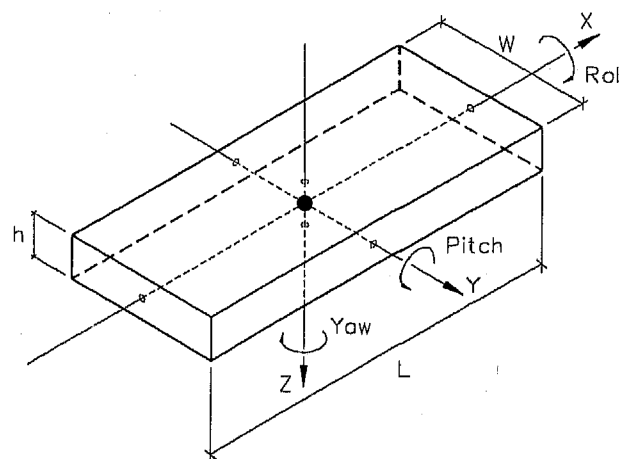

Figure 1 - The vehicle as a solid homogeneous slab or prism

The moments of inertia about the three axes of the homogeneous slab would be:[1]

$$I_{xx} = \frac{1}{12} m\left(W^2 + h^2\right) \qquad (1)$$

$$I_{yy} = \frac{1}{12} m\left(L^2 + h^2\right) \qquad (2)$$

$$I_{zz} = \frac{1}{12} m\left(L^2 + W^2\right) \qquad (3)$$

This is termed the prism method. The yaw moment of inertia for a solid slab is a function of the length and width as well as mass, not mass alone.

A motor vehicle is not a solid homogeneous slab. It has concentrated masses at the engine, transmission, suspension, etc., as shown in Figure 2.

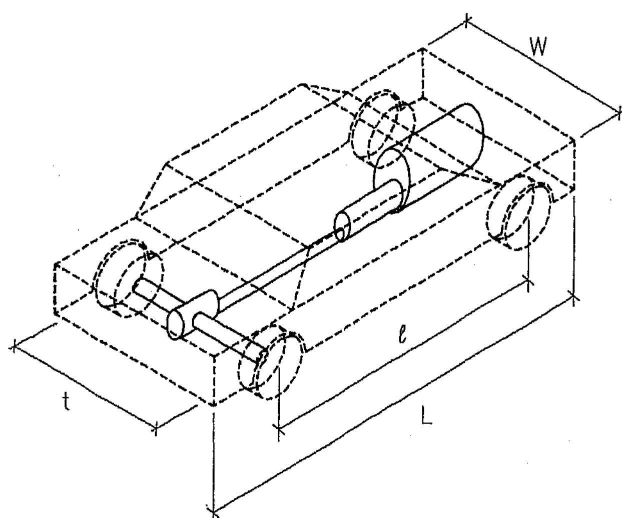

Figure 2 - The vehicle with concentrated masses

The moment of inertia for any object can be calculated, if enough is known about these distributed masses. However, the moment of inertia of a motor vehicle is more practically measured by testing.

A simplified top view of a vehicle is shown in Figure 3.

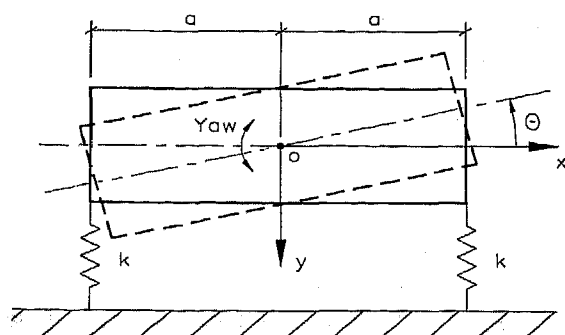

Figure 3 - Top view of a vehicle being tested for the yaw moment of inertia

The vehicle is allowed to pivot at its center of gravity, on a massless undamped frictionless frame. The fore/aft mass distribution is 50/50. The moments sum as follows:

$$\sum M = I\alpha \qquad (4)$$

$$-2(ka\theta)a = I\ddot{\theta} \qquad (5)$$

$$\ddot{\theta} + \left(\frac{2ka^2}{I}\right)\theta = 0 \qquad (6)$$

The period of this oscillating structure is: [2]

$$\tau = 2\pi\sqrt{\frac{I}{2ka^2}} \qquad (7)$$

In this idealized example, one measures the period, the geometry, and the spring constants, and the moment of inertia is readily determined:

$$I = \frac{1}{4\pi^2} 2ka^2\tau^2 \qquad (8)$$

The actual measurement of the inertial properties of vehicles is far more complex than presented here, and the details and complexities have been developed by Garrott.[3,4,5]

MEASURED VALUES

The NHTSA has measured the moments of inertia for a number of vehicles, as described by Garrott (1993). These values are published and available on disk.

Burg[6] (1982) in Germany tested a number of estimation methods against the measured values for 56 contemporary European vehicles. The original data has been lost.[7] The work of Rasmussen[8] (1970) at General Motors has been superseded by later researchers, and will not be included in this paper. Reide[9] (1984) tested a large number of passenger vehicles sold commercially "somewhere in the world." The data was not included in the published work. Curzon[10] (1991) measured the inertial properties of more than 100 passenger cars (not used in his study), sport utility vehicles, pickup trucks, and vans, but has not published the data. Bixel et al.[11] (1996)) measured the parameters for a total of 313 vehicles. The data was not included with their paper.

There has been work done by others as well, but the NHTSA work is the best available current source for measured values.

ESTIMATION TECHNIQUES

A number of methods have been proposed to estimate the moments of inertia, and in some cases the height of the center of gravity. These are listed here in chronological order.

Grime[12] (1969) proposed the prism method described previously. The work of Rasmussen[13] (1970) at General Motors has been superseded by later researchers, and will not be included in this paper.

mab -- The most commonly cited estimation of the yaw moment has been with us for some time. The original

source is uncertain. It has been recently cited and derived by Bastow[14]:

$$I_{zz} = mab \tag{9}$$

This method is intuitively satisfying in that it assumes the vehicle mass is concentrated at the center of the axles.

Burg -- Burg (1982) tested a number of methods against the measured values for 56 European vehicles and found that the method with the best correlation coefficient for the yaw moment for his sample was:

$$I_{zz} = 0.1269mlL \tag{10}$$

The Burg method has also been used by Reimpell.[15]

Reide -- Researchers at General Motors (1984) built on the earlier work by Rasmussen, testing a number of passenger vehicles "sold commercially somewhere in the world." No truck or bus types were included. The author describes the data as being applicable to moderate payload and driving conditions.

Body styles ranged from 2-passenger sports cars to station wagons, masses from 575 to 1761 kg, and wheelbases from 2025 to 2953 mm. Nine were front engine-rear drive, six were front engine-front drive, and two were rear engine-rear drive, for a total of 17 cars. They were tested in curb condition, no passengers and full gas tank.

The best fit for the whole vehicle moments of inertia in roll, pitch, and yaw, relative to the total vehicle centroidal axes, were:

$$I_{xx} = 0.37m - 86.4\,,\ R^2 = 0.893 \tag{11}$$

$$I_{yy} = 2.56m - 1{,}103\,,\ R^2 = 0.919 \tag{12}$$

$$I_{zz} = 2.86m - 1{,}315\,,\ R^2 = 0.920 \tag{13}$$

The sprung mass moments of inertia relative to the sprung mass centroidal axes were also given. No techniques for estimation of center of gravity heights were given.

Allen – Allen (1987) et al[16] proposed the rule of thumb values for the yaw moment as follows:

$$I_{zz} = mab \pm 10\% \tag{14}$$

The method proposed by Allen for the roll moment is a variant of the prism method:

$$I_{xx} = \frac{1}{12}m\left(W^2 + h^2\right) \tag{15}$$

Where,

$$h^2 = \alpha_1 h_1^{\,2} + \alpha_2 h_2^{\,2} \tag{16}$$

$$\alpha_1 + \alpha_2 = 1 \tag{17}$$

The values α_1 and α_2 shown on Figure 4 are weighting coefficients which consider the proportions of the vehicle at various heights. Allen suggests that this method of determining the roll moment is accurate to within ± 20%. However, the dimensional data to use this technique, α_1, α_2, h_1, and h_2 are not usually available in the tested or measured databases. These data are only available if the case vehicle or an exemplar is available to measure.

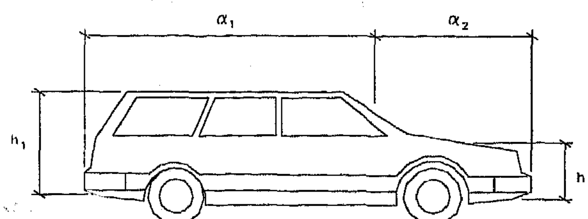

Figure 4 - The vehicle with Averaged Height

The center of gravity height is given as:

$$h_{cg} = 0.38h_{roof} \pm 5\% \tag{18}$$

Allen has offered no recommendations for the pitch moment.

Garrott -- The most complete listing of measured parameters was published by Garrott in 1988. In addition to the values measured, the authors presented a number of historic "rules of thumb", and proposed a set of revised rules of thumb (all units have been converted to metric) which are listed in Table 1.

Rules of Thumb:

$$h_{cg} = 533.4\,mm \tag{19}$$

$$h_{cg} = 0.40h_{roof} \tag{20}$$

$$I_{xx} = \frac{mt_{av}h_r}{4} \tag{21}$$

$$I_{yy} = mab \tag{22}$$

$$I_{zz} = I_{yy} \tag{23}$$

Table 1 - Garrott's Revised Rules of Thumb

Pass Cars	Light Trucks	
$h_{cg} = 540.8 \pm 38.1\,mm$	$h_{cg} = 678.4 \pm 101.6\,mm$	(24)
$h_{cg} = 0.395h_{roof} \pm 2.6\%$	$h_{cg} = 0.387h_{roof} \pm 3.5\%$	(25)
$I_{xx} = (0.73 \pm 0.13)\frac{mt_{av}h_r}{4}$	$I_{xx} = (0.67 \pm 0.16)\frac{mt_{av}h_r}{4}$	(26)
$I_{yy} = (1.07 \pm 0.17)mab$	$I_{yy} = (1.04 \pm 0.22)mab$	(27)
$I_{zz} = (1.03 \pm 0.08)I_{yy}$	$I_{zz} = (1.00 \pm 0..1)I_{yy}$	(28)

Garrott also fitted curves through the measurement data, and presented the moment of inertia parameters for passenger cars and light trucks as a function of vehicle mass.

Passenger Cars:

$$I_{xx} = 0.538m - 203,\ R^2 = 0.80 \qquad (29)$$

$$I_{yy} = 2.96m - 1{,}558,\ R^2 = 0.89 \qquad (30)$$

$$I_{zz} = 3.08m - 1{,}635,\ R^2 = 0.88 \qquad (31)$$

Light Trucks:

$$I_{xx} = 0.66m - 319,\ R^2 = 0.70 \qquad (32)$$

$$I_{yy} = 3.35m - 2{,}247,\ R^2 = 0.70 \qquad (33)$$

$$I_{zz} = 3.08m - 1{,}821,\ R^2 = 0.73 \qquad (34)$$

Curzon -- Later researchers developed the work of Garrott further. Curzon and colleagues (1991) measured the inertial properties of sport utility vehicles, pickup trucks, and vans, and developed a number of moment of inertia estimation techniques applicable to most light trucks. The authors devised a number of estimation equations and tested them against the sum total of light trucks tested by their company and also those tested by Garrott.

They found the prism method was the best estimate for the yaw moment for sport utility vehicles, using the track width instead of the vehicle width.

$$I_{zz} = \frac{1}{12} m\left(L^2 + t^2\right) \qquad (35)$$

For the yaw moment of pickup trucks, the rule of thumb was best:

$$I_{zz} = mab \qquad (36)$$

For the yaw moment for vans, they recommend either the prism method as for sport utility vehicles, or Garrott's value for light trucks:

$$I_{zz} = 3.08m - 1{,}821 \qquad (37)$$

The roll moment was best approximated by a sum of prisms, similar to the method first proposed by Allen, that account for the varying cross sections of the vehicles, as shown in Figures 5, 6, and 7.

The recommended relationship for the roll moment for sport utility vehicles is as follows:

$$I_{xx} = \frac{1}{12} m\left(\frac{L_r h_r^2}{L} + W^2\right) + \frac{1}{12} m\left(1 - \frac{L_r}{L}\right)(h_w - h_a)^2 \qquad (38)$$

Like the earlier work by Allen, the roof length is required to use this technique. The roof length is not usually available in the tested or measured databases. This data is only available if the case vehicle or an exemplar is available to measure.

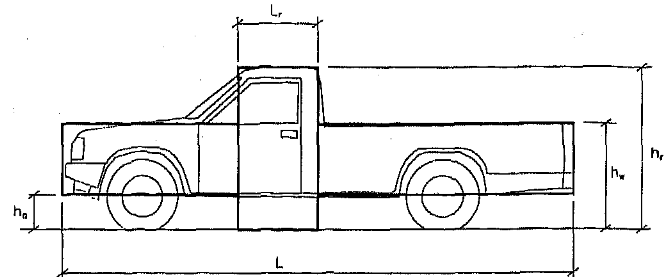

Figure 5 - Prism Models for Pickup Truck

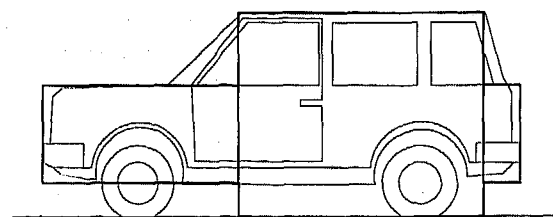

Figure 6 - Prism Models for Sport Utility

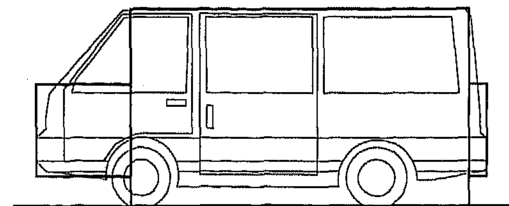

Figure 7 - Prism Models for Van

For the roll moment for vans, Curzon recommends either the method above for sport utility vehicles, or Garrott's value for light trucks:

$$I_{xx} = 0.66m - 319 \qquad (39)$$

Curzon offered no recommendations for the pitch moment or the center of gravity height.

Noon -- Noon[17] (1994) has proposed three methods to estimate the yaw moment. These methods for convenience have been called Noon-1, Noon-2, and Noon-3. The first method has the moment being a function of the mass and the overall length:

$$I_{zz} = \frac{mL^2}{12} \quad \text{Noon-1} \qquad (40)$$

The second has the moment being a function of the mass and the wheelbase alone, assuming the masses are concentrated at half the wheelbase from the geometric center:

$$I_{zz} = \frac{ml^2}{4} \quad \text{Noon-2} \quad (41)$$

Noon's third method, considering the engine to be the most significant concentrated mass affecting the application of the prism method, accounts for the effect of the engine mass with a combination of methods one and two:

$$I_{zz} = 2(1-x)\frac{mL^2}{12} + (2x-1)m\frac{l^2}{4} \quad \text{Noon-3} \quad (42)$$

where,

x = fraction of vehicle mass borne by front axle

This third method assumes that the difference between the weights on the axles is due to a point mass at the heavier axle, and that the centroid is at the geometric center. Although contradictory, these assumptions are justified for an estimation technique.

Noon offered no recommendations for the pitch or roll moments or the center of gravity height.

Bixel – Bixel (1996) measured the parameters for 104 passenger cars, 84 multi-purpose vehicles, 82 pickup trucks, and 43 vans,.and recommended a number of estimation techniques. They found the roll moment for all vehicles can be estimated as:

$$I_{xx} = \frac{m(h_{roof} + h_{cg})t}{K} \quad (43)$$

Where K is an approximation constant determined for each class of vehicle.

The pitch moment for passenger cars can be estimated as:

$$I_{yy} = \frac{m(h_{roof} + h_{cg})L}{K} \quad (44)$$

The pitch moment for multi-purpose vehicles, pickup trucks and vans can be estimated as:

$$I_{yy} = \frac{m(h_{roof} + h_{cg})l}{K} \quad (45)$$

The yaw moment for all vehicles can be estimated as:

$$I_{zz} = \frac{mtl}{K} \quad (46)$$

All of the methods proposed by Bixel except yaw use the center of gravity height, a quantity that is not generally available on published databases.

The Bixel K factors are summarized in Table 2. Bixel notes that these approximation constants must evolve with evolving vehicle design.

Table 2 - Bixel's Approximation Constants (K)

Vehicle Class	Pitch	Roll	Yaw
Passenger Cars	5.2901	7.9846	2.1942
Sport Utility, l<2.41 m	4.2193	9.4212	2.2048
Sport Utility, l>2.41 m	3.4510	9.4212	2.2048
Pickups	3.3783	9.4738	2.1858
Vans	3.4734	7.8854	2.2168

COMPUTER SIMULATION PROGRAMS

A number of computer programs are available to simulate the behavior of motor vehicles in collision and spin-out. The most common products are the crush-energy based progeny of the original Crash III program, EDCRASH[18] and SLAM[19], and EDSMAC[20] based on the early work of McHenry.[21] More recently PC-Crash[22], a collision and trajectory program developed by Dr. Steffan,[23] has become available.

EDCRASH and EDSMAC use a default value for the yaw moment of inertia derived from the vehicle class categories. These values can be altered by the user.

WinCRASH, the Windows version of the SLAM program, uses a default value for the radius of gyration, k, that can be used to calculate the yaw moment:

$$k_{zz} = (1.023 \pm 0.085)\sqrt{ab} \quad \text{Slam-1} \quad (47)$$

Alternatively WinCRASH proposes:

$$k_{zz} = (0.298 \pm 0.030)L \quad \text{Slam-2} \quad (48)$$

When expressed as the moment of inertia, the WinCRASH values are used as follows:

$$I_{zz} = mk^2 \quad (49)$$

The WinCRASH default value can be altered by the user.

PC-Crash uses the method of Burg for the default yaw moment of inertia for passenger cars:

$$I_{zz} = 0.1269mlL \quad (50)$$

PC-Crash uses the roll and pitch moments as functions of the Burg yaw moment:

$$I_{xx} = 0.3I_{zz} \quad (51)$$

$$I_{yy} = I_{zz} \quad (52)$$

For trucks and trailers, PC-Crash recommends the prism method. Because the height of a truck is similar to the width, PC-Crash reduces the roll, pitch, and yaw moments to:

$$I_{xx} = \frac{2}{12}mW^2 \quad (53)$$

$$I_{yy} = \frac{1}{12} m(L^2 + W^2) \quad (54)$$

$$I_{zz} = I_{yy} \quad (55)$$

The PC-Crash default values can be altered by the user.

COMPARISON OF MEASURED VALUES WITH ESTIMATED VALUES

The NHTSA has measured the moment of inertia for a large number of vehicles, as described by Garrott. These values, for about 414 tests, are published and available on disk. Many of the tests were performed with multiple occupants and significant ballast to load the vehicles to the GVW. About 215 of the tests with multiple occupants or ballast appear to be repeats of tests done on the same vehicle with one or no occupants. Therefore, vehicles loaded with more than one occupant and those carrying loads have been eliminated from the samples used here. Also eliminated were multiple tests involving identical vehicles so as not to weight the sample set toward any particular vehicle.

The comparisons have been done by dividing the vehicles into five categories, as shown on Table 3, where n is the number of vehicles in a category sample. In each case the measured pitch, roll, and yaw moments of inertia and the center of gravity height are compared with the estimated values. The estimation methods compared are given in Table 4.

Table 3 - Vehicle categories for comparison

Vehicle Category	n
Passenger Car - front wheel drive	46
Passenger Car - rear wheel drive	24
Sport Utility (Multi-Purpose)	22
Pickup Truck	25
Van	17

The estimated/measured values for the 46 front wheel drive passenger cars was tested to confirm it had a nearly normal distribution. Although some of the data is skewed, the mean, median, and mode are generally in agreement.

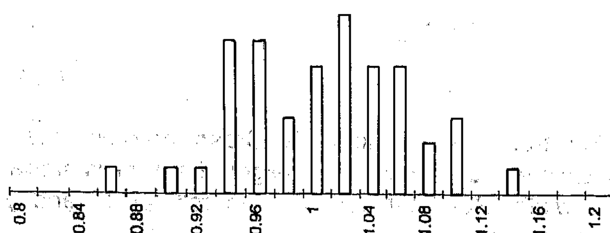

Figure 8 - Histogram of Estimated/Measured Values for FWD Passenger Cars

A histogram for the prism pitch data is as shown on Figure 8. This data set had a mean of 1.00, mode of 0.94, median of 1.01 and a skew of -0.04.

The distribution of the errors about the median shown on Figure 8 is approximately bell-shaped, thus standard statistical tests of the quality of the data will be used.

Slam 2			✓	

For each vehicle in the comparison category, the estimated value has been compared to the measured value in the following way. First the individual error, E, of each estimated value compared to its measured value is calculated as:

$$E = \frac{V_e}{V_m} - 1 \quad (56)$$

Where:

V_e = estimated value

V_m = measured value

The average error, E_{ave}, is:

$$E_{ave} = \frac{\pm \sum_{1}^{n} E}{n} \quad (57)$$

Where:

n = number of vehicles in category sample

The range, R, of the errors is:

$$R = E_{max} - E_{min} \quad (58)$$

Where:

E_{max} = maximum positive error in sample category

E_{min} = minimum positive error in sample category

The standard deviation, SD, is:

$$SD = \sqrt{\frac{1}{n-1}\sum\left(E - E_{ave}\right)^2} \quad (59)$$

The 68% confidence limit, L_{68}, is

$$L_{68} \cong E_{ave} \pm SD \quad (60)$$

The 95% confidence limit, L_{95}, is;

$$L_{95} \cong E_{ave} \pm 2SD \quad (61)$$

All the estimation methods were adjusted with a correction factor as follows:

$$V_{Correct} = CV_e \quad (62)$$

Where the correction factor, C, is:

$$C = \frac{1}{E_{ave} + 1} \quad (63)$$

The adjusted equations were then compared, and the best estimation equations were chosen based on the smallest standard deviation. In the event of a tie, the equation with the narrowest range was chosen.

Figure 9 shows the unadjusted values for the yaw moment of inertia for rear wheel drive passenger vehicles. The equation numbers are shown in brackets.

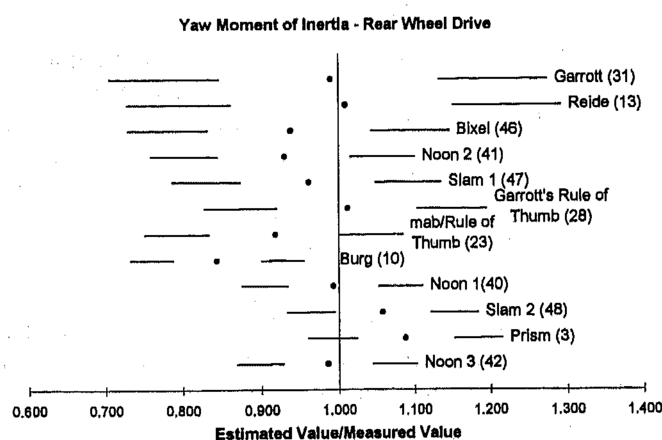

Figure 9 - Unadjusted Estimates

Figure 10 shows the adjusted values for the yaw moment of inertia for rear wheel drive passenger vehicles. The error bands on each graph connect the standard deviation to the 95th percent confidence limit, as on Figure 9. Note that the error bands for each equation have been adjusted as well.

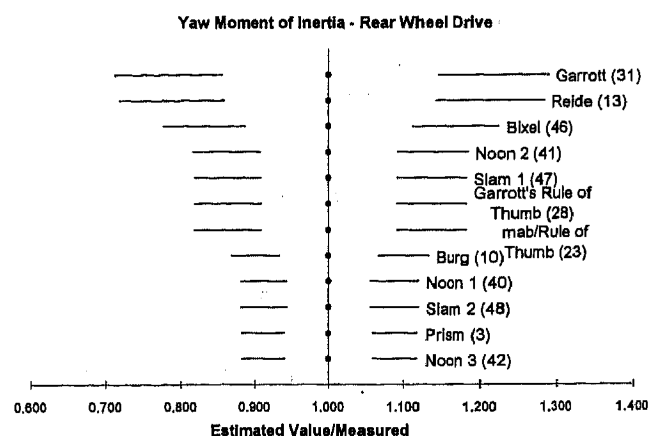

Figure 10 - Adjusted Estimates

RECOMMENDED ESTIMATION TECHNIQUES

The tables in Appendix B provide the correction factors applied to each of the estimation equations as well as statistical information indicating their accuracy. The equation numbers for each estimation technique are shown in brackets.

Each table is accompanied by a chart which graphically ranks the equations as described previously. The equations providing the smallest range of standard deviation error (68% confidence limit) are given in Tables 5 to 9. Note that these equations have been multiplied through by their individual correction factors.

If the information required to use a recommended equation is not available, another equation may be used with its correction factor taken from the tables in Appendix B. The user must then be aware of the slightly greater error being introduced.

When adjusted, it was found that Garrott's revised rules of thumb provided identical results to the original rules of thumb. This was expected as Garrott's revised rules are the result of multiplying the original rules by a constant. Allen's adjusted equation for center of gravity height also provided identical results to those of the second rule of thumb (equation 20) for the same reason.

The inertia estimation methods proposed by Garrott and Reide had greater deviations than the other methods. Both the Reide and Garrott methods consider the moments of inertia to be linearly related to the vehicle mass and do not consider the vehicle geometry.

The only available body of moment of inertia data for European vehicles has been given in the Burg study. No guidance can be offered for those European vehicles not included in the NHTSA data used for this comparison study.

Table 5 - Best Equations for Front Wheel Drive Passenger Cars

	Adjusted Equation
I_{xx}	$0.1274m(h_{roof} + h_{cg})t \pm 6.5\%$
I_{yy}	$0.1425mlL \pm 5.7\%$
I_{zz}	$0.1478mlL \pm 4.8\%$
h_{cg}	$535.0\ mm \pm 3.0\%$

Table 6 - Best Equations for Rear Wheel Drive Passenger Cars

	Adjusted Equation
I_{xx}	$0.120m(h_{roof} + h_{cg})t \pm 9.5\%$
I_{yy}	$0.0733m\left(L^2 + h^2\right) \pm 5.2\%$
I_{zz}	$1.015\left[2(1-x)\frac{mL^2}{12} + (2x-1)m\frac{l^2}{4}\right] \pm 5.9\%$
h_{cg}	$0.390h_{roof} \pm 4.9\%$

Table 7 - Best Equations for Sport Utility Vehicles

	Adjusted Equation
I_{xx}	$0.145mt_{av}h_r \pm 7.6\%$
I_{yy}	$0.1561mlL \pm 5.5\%$
I_{zz}	$0.4622mtl \pm 6.7\%$
h_{cg}	$0.390h_{roof} \pm 5.4\%$

Table 8 - Best Equations for Pickup Trucks

	Adjusted Equation
I_{xx}	$0.138mt_{av}h_r \pm 7.4\%$
I_{yy}	$0.952mab \pm 5.2\%$
I_{zz}	$0.958mab \pm 4.6\%$
h_{cg}	$0.376h_{roof} \pm 3.5\%$

Table 9 - Best Equations for Vans

	Adjusted Equation
I_{xx}	$0.1212m(h_{roof} + h_{cg})t \pm 8.0\%$
I_{yy}	$0.1508mlL \pm 7.4\%$
I_{zz}	$0.1525mlL \pm 7.4\%$
h_{cg}	$0.381h_{roof} \pm 2.8\%$

EFFECT OF VEHICLE LOADING

The comparisons have been done with the NHTSA tests of unloaded vehicles (no more than one occupant). If the passenger and loading mass and distribution is significant, the estimated values must be adjusted.

Occupant positioning in a passenger car is relatively close to the radius of gyration about the centroid, thus the increase in the moments of inertia due to the passenger loading will generally be proportional to the increase in the mass.

If there is a known concentrated mass in a vehicle, due to occupant positioning or cargo loading remote from the radius of gyration, then the moments can be summed using the parallel axis theorem:

$$I' = I + mr^2 \qquad (64)$$

Arndt[24] has identified the effect of passenger and cargo loading on the inertial properties, and provided methods of adjusting the estimated (or measured) moments for specific loading conditions.

SENSITIVITY ANALYSIS

The pitch and roll behavior of the vehicles in 3D simulation will be affected by the respective moments during collision and once the vehicles have separated. The inertial parameter with the greatest potential to influence a simulation is the yaw moment. Variations in the yaw moment of inertia will affect the forces developed between the two vehicles in collision and the immediate post-impact spin rate. When the vehicles have separated, the angular acceleration will be governed to a great extent by the yaw moment. A greater yaw moment of inertia will reduce the yaw angular acceleration when compared to the case of lesser yaw moment.

A test case has been selected to demonstrate the effect of variations in the yaw moment of inertia. The case uses a highly eccentric collision to maximize the sensitivity of the model to the yaw moment. The case uses a 1991 Ford Mustang and a 1989 Honda Accord, both arbitrarily chosen. The vehicle parameters used in PC-Crash are shown on Table 10.

The eastbound Mustang struck the right side at the rear of the southbound Accord, with both vehicles traveling at 50 km/h. The baseline run arbitrarily uses the moments of inertia calculated with the Burg method.

Both vehicles were permitted to spin out to rest. For the Mustang, the front wheels were locked at the instant of collision, and the rear wheels set to a drag of 5%. The Accord rear wheels were locked at impact, and the front wheels set at 5% drag. There was no steering introduced to simulate rolling damaged wheels. The force location at maximum engagement was set at the center of the overlap area (45 ms after contact), and the contact plane was set parallel to the longitudinal axis of

the Accord. The collision coefficient of restitution was set at 0.1, and the inter-vehicle coefficient of friction was set at 1.00.

Table 10 - Test Vehicles

Parameter	Description	V1	V2
	Year & Make	91 Ford	89 Honda
	Model	Mustang	Accord
L	Length, m	4.56	4.57
W	Width, m	1.73	1.71
l	Wheelbase, m	2.55	2.60
h	Height, m	1.32	1.35
t	Track width, m	1.42	1.48
m	mass, kg	1270	1210
a	CG to front axle, m	1.07	0.96
I_{xx}	roll, kg-m^2	562	547
I_{yy}	pitch, kg-m^2	1874	1824
I_{zz}	yaw, kg-m^2	1874	1824
h_{cg}	CG Height	0.53	0.54
V	Speed, km/h	50	50

These simulation parameters are not intended to be representative of any particular vehicle or collision circumstance. The case was selected to illustrate the sensitivity of the collision to variance of the one variable, the yaw moment of inertia.

The yaw moment was varied from 70% to 130% of the default value. The altered values for the yaw moment of inertia are as shown in Table 11.

Table 11 - Altered Yaw Moment Values, kg-m^2

Description	Mustang	Accord
70% Value	1312	1277
80% Value	1499	1459
90% Value	1687	1642
100% Value	1874	1824
110% Value	2061	2006
120% Value	2249	2189
130% Value	2436	2371

First, the simulation was run with the default values. This run is shown graphically in Figure 11. The tire marks are drawn to simulate the actual tire marks assuming tire marks are visible if the tires are 95% saturated.

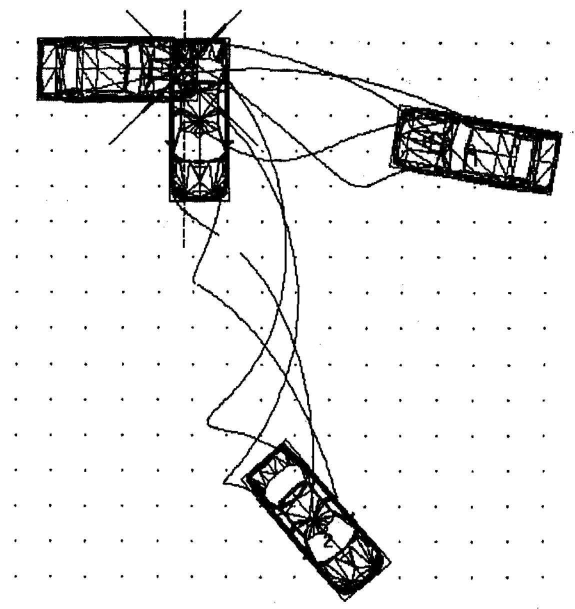

Figure 11 - Simulation with Default Yaw Moments

Next, runs were done varying only the yaw moment of inertia. The run with the yaw moment set to 130% is shown in Figure 12. The DXF drawing showing the rest positions and the tire marks for the run at 100% is plotted for comparison. The 100% run rest positions are shown as rectangles beneath the vehicles. The remainder of the runs are shown in Appendix C.

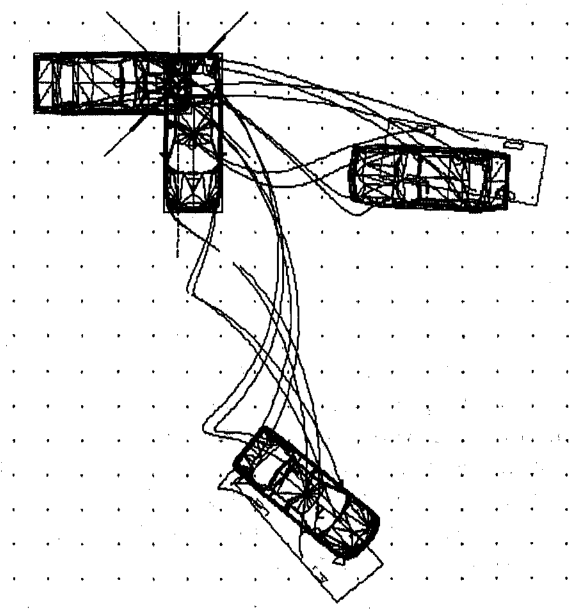

Figure 12 - Simulation with Yaw Moments increased to 130%

Finally, the 130% run was redone, varying the impact speeds and the orientation at impact to duplicate as closely as possible the rest positions for the default moments. The impact speeds were adjusted to 51.5 km/h (+3%) on the Mustang and 51 km/h (+2%) for the Accord and the Mustang was repositioned about 22 cm north at impact. This run is shown on Figure 13.

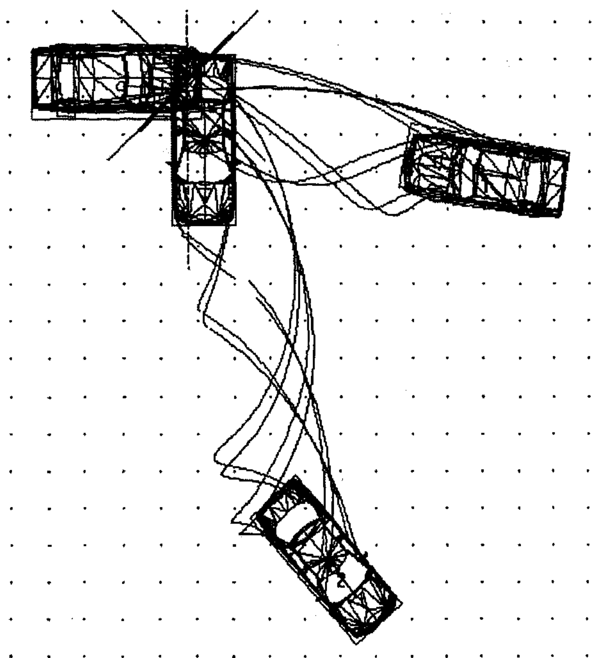

Figure 13 - 130% Simulation varied to match rest positions for 100% case

Note that although the rest positions are similar to the default case in Figure 11, the tire traces are quite different.

Runs were done to test the sensitivity of the simulation to variations in the pitch and roll moments, and the centroid height. As expected, the simulation was not very sensitive to variation in these parameters.

The simulations were very sensitive to variations in the wheel lockup factors, and steer angles on individual tires. The rest positions were more sensitive to these factors than to the yaw moments.

SUMMARY

The values measured by Garrott of the NHTSA have been compared to the values determined by the estimation techniques in five different vehicle categories. Correction factors were applied to each of the estimation equations to eliminate the average error. The adjusted equations were ranked by standard deviation, and the best equations, those with the smallest standard deviation, were chosen and presented.

The recommended equations will predict the moments of inertia and the centroid height parameters of the Garrott sample to better than ±10% with 68% confidence. The 95% confidence limit for the yaw moment was less than ±10% for front wheel drive cars and pickups, and less than ±15% for the other vehicle categories.

In some cases the differences between the recommended equations and the next best equations were very small. Where the dimensional data necessary to estimate the parameters with a recommended equation are not available, alternative equations are presented, with the expected errors given.

The inertia estimation methods proposed by Garrott and Reide consider the moments of inertia to be linearly related to the vehicle mass and do not consider the vehicle geometry. These methods generally produced greater errors than the other estimation methods.

Simulations of a highly eccentric collision and spin-out with PC-Crash have shown that if the estimated values for the yaw moment of inertia are within about ±10% of the actual values, the impact speeds in the simulation will vary less than about 1%. Variations in pitch and roll moments have been shown to have little influence on the calculated vehicle speeds for the simulated 3D planar cases.

If the selected yaw moment of inertia is greater than the actual value by about 30%, the simulation will tend to overestimate the collision speed of the vehicles by as much as 3%. If the selected yaw moment of inertia is less than the actual value by about 30%, the simulation will tend to underestimate the collision speed.

If the estimation method has 95% confidence limits greater than ±30% for the yaw moment, as could occur if the estimation method is based on mass alone, then the simulation errors could become significant.

The simulations indicate the rest positions of vehicles are more sensitive to wheel lockup factors and steer angle than to variations in moments of inertia.

The idealized vehicle prism method and "mab" rule of thumb have often yielded very good results.

This work is based on the measurement data of Garrott and the NHTSA. Others, notably Curzon and Bixel, have measured a number of vehicles. If these data were available, the results may vary.

APPENDICES

The following appendices are attached:

A. Nomenclature

B. Tables and charts of adjusted equations

C. PC-Crash runs

APPENDIX A -- NOMENCLATURE

The following nomenclature will be used throughout:

I = moment of inertia
L = overall vehicle length
l = wheelbase
W = overall vehicle width
h = height
t = track width
a = distance center of mass to front axle
b = distance center of mass to rear axle
T = torque
ω = angular velocity
α = angular acceleration
τ = period of oscillation
k = spring constant
or radius of gyration
r = radius

Subscripts have been used as appropriate, and the meaning will generally be self-evident. The nomenclature of some cited authors has been altered for consistency. Where necessary, the units used in older cited works have been converted to metric.

Table A1 - Metric/US Conversions

1 lb force	4.448 N
1 in	25.4 mm
1 lb-ft-sec^2	1.356 kg-m2

The SAE frame of reference shown in Figure A1 is used:

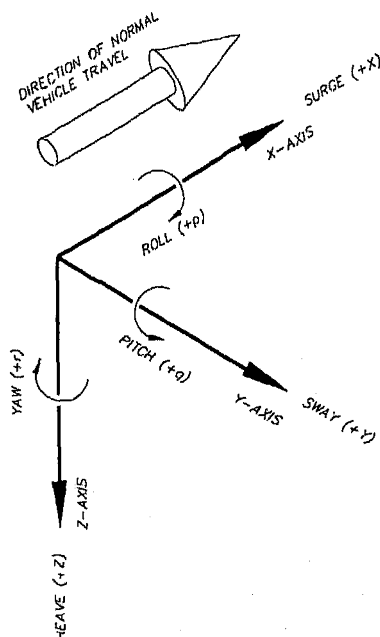

Figure A1 - The SAE frame of reference

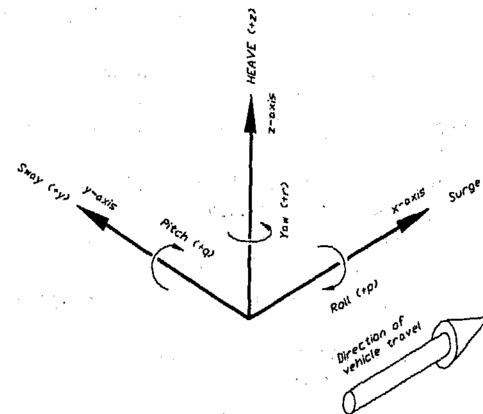
Another common frame of reference, shown in Figure A2, has the positive direction for the Z axis directed upwards. The standard instruction in engineering schools, for example, has the X axis pointing to the right with angles about Z measured counterclockwise from the X-axis.



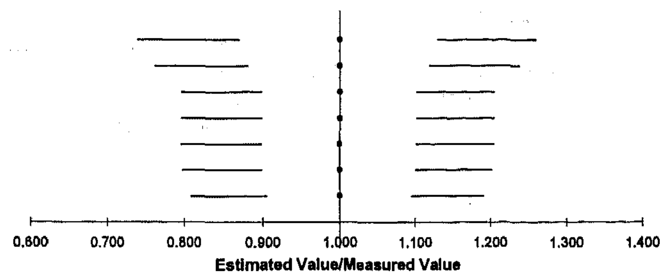


Figure A2 - A Common frame of reference

For both frames the positive angles are defined using the right hand rule.

APPENDIX B - ACCURACY OF CORRECTED EQUATIONS

A Comparison of Moment of Inertia Estimation Techniques for Vehicle Dynamics Simulation

William E. Cliff, Duane D. MacInnis, Craig A. Brown, Colin W. Blair, Authors

In "A Comparison of Moment of Inertia Estimation Techniques for Vehicle Dynamics Simulation", MacInnis et. al. provide a useful summary of the various vehicle parameter estimation techniques developed over the years. Their review of the vehicle dynamics models assists readers to compare the various techniques and methods used. The authors present the distribution for one vehicle category which is approximately normal. The use of standard statistical tests appear appropriate. However, the reader is left to assume that the other vehicle categories are also approximately normally distributed.

The authors' analysis indicate that earlier estimation techniques for the yaw moment of inertia were quite robust. It is encouraging to find that early and perhaps less sophisticated estimation efforts provide robust results when compared with current analytical capabilities.

MacInnis et. al. accurately use the term "corrected" in the sense that the work of prior authors has been adjusted to minimize the deviation from a calculated value to the measured value. This should not be interpreted as a criticism of the prior work or that the prior work is "incorrect". Rather, the current authors present an analysis to reduce the level of variation between the estimated and measured values.

MacInnis et. al. provide a concise summary of the estimation techniques for moments of inertia for vehicle dynamics simulations. Their analyses of the techniques which provide the smallest error will provide engineers a useful resource for reconstruction analyses.

An Evaluation of Rectified Bitmap 2D Photogrammetry with PC-Rect

William E. Cliff, Duane D. MacInnis, and David A. Switzer
MacInnis Engineering Associates

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Without good-quality measurements taken at the time of an accident the analyst is faced with the need to extract measurement data from incident scene photographs. This paper discusses the history and development of the mathematical model for two-dimensional (2D) single exposure analytical photogrammetry, presents the software PC-Rect, and compares the analytical results obtained with PC-Rect to survey results. The sensitivity of the analytical results to the variation in such parameters as subject distance, camera height, digital photograph resolution, and bitmap density is discussed. The concept of using the directly rectified scanned photograph in the reconstruction task is introduced, and the utility of performing the dynamic simulation directly on the rectified photograph is discussed.

INTRODUCTION

Photogrammetry is the science of producing real world measurements from photographs. 3D photogrammetry requires at least two photographs, both containing all the points of interest, and will yield measurements in three dimensions. Relatively simpler 2D photogrammetry, the subject of this study, can be done from a single photograph and is all that is required for planar surfaces.

Photogrammetry as we know it began in the latter half of the nineteenth century and a good synopsis of its general history is given in the ASP Manual[1]. The history and techniques of non-topographical photogrammetry have been summarized by Karara[2].

The use of photogrammetry in accident reconstruction is not new. The Zurich City Police[3] have been conducting 3D photogrammetric accident reconstruction since at least 1933, over 60 years ago. Their technique, using a pair of "metric" cameras and an optical/mechanical stereo plotter, is discussed in a paper by Lillesand[4]. Bryner[5] published a study in 1974 which used stereo cameras and the "parallax" method of data reduction.

Developments in 3D photogrammetry for use in accident reconstruction have been reported by Sherz[6] and Gillen[7], both using a MACO (AMI) 35/70 analytical stereo plotter developed by H. Dell Foster. Wester-Ebbinghaus[8] has proposed 3D photogrammetry for vehicle crush measurements, and Wolf[9] has presented a general discussion of the use of photogrammetry in forensic work. More recent developments have included the camera reverse projection technique discussed by Main[10], and 3D methods reported by Pepe[11,12] and Fay[13]. A good summary of the accuracies expected was offered by Tumbas[14].

Graphical 2D methods include the "perspective grid" approach, discussed by Baker[15], Whitnall[16] and Kerkoff[17], and the less well-known "paper strip" method[18]. A good summary of graphical photogrammetry techniques is given by Williamson[19]. Although graphical methods can yield useful information when carefully applied, they are time-consuming and prone to error.

In the early 1970's, Bleyl[20,21] proposed an analytical technique using the projectivity equations and published a Fortran IV algorithm. Since then, a number of 2D software packages for microcomputers, including those by Niederer[22], Brelin[23], Kinney[24], and Smith[25], have been developed and published. 2D analytical photogrammetry can be done by rectifying the entire bitmap image rather than calculating the coordinates for discrete points, presented by Pepe[26] and Rohde[27].

For most accident scenes, 2D photogrammetry is the preferred method, because of its relative simplicity and because the accident reconstructionist often has only one photograph of a particular area of the road surface.

PC-Rect[28] is a Windows©-based 2D photogrammetry program. PC-Rect will rectify an oblique photograph of a planar accident scene into a scaled plan view "photographic" image. This image contains all the skid marks, road lines and other road markings that appear in the original oblique photograph, as well as discrete points of interest.

Even when no measurements have been taken at the time of an accident, the reconstructionist can obtain enough dimensional data to rectify photographs by going to the scene and taking measurements of painted lines or other long-lasting roadway features that appear in the original photographs.

The purpose of this study was to evaluate PC-Rect's accuracy by comparing scene images rectified with PC-Rect to survey results. Camera lens focal length, camera location and the number and type of input dimensions have been varied to assess the effect of these factors on the accuracy of the results.

THEORY

The typical case encountered in accident reconstruction is a scene photograph taken by a police officer of the roadway and incident artifacts. In this case, the film plane, or image plane, is nearly vertical with respect to the roadway or object plane, and the photograph is simply a projection of the object plane onto the image plane. The process of reversing this projection, i.e., creating a map from the photograph, is known as rectification.

The theory of 3D and 2D rectification is quite similar. The fundamental assumption of rectification is that the camera focal point, a point on the negative and the corresponding surface point are collinear (there is no bending of the rays between object and image). In 2D rectification there is an additional assumption that the surface to be rectified is planar.

The theory of 2D and 3D rectification has been included as Appendix C. The 3D and 2D mathematics rely on the published works by Moffit[29], Wolf[30], Strang[31], and the ASP Manual. The theory outlines methods for developing the solution for 3D rectification and then shows the simplification for 2D rectification with PC-Rect.

ACCURACY

The accuracy presently expected when reconstructing an accident is less than that required in many "high-tech" applications. Accuracies of 0.3 m for the scene information may be adequate to reconstruct collisions where speed from skid distance is the task. Greater precision is required in some cases, as discussed later in this paper.

An analyst's equipment can be calibrated by staging a scene, carefully surveying it, mapping it by photogrammetry, and then comparing the two results. This check has been performed by Kerkoff, Niederer, Smith, Grimes[32], Tumbas and others for the 2D case.

Kerkoff reported an error of 0.05 m from an 8"x10" enlargement of a photograph taken through an inexpensive zoom lens 11.0 m from the subject. Niederer reported an accuracy of 0.2 m using 2D photogrammetry from the negative compared to measurements obtained from routine 3D photogrammetry performed by the Zurich Police. Using Brelin's program, Grimes found a maximum error of 0.64 m at a distance of about 33 m from both 8"x10" enlargements and color slides. Tumbas provided a good summary of a number of 2D and 3D methods, and the accuracy expected.

The potential sources of error in 2D rectification include:

CAMERA IMPERFECTIONS - There is no perfect camera. The "metric" camera traditionally used in photogrammetry has a fixed focal length, and the variations from the ideal optical axis and principal point are known. The distortion of the lens has been determined and can be accommodated in the analysis.

Standard 35 mm cameras commonly used by police agencies, insurance adjusters and analysts are "non-metric" cameras. However, these cameras are thought to produce adequate accuracy for accident reconstruction purposes. Hatzopoulos[33] tested a common high-quality non-metric camera (Olympus OM-2N) and found that it provided accuracies of at least 1:7000.

IMPERFECTIONS IN CREATING THE BITMAP - There are several methods available to create a bitmap from a negative. Likely the most common method used is scanning a print made from the negative, which involves the accuracy of the printing process and the accuracy of the scanner. The accuracy of the printing process, which depends on the equipment used, would often be difficult to obtain from the print shop. The accuracy of the scanning process depends on the scanner, and is thought to be significantly better for flat bed scanners than for hand held scanners.

NON-PLANARITY OF THE ROAD SURFACE - The greatest potential source of error in 2D rectification of photographs taken from oblique angles is any vertical variance of the ground points with respect to the plane defined by the control points. This condition, which has been discussed by Kinney, Niederer and Smith, can be illustrated in an example where the measured points are all at the pavement edges and the road is crowned as shown in Figure 1.

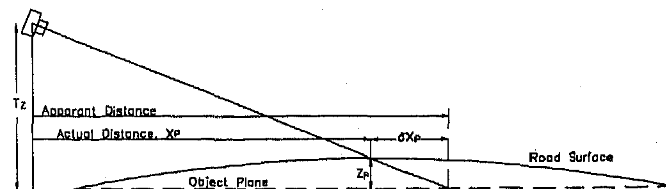

Figure 1 - Non-planarity error

When rectified, points on the road surface which lie above the object plane will appear farther away from the camera than they actually are. Similarly, points on the road surface which lie below the object plane would appear closer to the camera when rectified. The amount of error in the rectification of a point at some height

above or below the object plane can be derived from similar triangles on Figure 1, as follows:

$$\delta X_P = \frac{Z_P X_P}{T_Z - Z_P} \quad (1)$$

where

T_Z = camera height
Z_P = height of point P
X_P = distance on road plane from camera
δX_P = apparent distance - actual distance

The non planarity error increases linearly by the horizontal distance from the camera, although the error also depends on the camera height and the point height. The error increases as the height of the point above the object plane increases, and decreases as the camera height increases. For example, if a 14.6 m wide road with a crown having a two percent cross slope is defined by measurements along each curb edge, a point at the centerline of the road (Z_P= 0.146m) that is 15 m from the photographer with a camera height of about 1.63 m would appear 1.48m further away than it actually is.

This problem can, however, be overcome with a piece-wise analysis in which each side of the road is rectified separately. In this case the maximum error can be reduced significantly as shown in Figure 2 below. This can be done with PC-Rect, as will be shown later.

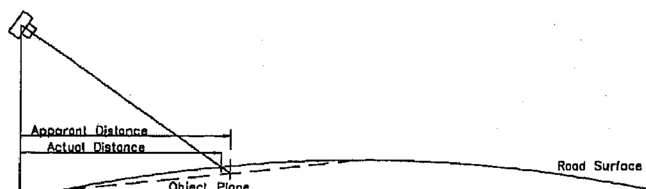

Figure 2 - Non planarity error for half of road surface

CONTROL POINT ACCURACY AND LOCATION - The accuracy in the measurement of the control points will also influence the accuracy of the rectification process. In general for nominally flat surfaces, control points with long distances between them will result in greater accuracy than for control points with short distances between them, since any uncertainty in the position of the points will be averaged over the longer distance.

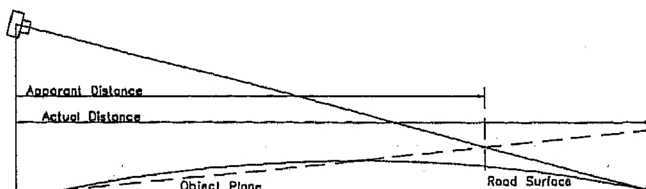

Figure 3 - Error in far side based on near side control points

Also, it is important to choose control points which surround the area of interest. In Figure 3, even though the error on the near side of the road surface may be low, the error on the far side could be great, if the rectified image is based on a plane defined by near side curb and road centerline control points, as shown.

BITMAP RESOLUTION - The resolution of the bitmap will influence the accuracy of the rectification, especially at increasing distances from the camera.

In a typical scene photograph, moving from the bottom of the photograph upwards, the road surface occupies less and less of the photograph width (Figure 4). In the upper portion of the photograph, each pixel represents a greater length and width of the road surface. Therefore, when a bitmap is rectified the resolution will diminish as the distance from the camera increases. The final resolution of the rectified bitmap will depend largely on the pixel density of the original bitmap and the distance from the camera to the area of interest, but will also depend on factors such as camera height, focal length, and photograph print size.

Figure 4 - Typical oblique photograph of road surface

In PC-Rect the user must input the desired resolution (in pixels/meter) of the rectified bitmap. The resolution of a particular point of interest on the rectified bitmap will depend on both the original bitmap resolution and the rectified bitmap resolution, with the original bitmap resolution affecting the quality largely for points far from the camera and the rectified bitmap resolution affecting the quality largely for points near the camera. Images 15 to 22 in Appendix D show the effects of varying the original bitmap resolution and the rectified resolution. It is clear from these images that scanning the photograph at a higher resolution will give superior results, even when rectifying at a lower resolution.

PROCEDURE

Two scenes were photographed from various positions and surveyed. Camera height was kept constant (at normal standing height) at one scene (Scene A) and was varied at the other (Scene B).

Scene A was a flat, slightly sloped parking lot with parallel painted divider lines at right angles to a concrete curb. Two different SLR cameras were used to take photographs from various positions. Camera 1 had a fixed nominal 50mm focal length lens, while Camera 2, which was equipped with a 28-70mm zoom lens, was used to take photographs at 35 and 70mm zoom settings. The photographs were all taken by a person

standing on the ground, resulting in a lens height of about 1.56 meters.

For Scene A, color 100 ASA film was used, and the negatives were developed onto 4" x 6" prints. These prints were scanned into bitmap files at 150 dpi with a flat bed scanner. This resulted in 600 x 900 pixel image with a file size of about 1.5 MB (color image) or 0.5 MB (256 shade black & white image). After confirming the black & white images would show all the required information, they were used in all cases presented. The images were rectified in PC-Rect to a resolution of 30 pixels/meter, and then overlayed on a DXF scale drawing of the incident scene so that the accuracy of the rectified image could be easily judged.

When scanned prints are used, it is important to scan the full print, such that the center of the scanned image is near the center of the negative. A distorted rectified image will result if only one side of a print is used. If the print is cropped so that the new center is the same as the original one, the rectified image will be correct, but the calculated focal length and camera height will be incorrect. This is also true if the specified film size is incorrect.

Scene B was a straight length of 12 meter wide two lane roadway with numerous tire marks. Scene B had a significant crown of approximately constant curvature, with the center of the road being about 16 cm higher than the outside edges. At this scene, photographs were taken from two heights: by a person standing on the ground (nominal lens height of about 1.56 meters) and a person standing on a step ladder (nominal lens height of about 2.42 meters). An SLR camera with a fixed lens focal length of 50mm was used for this scene.

Color 100 ASA film was again used, and the negatives were digitized onto a Kodak Photo CD. The digitized photographs were rectified from 2048 x 3072 pixel bitmaps. This resulted in a file size for each picture of about 6 MB (256 shade black & white image). The images were rectified in PC-Rect to a resolution of 30 pixels/meter, and then overlayed on a DXF scale drawing in the same manner as Scene A.

RESULTS

The results of the rectifications are shown in bitmap image form in Appendix A. Cases 1 to 10 are from Scene A and Cases 11 to 14 are from Scene B.

SCENE A - Cases 1 to 10 are presented in groups of three images (Image 1a, 1b, and 1c, etc.), one group per page. All images with the subscript "a" (and Image 5b) show the original oblique photographs with the reference lines (known dimensions) used to rectify the photographs. All images with the subscript "b" (except Image 5b) show the rectified photographs overlayed on the scale drawing of the scene. All Images with the subscript "c" (except Image 5c) show close-up views of the area of the scene within about 12*h* (where *h* is the camera height above the scene surface) of the camera position. A 12*h* radius is shown with a dotted line, as are each photograph's field of view limits running from the camera position.

Case 5 shows the results of combining two rectified images in PC-Rect. This is done by selecting two common points in each of the rectified images. The overall accuracy of the resulting joined image depends primarily on how accurately the common points were selected, and the distance between them. The larger this distance is, the less will be the angular error between the two images.

For the connected Image 5c, the error is not reported. The distance errors in each image were similar to the errors reported for the other images. There was little or no increase in these values when the images were joined (this depends only on how accurately the connection points are chosen), and so the overall error of the joined image, as a percentage of the combined scene length, was lower than for the individual images.

As the distance from the camera increases, the clarity of the rectified image decreases, as expected. A radius of about 20*h* is about the maximum practical distance for viewing the location of the white lines in the images shown, which, as stated previously, were all rectified at 30 pixels/meter from a 150 dpi original.

The maximum errors between points in the rectified images and the actual scene are shown in Table 1. The scene depth in each case is defined as the distance between the camera and the farthest (unmeasured) point from it in the portion of the scene under consideration (12*h* to 22*h* for the given cases).

Table 1 indicates that errors of less than 1% of the scene depth occurred where the scene depth was less than about 12*h*, except for Case 6, where an error of about 2% occurred. In most cases, the maximum error was lengthwise in the photograph, as expected.

The 2% error in Case 6 occurred at the two parking lot divider lines closest to the camera (on the near side of the raised curb divider). It is not necessarily true that the least amount of error in the scene will be closest to the camera, because the location of the area of maximum error in the rectified image is also dependent on where the measurements have been taken in the scene.

It can be seen in Image 6a that the measurements used to rectify the photograph are in the middle portion of the photograph, with none in the foreground. When two foreground reference lengths were added to this photograph (see Case 7), the error in the rectified image decreased from 2% to 0.6%.

Generally, if foreground measurements are included, this area will contain the least error. This is primarily because of the increased angle (from horizontal) between a straight line from the camera to a foreground

point over one running to a point further in the distance. This increased angle will have the same effect as an increased camera height, in that it will reduce the error effects of any unevenness in the scene.

Table 1 - Scene A Errors

Case No.	Focal Length	Camera Ht. (m)	Scene Depth (m)	Scene Depth / Camera Ht.	Maximum Error cm	Maximum Error % Dist.
			20	12	13	0.7
1	50mm	1.71	26	15	18	0.7
			31	18	46	1.5
			20	13	13	0.7
2	50mm	1.56	26	17	25	1.0
			31	20	25	0.8
			20	13	9	0.5

			34	22	120	3.5
			20	12	11	0.6
9	70mm	1.71	26	15	22	0.8
			31	18	42	1.4
			20	13	16	0.8
10	70mm	1.56	27	17	25	0.9
			34	22	102	3.0

Even at scene depths of 15*h* - 17*h*, the errors for all but Case 6 were still in the 1% range. Errors increased markedly at greater scene depths, however, to the 2% to 4% range at scene depths of 18*h* - 22*h*.

PC-Rect reports the individual errors for the entered reference lengths, as well as a weighted total error, defined as follows:

$$\text{Weighted total error} = \frac{\sqrt{\sum_{i=1}^{n}(w_i \cdot \delta L_i)^2}}{\sum_{i=1}^{n} w_i} \quad (2)$$

where

n = Number of the reference distances
w_i = Weight of the distance i (in %)
δL_i = Relative error of the distance i

The weighted total errors for the reported cases were less than 0.5% except for Case 5 (Image 5b) and Case 6, which were 1.25% and 0.94%, respectively.

Table 1 shows that, for this scene and camera combination anyway, the error differences between lens focal lengths was relatively minor. The 35mm focal length rectified images were, however, less clear than the 50mm or 70mm ones, especially at the end of the scene furthest from the camera.

The focal lengths reported by PC-Rect were close to the actual camera focal length settings. For the 50mm fixed lens, PC-Rect gave values of 52 to 55mm. For the zoom lens, PC-Rect gave values of 35 to 38mm at the 35mm setting and 68 to 71mm at the 70mm setting. Thus, assuming the film negative size (commonly "35mm") is known, the approximate lens focal length can be determined with PC-Rect.

The camera heights reported by PC-Rect were also close to the actual heights. Values of 1.59 to 1.70m were returned for the 1.71m height (photographer on a 0.15m high curb) and 1.51 to 1.60m for the 1.56m height. The approximate elevation of the camera used to take a scene photograph can also thus be determined with PC-Rect.

If the camera focal length and/or height are known for a photograph, these values can be entered and fixed in PC-Rect. This is especially useful in cases where only a few scene dimensions are known. Normally at least four scene dimensions are required, but this can be reduced if one or more camera parameters are known. For all the cases referred to in this paper, none of the four camera parameters (focal length, height, rotation or inclination) were fixed in PC-Rect.

Note that there are diagonal reference lengths in all the reported cases. When only longitudinal and lateral reference lengths are included (Figure 5), the rectified picture can become skewed slightly, as shown in Figure 6 (compare with Image 6c). However, the overall error in the area of the rectified image shown in Figure 6 was still less than +/-1%, indicating the skewing was not that significant.

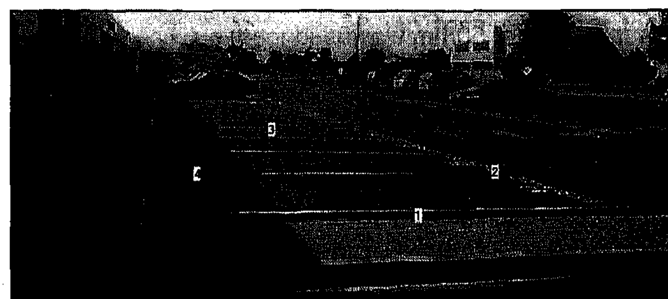

Figure 5 - Image 6a without diagonal reference lengths

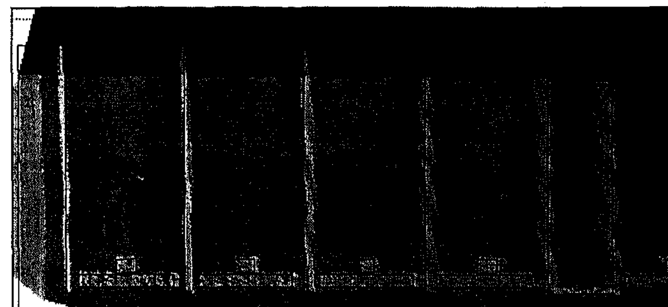

Figure 6 - Rectified without diagonal reference lengths

SCENE B - Cases 11 to 14 are presented in groups of three images in the same manner as Scene A, with the exception of Case 13 which has a fourth image showing

two bitmaps joined together. The images from Scene B are shown in Appendix B.

The photographs for Cases 11-14 were taken from opposite ends of several skid marks. Cases 11 & 12 show photographs taken from approximately the same location but at different heights. Case 11 was taken from a camera height of about 2.42 meters, and Case 12 was taken from a camera height of about 1.56 meters. Cases 13 & 14 show the same section of road surface taken from the opposite direction and show both the near and far sides of the road. As for Cases 11 and 12, Case 13 was taken from a camera height of about 2.42 meters, and Case 14 was taken from a camera height of about 1.56 meters. For each photograph pair (Cases 11&12, and Cases 13&14), the lengths between four points on the near lane of the road surface were chosen as the known distances. Also, for each pair the same four points were used.

The maximum errors between points in the rectified images and the scaled scene drawing are shown in Table 2. The maximum errors shown are for the near lane of the road surface. The errors in the far lane of the road surface are much higher. The weighted total errors for Cases 11-14 were less than 0.5% except for Case 11 (Image 11b) where the weighted total error was 0.67%

For Cases 11 and 12 the maximum errors were all 1% of the scene depth or less. The errors in Case 11, with the higher camera height were slightly greater than in Case 12, with the lower camera height. This is opposite to what was expected. The higher camera height should have produced less error based on reducing the effect of non-planarity of the road surface. Since all the errors were low for these cases, the road surface was likely quite flat and non-planarity was probably not a large factor in the error. The weighted total errors for Case 11 and Case 12 were 0.67% and 0.47% respectively, so the overall lower error in Case 12 may be due to the difference in the weighted total error.

The errors on the near side of the road from Cases 13 and 14 were also quite similar. The errors on the far side of the road surface were larger for the lower camera height (Case 14), than for Case 13. For both cases the far side of the road is reduced in width considerably (Image 13b, c and Image 14b, c). This demonstrates the error on the far side of a road surface based on near side measurement points, as illustrated in Figure 3. Once again, the error can be reduced by rectifying both sides of the road separately and then joining them. Image 13d shows the rectified bitmap with both sides of the road rectified separately and connected together along the centerline of the road.

Cases 11-14 did not show any appreciable increase in accuracy for the higher camera heights, with the exception of the far lane of the road in Cases 13 and 14. In each of Cases 11-14 the long curved skid mark on the near lane was reproduced quite accurately, both on overall length and in radius of curvature.

Table 2 - Scene B Errors

Case No.	Focal Length	Camera Ht. (m)	Scene Depth (m)	Scene Depth / Camera Ht.	Maximum Error cm	Maximum Error % Dist.
			20	8	10	0.5
11	50mm	2.42	26	11	15	0.6
			30	12	30	1.0
			19	12	10	0.5
12	50mm	1.56	24	15	10	0.4
			28	18	10	0.4
			16	7	10	0.6
13	50mm	2.42	24	10	20	0.8
			30	12	40	1.3
			18	12	8	0.4
14	50mm	1.56	23	15	5	0.2
			25	16	25	1.0

DISCUSSION

It is beneficial to know what effect the errors in a rectified photograph can have on the accuracy of the reconstruction of an accident. A 1% error in the overall length of a skid will only cause a 0.5% error in the calculated slide to stop speed, since this is a function of the square root of the skid distance. However, a 1% overall scene depth error does not mean the skid length error is also 1%, unless the skid length is as long as the scene depth. This is because the stated error could be between any two points in the photograph, due mainly to local irregularities in the road surface.

For example, with a scene depth of 20m and a rectified image error of 1%, or 20cm, the error of a 5m long skid in that scene could be 5m +/-20cm, or +/-4%. Table 3 shows what effect this can have on the calculated speed of a vehicle skidding at 0.75g to a stop from distances of 5 to 20m.

Table 3 - Slide to Stop Speed Errors

Skid Dist. (m)	Error in Skid Dist. (cm)	Error in Skid Dist. (%)	Speed (km/h) Min.	Speed (km/h) Max.
5	+/-20	+/-4.0	30.3	31.5
10	+/-20	+/-2.0	43.2	44.1
15	+/-20	+/-1.3	53.1	53.8
20	+/-20	+/-1.0	61.4	62.1

The effect of speeds calculated from yaw marks is more complex. The speed V of a vehicle along a curved path is as follows:

$$V = \sqrt{aR} \qquad (3)$$

where

a = centripetal acceleration
R = radius of vehicle's path

If there is a 1% error in R, this will only cause a 0.5% error in the calculated speed, similar to the skid case. However, the radius of yaw marks is usually not measured directly, but is instead calculated from measured chords and offsets using the formula:

$$R = \frac{C^2}{8m} + \frac{m}{2} \quad (4)$$

where

C = chord length
m = offset at center of chord

If there is a 1% error in C, the calculated speed error will also be 1%, a direct relationship. For most accident reconstruction cases, the $m/2$ term is insignificant and a 1% error in m will cause only a 0.5% error in speed.

The offset m is, however, usually a very small dimension. For example, a vehicle cornering at 100 km/h at a centripetal acceleration of 0.75g in pure yaw (no longitudinal drag from the wheels) can leave yaw marks with an average radius R of about 105m. If the measured chord length C of a 105m radius yaw mark is 10m, the offset m will be only about 12cm. A +/-20cm error (1% of a 20m long scene) in the offset m would thus produce an unacceptable error in the calculated speed.

However, it is the relative error between the end points of the chord and the offset at its center, not the overall scene error, that determines the accuracy of the calculated radius.

Good results will generally be obtained if the photograph to be rectified is a view looking along the yaw mark. In this case there will be little or no relative error in the curved mark between the endpoints of the chord, in the direction across the photograph (in line with the offset m). Although this will also give the greatest amount of possible error in C, a +/-20cm scene length error will result in only a maximum error of +/-2% in a 10m long chord.

If there was a +/-20cm overall error in the rectified photograph (1% of a 20m long scene), there should be only a +/- 1 or 2% error in both the 10m chord length and the offset m. If the chord and offset were both either +2% or -2%, the calculated speed error would be about +/-1%. If the chord error was +2% and the offset error was -2%, the calculated speed error would be about +3%.

However, the error in the offset m could be higher than this, depending on the resolution of the scanned image and also the rectified image. In practice the error would likely be on the order of +/-1cm, or about +/-10% for the stated case with m = 12cm. This error could be higher for uneven scenes where the view is not along the length of the curved mark. A +/-10% error in m will result in speed calculation errors of +/-3 to 8% when combined with a +/-2% chord length error, compared to 1% to 3% with a +/-2% error in both m and the chord length.

The analyst must be cautious when measuring chord offsets in a rectified photograph when a wide angle lens has been used. Figures 7 and 8 each show overhead photographs of a grid of 1x1 unit squares along with 105 unit radius curves, with a chord and offset of 10 units and 0.12 units, respectively. Figure 7 was taken with a 28mm wide angle lens and Figure 8 was taken with a 50mm lens. It can easily be seen that the distortion is so great near the edge of the 28mm photograph in Figure 7 that the radius of the actual curve would be calculated incorrectly.

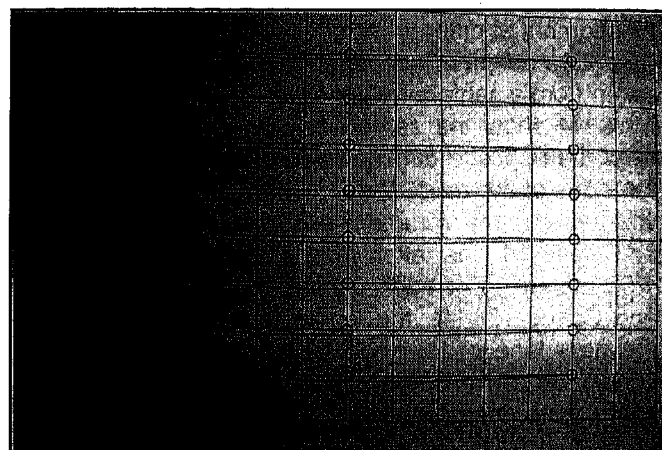

Figure 7 - Plan view of grid with 28mm lens

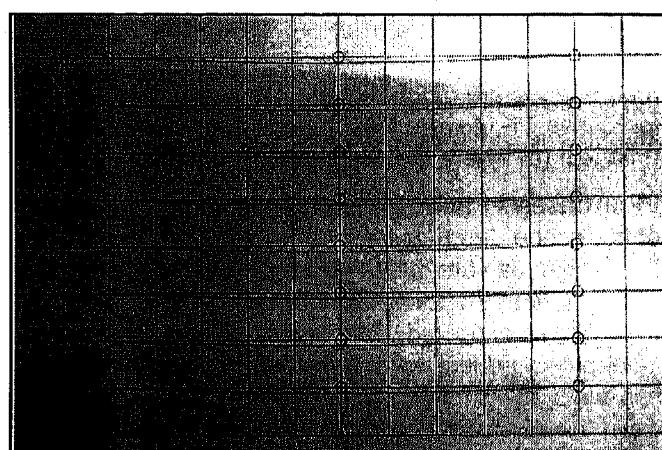

Figure 8 - Plan view of grid with 50mm lens

Thus, if a wide angle lens was used as the basis of a rectified photograph, curve radius calculations should not be relied on unless the curve is near the center of the photograph. The 50mm photograph in Figure 8 is relatively distortion free, and would give good results even in areas near the edge of the photograph.

To illustrate this, an oblique photograph of the grid in the previous two figures was taken with a 50mm lens from a point about two units above the grid plane (Figure 9). This photograph was rectified using the reference lengths shown, resulting in the image in Figure 10.

Chord and offset lines were drawn for all the 105 unit radius curved lines in Figure 10, as shown. The error in the offset m (which was 0.12 units long) was within +/-0.01 units, regardless of where the curved line was in the photograph. Note that the rectified line width in Figure 10 is about 0.02 units, which could be the main source of the error.

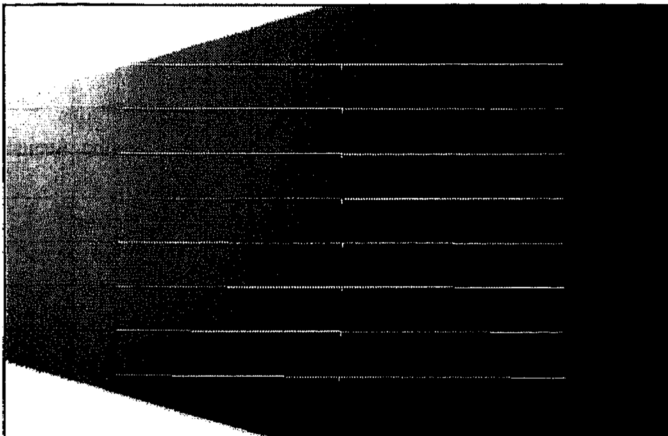

Figure 10 - Rectified view of grid from Figure 9

CASE EXAMPLE

Figure 11 shows an accident scene photograph taken by the attending police. In this accident, a Ford Mustang was struck on its left side by the front of a GMC van. Although the police measured the impact point and rest positions at the scene, no measurements were made of the Mustang's post-impact tire marks. In order to do an accurate reconstruction, the positioning of these marks was required.

PC-Rect was used to rectify this photograph, which was then exported to PC-Crash[34], along with a DXF drawing including the police measurements. The accident was reconstructed with PC-Crash over the drawing and the rectified image, as shown in Figure 12.

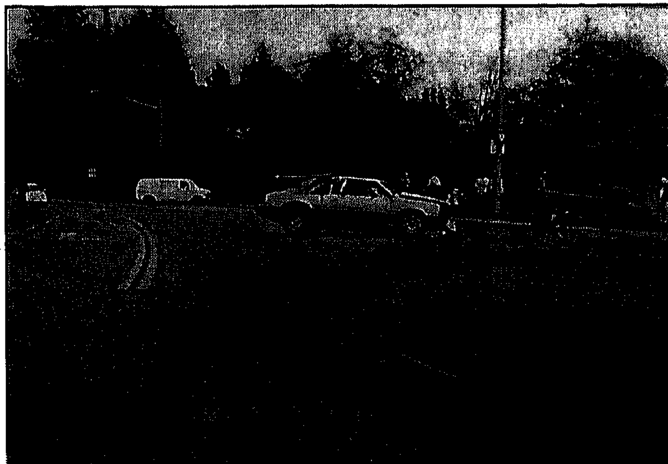

Figure 11 - Police scene photograph

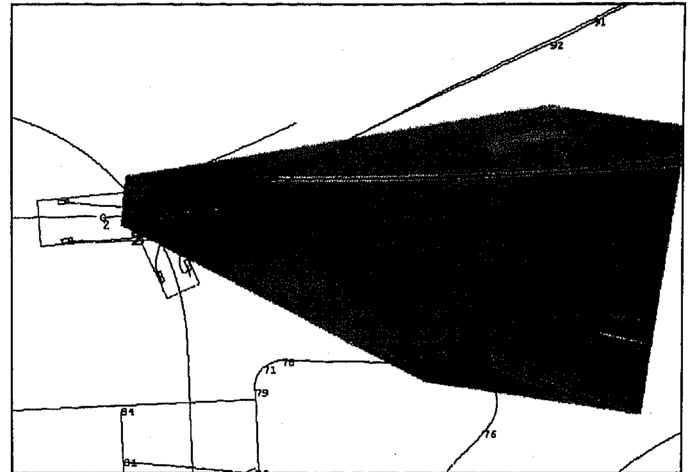

Figure 12 - Simulation over drawing and rectified image

The post-impact tire marks in Figure 12 allowed the reconstructionist in this case to vary the pre-impact speeds until both simulation vehicles matched the incident vehicles' post-impact trajectories, providing a unique solution for the speeds of each. The resulting pre-impact speeds were approximately 16 km/h for the left-turning Mustang (which was accelerating from a stop sign) and 81 km/h for the striking GMC van, which was travelling straight through the intersection in a 50 km/h speed zone.

CONCLUSIONS

1. PC-Rect can be used to rectify photographs of flat accident scenes, resulting in a high degree of accuracy (less than 1% error for scene depth / camera height ratios less than about 12, with no significant increase in error until this ratio was over the 15 to 17 range).

2. Accuracy differences between the 50mm fixed lens and the zoom lens at 35mm and 70mm were relatively minor.

3. PC-Rect can be used to determine the approximate height and lens focal length of the camera used to take a photograph.

4. It is desirable to have diagonal reference lengths in the photograph as well as lateral and longitudinal ones, to avoid skewing of the rectified image. However, when no diagonal reference lengths were used in one of the examples, the resulting small amount of skewing did not cause a significant increase in error.

5. PC-Rect can be used to rectify photographs of non-flat scenes, although lower accuracies can be expected than for flat scenes. For better accuracy, non-flat scenes can be divided into smaller areas of relatively small unevenness, which are each rectified into a separate image. These can then be joined together into one image which has the same absolute accuracy as each individual image.

6. Two different methods were used for generating the photograph bitmaps for Scenes A & B, and there was no clear difference in accuracy between the two. Thus,

scanning the photograph print with a flat bed scanner, and digitizing the negatives onto a Kodak Photo CD both appear to be acceptable methods for generating the photograph bitmap for accident reconstruction purposes. The Kodak Photo CD is, however, likely the most accurate as it eliminates any errors in printing.

7. Caution should be exercised when calculating the radius of curved marks from rectified photographs. Only views looking along the curved marks should be used. When a wide angle lens has been used to take the photograph, the calculated radius of a mark not near the center of the photograph would be suspect.

APPENDIX C - 3D and 2D Theory

The generalized 3D case is developed first, then simplified for the 2D "co-planarity" condition.

EXTERIOR ORIENTATION

The first task in any analytical photogrammetric project is determination of the properties of the camera, such as the geometric distortion, the precise focal length, and the coordinates of the principal point (the point where the optical axis of the camera passes through the film plane). This is termed interior orientation, and a camera with these properties known is termed a "metric" camera. For the mathematics that follow, a perfect camera is assumed: distortion-free with known focal length and with the optical axis aligned with the center of the image, or photograph.

The second task is to locate the camera exposure center , *O*, (also called the focal point) in space. This is termed exterior orientation.

Exterior orientation consists of locating the camera exposure center on the global coordinate system, T_x, T_X, and T_Y, determination of the alignment of the camera optical axis, ω, ϕ, and k,and determination of the scale factor, s, between the image and the object space (the ground plane in our case).

NOMENCLATURE

The following nomenclature will be used throughout this paper:

- X_J, Y_J, Z_J = coordinates of object point J on global frame X, Y, Z
- x_j, y_j, z_j = coordinates of photo point j on camera frame x, y, z, origin at exposure center, 0.
- x'_j, y'_j, z'_j = coordinates of photo point j on frame x', y', z', parallel to X, Y, Z, origin at exposure center, 0.
- T_X, T_Y, T_Z = coordinates of exposure center, 0, on global frame
- ω, ϕ, k, = direction of optical axis from exposure center, 0,
- s = scale between the image and the object space.
- h = camera height.

These parameters are shown in Figures C1 and C2.

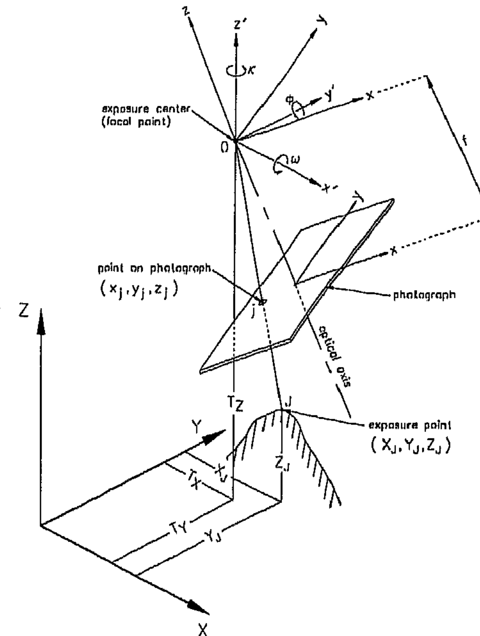

Figure C1 - The image space and the object space

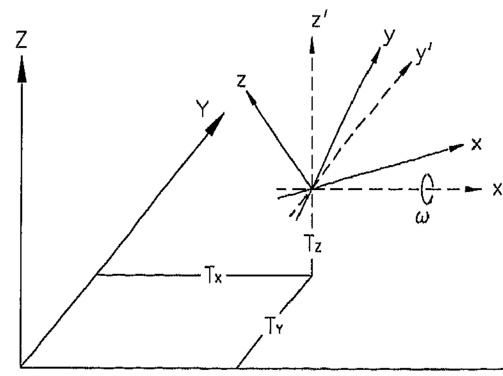

Figure C2 - The three coordinate frames of reference

ROTATIONS

The convention is to first convert (by rotations) from coordinates in the parallel frame x', y', z' to the coordinates of the photo point in the camera frame to x_j, y_j, z_j, and later, by matrix transformation (because it is x', y', z' that is usually given) convert back to x_j, y_j, z_j by $X = MX'$ (see later). These rotations take place about the three axes of the parallel frame in the order shown in Figure C3.

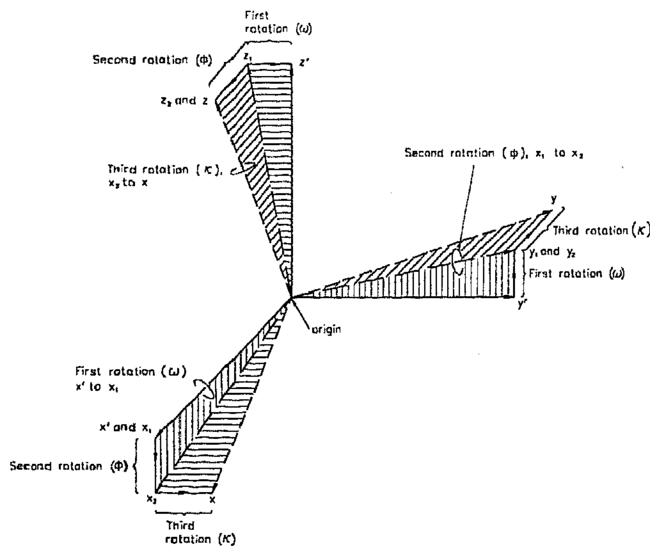

Figure C3 - Order of rotations

First, rotate through ω about x' axis, get x_1, y_1, z_1, from x', y', z', as shown in Figure C4:

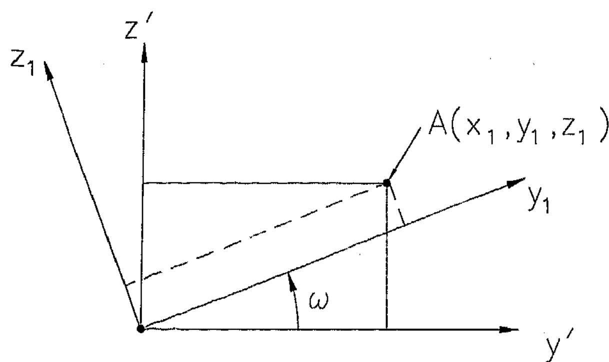

Figure C4 - Rotation about x' axis

$$\begin{aligned} x_1 &= x' \\ y_1 &= y' \cos\omega + z' \sin\omega \\ z_1 &= -y' \sin\omega + z' \cos\omega \end{aligned} \qquad \text{(C1)}$$

Second, Rotate through ϕ about y_1 axis, get x_2, y_2, z_2, as shown in Figure C5:

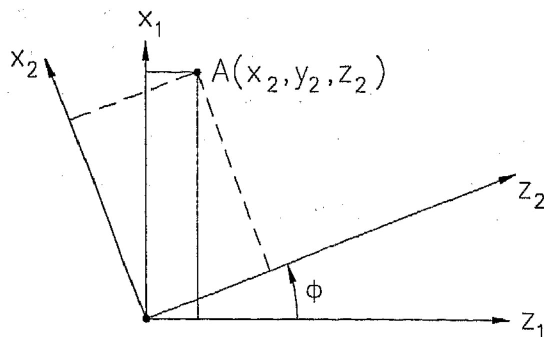

Figure C5 - Rotation about y_1 axis

$$\begin{aligned} x_2 &= x_1 \cos\phi - z_1 \sin\phi \\ y_2 &= y_1 \\ z_2 &= x_1 \sin\phi + z_1 \cos\phi \end{aligned} \qquad \text{(C2)}$$

and by substitution:

$$\begin{aligned} x_2 &= x' \cos\phi - \left(-y' \sin\omega + z' \cos\omega\right) \sin\phi \\ y_2 &= y' \cos\omega + z' \sin\omega \\ z_2 &= x' \sin\phi + \left(-y' \sin\omega + z' \cos\omega\right) \cos\phi \end{aligned} \qquad \text{(C3)}$$

Third, rotate through k about z_2 to x, y, z, as shown in Figure C6:

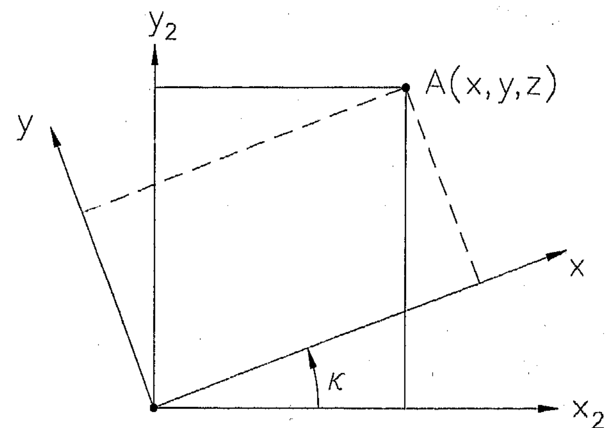

Figure C6 - Rotation about z_2 axis

$$\begin{aligned} x &= x_2 \cos k + y_2 \sin k \\ y &= -x_2 \sin k + y_2 \cos k \\ z &= z_2 \end{aligned} \qquad \text{(C4)}$$

and substitute again:

$$\begin{aligned} x &= \left(x' \cos\phi - \left(-y' \sin\omega + z' \cos\omega\right) \sin\phi\right) \cos k \\ &+\left(y' \cos\omega + z' \sin\omega\right) \sin k \\ y &= -\left(x' \cos\phi - \left(-y' \sin\omega + z' \cos\omega\right) \sin\phi\right) \sin k \\ &+\left(y' \cos\omega + z' \sin\omega\right) \cos k \\ z &= x' \sin\phi + \left(-y' \sin\omega + z' \cos\omega\right) \cos\phi \end{aligned}$$

(C5)

Expanding and factoring:

$$\begin{aligned} x &= x'\left(\cos\phi \cos k\right) - \sin\phi \cos k\left(-y' \sin\omega + z' \cos\omega\right) \\ &\quad + y'(\cos\omega \sin k) + z'(\sin\omega \sin k) \\ &= x'\left(\cos\phi \cos k\right) - y'\left(-\sin\omega \sin\phi \cos k\right) \\ &\quad - z'\left(\cos\omega \sin\phi \cos k\right) \\ &\quad + y'(\cos\omega \sin k) z'(\sin\omega \sin k) \end{aligned}$$

$$= (\cos\phi\cos k)x' + (\cos\omega\sin k + \sin\omega\sin\phi\cos k)y' + (\sin\omega\sin k - \cos\omega\sin\phi\cos k)z' \quad \text{(C6)}$$

By similar means, the relationships for y and z can be found.

These rotations can be expressed in matrix form by substituting m_{ij} for the coefficients of x', y', z'

$$\begin{aligned} x &= m_{11}x' + m_{12}y' + m_{13}z' \\ y &= m_{21}x' + m_{22}y' + m_{23}z' \\ z &= m_{31}x' + m_{32}y' + m_{33}z' \end{aligned} \quad \text{(C7)}$$

where,

$$\begin{aligned} m_{11} &= \cos\phi\cos k \\ m_{12} &= \cos\omega\sin k + \sin\omega\sin\phi\cos k \\ m_{13} &= \sin\omega\sin k - \cos\omega\sin\phi\cos k \end{aligned} \quad \text{(C7)}$$

and, proven similarly,

$$\begin{aligned} m_{21} &= -\cos\phi\sin k \\ m_{22} &= -\sin\omega\sin\phi\sin k + \cos\omega\cos k \\ m_{23} &= \cos\omega\sin\phi\sin k + \sin\omega\cos k \\ m_{31} &= \sin\phi \\ m_{32} &= -\sin\omega\cos\phi \\ m_{33} &= \cos\omega\cos\phi \end{aligned} \quad \text{(C8)}$$

In matrix form

$$X = MX' \quad \text{(C9)}$$

$$X = \begin{bmatrix} x \\ y \\ z \end{bmatrix},\ M = \begin{bmatrix} m_{11}m_{12}m_{13} \\ m_{21}m_{22}m_{23} \\ m_{31}m_{32}m_{33} \end{bmatrix},\ X' = \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix}$$

Recall the convention is to go from photo points on parallel axes (x', y', z') to photo points on rotated axes (x, y, z). Because M is an orthogonal Matrix,

$$M^{-1} = M^T \quad \text{(C10)}$$

$$\therefore\ X' = M^T X \quad \text{(C11)}$$

Yielding the relationship for going from general parallel axes to photo points (i.e. transposed $m_{ij} = m_{ji}$)

$$\begin{aligned} x' &= m_{11}x + m_{21}y + m_{31}z \\ y' &= m_{12}x + m_{22}y + m_{32}z \\ x' &= m_{13}x + m_{23}y + m_{33}z \end{aligned} \quad \text{(C12)}$$

This is the general relationship to go back from the rotated axes (x, y, z) to the parallel axes, (x', y', z').

SCALING AND TRANSLATION

To get the coordinates of the photo points in X, Y, Z, the global coordinate system, we must deal with the position of the exposure center and the scale factor.

$$\begin{aligned} X &= sx' + T_X = s(m_{11}x + m_{21}y + m_{31}z) + T_X \\ Y &= sy' + T_Y = s(m_{12}x + m_{22}y + m_{32}z) + T_Y \\ Z &= sz' + T_Z = s(m_{13}x + m_{23}y + m_{33}z) + T_Z \end{aligned} \quad \text{(C13)}$$

Or, in matrix form:

$$\overline{X} = SM^T X + T \quad \text{(C14)}$$

Where

$$\overline{X} = \begin{bmatrix} X \\ Y \\ Z \end{bmatrix},\ T \begin{bmatrix} T_X \\ T_Y \\ T_Z \end{bmatrix}$$

This can read as the object points equals the scaled rotated photo points plus the translations,

SOLVING FOR SEVEN UNKNOWNS

Recall that we have seven unknowns, the three translations T_X, T_Y, and T_Z, the three rotations ω, ϕ, and k, and the scale factor s.

Each point on the photograph whose global coordinates are known will yield three equations. Thus, since we need at least seven equations, we need at least three points whose coordinates are known in both systems. We will for convenience label these points p, q, r in the photograph, and P, Q, R in the global system.

$$\begin{aligned} X_P &= s(m_{11}x_p + m_{21}y_p + m_{31}z_p) + T_X \\ Y_P &= s(m_{12}x_p + m_{22}y_p + m_{32}z_p) + T_Y \\ Z_P &= s(m_{13}x_p + m_{23}y_p + m_{33}z_p) + T_Z \\ X_Q &= s(m_{11}x_q + m_{21}y_q + m_{31}z_q) + T_X \\ Y_Q &= s(m_{12}x_q + m_{22}y_q + m_{32}z_q) + T_Y \\ Z_Q &= s(m_{13}x_q + m_{23}y_q + m_{33}z_q) + T_Z \\ X_R &= s(m_{11}x_r + m_{21}y_r + m_{31}z_r) + T_X \\ Y_R &= s(m_{12}x_r + m_{22}y_r + m_{32}z_r) + T_Y \\ Z_R &= s(m_{13}x_r + m_{23}y_r + m_{33}z_r) + T_Z \end{aligned} \quad \text{(C15)}$$

These equations are non-linear (degree>1)

LINEARIZATION

Using Taylor's theorem, with the angles given in radians:

$$X_P = X_{P_0} + \left(\frac{\partial X_P}{\partial s}\right)_0 ds + \left(\frac{\partial X_P}{\partial \omega}\right)_0 d\omega + \left(\frac{\partial X_P}{\partial \phi}\right)_0 d\phi$$

$$+ \left(\frac{\partial X_P}{\partial k}\right)_0 d\kappa + \left(\frac{\partial X_P}{\partial T_X}\right)_0 dT_X + \left(\frac{\partial X_P}{\partial T_y}\right)_0 dT_Y$$

$$+ \left(\frac{\partial X_P}{\partial T_Z}\right)_0 dT_Z \quad \text{(C16)}$$

A total of nine equations can be written in this form for x, y, and z for each point p, q, and r.

The first few coefficients will be:

$$a_{11}\left(\frac{\partial X_P}{\partial s}\right)$$

$$X_P = s\left(m_{11}x_p + m_{21}y_p + m_{31}z_p\right) + T_X$$

$$\therefore a_{11} = m_{11}x_p + m_{21}y_p + m_{31}z_p \quad \text{(C17)}$$

$$a_{12} = \frac{\partial X_P}{\partial \omega}$$

$$X_P = s\left((\cos\phi\cos k)x_p + (-\cos\phi\sin k)y_p + (\sin\phi)z_p\right) + T_x$$

now, because $\frac{\partial X_P}{\partial \omega} = 0$

$$a_{12} = 0 \quad \text{(C18)}$$

$$a_{13} = \frac{\partial X_P}{\partial \phi}$$

$$\therefore a_{13} = s\left[(-\sin\phi\cos k)x_p + (\sin\phi\sin k)y_p + (\cos\phi)z_p\right] \quad \text{(C19)}$$

through to

$$a_{97} = \frac{\partial Z_R}{\partial T_Z} \quad \text{(C20)}$$

The partial derivative coefficients can be expressed as a_{ij}:

$$a_{11}ds + a_{12}d\omega + a_{13}d\phi + a_{14}dk + a_{15}dTx + a_{16}dTy + A_{17}dT_z = \left[X_P - X_{P_0}\right] + V_{X_P} \quad \text{(C21)}$$

through to:

$$a_{91}ds + a_{92}d\omega + a_{93}d\phi + a_{94}d\kappa + a_{95}dT_X + a_{96}dT_Y + a_{97} = \left[Z_R - Z_{R_0}\right] + V_{Z_R} \quad \text{(C21)}$$

or

$$nAX = L + V \quad \text{(C22)}$$

where,

$A = \begin{bmatrix} a_{11} \ldots\ldots\ldots\ldots a_{17} \\ \\ a_{91} \ldots\ldots\ldots\ldots a_{97} \end{bmatrix}$, the coefficient matrix,

$X = \begin{bmatrix} ds \\ d\omega \\ d\partial \\ dk \\ dT_X \\ dT_Y \\ dT_Z \end{bmatrix}$, the unknowns,

$L = \begin{bmatrix} X_P - X_{P_0} \\ \\ Z_R - Z_{R_0} \end{bmatrix}$, the constants (should tend to zero)

$V = \begin{bmatrix} V_{X_P} \\ \\ V_{Z_R} \end{bmatrix}$, the residual values

Using the least squares solution

$${}_mA_{nm}X_1 = {}_mL_1 + {}_mV_1 \quad \text{(C23)}$$

Which can also be expressed as

$$A^TAX = A^TL \quad \text{(C24)}$$

Which is the matrix of the "normal" equation coefficients of the unknowns.

Multiplying by $\left(A^TA\right)^{-1}$

$$\left(A^TA\right)^{-1}A^TAX = \left(A^TA\right)^{-1}A^TL$$

$$IX = \left(A^TA\right)^{-1}A^TL \quad \text{(C25)}$$

$$X = \left(A^TA\right)^{-1}A^TL$$

(equally weighted)

Standard Deviation

$$S_0 = \sqrt{\frac{V^T V}{r}} \qquad \text{(C26)}$$

r = degrees of freedom
= # equations - # unknowns
= 9-7
= 2

check:

$$L: \begin{bmatrix} X_P - X_{P_0} \\ \\ Z_R - Z_{R_0} \end{bmatrix}$$

These terms can be tested to satisfy the required precision.

SIMPLIFICATION FOR 2D RECTIFICATION

In motor vehicle collision analysis, the events most often occur on a two-dimensional plane, the road surface. 2D rectification requires only one photograph and deals with the projection of the photograph plane (image plane) onto the road surface plane (object plane). These conditions lead to a number of simplifying assumptions that reduce the mathematical complexity.

As stated earlier the fundamental assumptions of 2D rectification are that the focal point of the camera, the point on the negative (or positive), and the corresponding surface point are collinear, and that the surface is planar. The geometry of 2D rectification is illustrated in Figures C7 and C8.

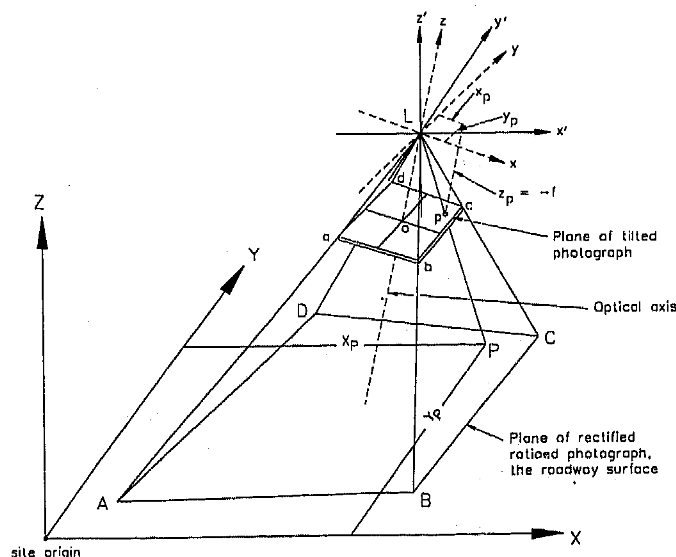

Figure C7 - The image space and the object space

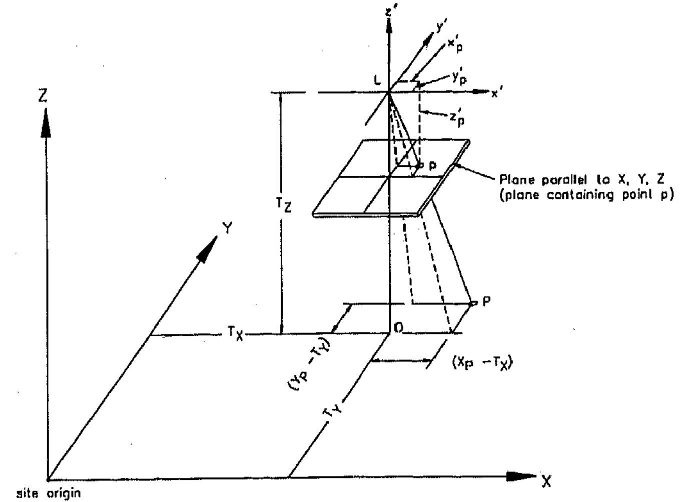

Figure C8 - The image space rotated parallel to the object space

Starting from the equations for rotation of the image plane:

$$\begin{aligned} x_p &= m_{11}x'_p + m_{12}y'_p + m_{13}z'_p \\ y_p &= m_{21}x'_p + m_{22}y'_p + m_{23}z'_p \\ z_p &= m_{31}x'_p + m_{32}y'_p + m_{33}z'_p \end{aligned} \qquad \text{(C27)}$$

From similar triangles in Figure 8:

$$x'_p = \frac{z'_p(X_P - T_X)}{T_Z}, \qquad \text{(C28)}$$

$$y'_p = \frac{z'_p(Y_P - T_Y)}{T_Z}, \text{ and} \qquad \text{(C29)}$$

$$z'_p = \frac{z'_p(T_Z)}{T_Z} \qquad \text{(C30)}$$

Substituting and rearranging:

$$\begin{aligned} x_p &= m_{11}z'_p\frac{(X_P - T_X)}{T_Z} + m_{12}z'_p\frac{(Y_P - T_Y)}{T_Z} + m_{13}z'_p\frac{(T_Z)}{T_Z} \\ y_p &= m_{21}z'_p\frac{(X_P - T_X)}{T_Z} + m_{22}z'_p\frac{(Y_P - T_Y)}{T_Z} + m_{23}z'_p\frac{(T_Z)}{T_Z} \\ z_p &= m_{31}z'_p\frac{(X_P - T_X)}{T_Z} + m_{32}z'_p\frac{(Y_P - T_Y)}{T_Z} + m_{33}z'_p\frac{(T_Z)}{T_Z} \end{aligned}$$

(C31)

Expanding and collecting terms:

$$x_p = \frac{z'_p}{T_Z}[m_{11}(X_P - T_X) + m_{12}(Y_P - T_Y) + m_{13}T_Z]$$

$$y_p = \frac{z'_p}{T_Z}[m_{21}(X_P - T_X) + m_{22}(Y_P - T_Y) + m_{23}T_Z]$$

$$z_p = \frac{z'_p}{T_Z}[m_{31}(X_P - T_X) + m_{32}(Y_P - T_Y) + m_{33}T_Z] \qquad \text{(C32)}$$

Next, dividing the equations for x and y by the equation for z:

$$x_p = z_p \frac{[m_{11}(X_P - T_X) + m_{12}(Y_P - T_Y) + m_{13}T_Z]}{[m_{31}(X_P - T_X) + m_{32}(Y_P - T_Y) + m_{33}T_Z]}$$

$$y_p = z_p \frac{[m_{21}(X_P - T_X) + m_{22}(Y_P - T_Y) + m_{23}T_Z]}{[m_{31}(X_P - T_X) + m_{32}(Y_P - T_Y) + m_{33}T_Z]} \qquad \text{(C33)}$$

Next, by dividing each term in the numerator and denominator by $m_{33}T_z$:

$$x_p = \frac{\frac{z_p m_{11}}{m_{33}T_Z}(X_P - T_X) + \frac{z_p m_{12}}{m_{33}T_Z}(Y_P - T_Y) + \frac{z_p m_{13}}{m_{33}T_Z}T_Z}{\frac{m_{31}}{m_{33}T_Z}(X_P - T_X) + \frac{m_{32}}{m_{33}T_Z}(Y_P - T_Y) + \frac{m_{33}T_Z}{m_{33}T_Z}}$$

$$y_p = \frac{\frac{z_p m_{21}}{m_{33}T_Z}(X_P - T_X) + \frac{z_p m_{22}}{m_{33}T_Z}(Y_P - T_Y) + \frac{z_p m_{23}}{m_{33}T_Z}T_Z}{\frac{m_{31}}{m_{33}T_Z}(X_P - T_X) + \frac{m_{32}}{m_{33}T_Z}(Y_P - T_Y) + \frac{m_{33}T_Z}{m_{33}T_Z}} \qquad \text{(C34)}$$

Since the camera height (T_Z), focal length ($-z_p$), rotation angles (φ, ω, κ), and translations (T_X, T_Y) are all constant:

$$x_p = \frac{c_1 X_P + c_2 Y_P + c_3}{c_4 X_P + c_5 Y_P + 1}$$

$$y_p = \frac{c_6 X_P + c_7 Y_P + c_8}{c_4 X_P + c_5 Y_P + 1} \qquad \text{(C35)}$$

where

$$c_1 = \frac{z_p m_{11}}{m_{33}T_Z} \qquad c_2 = \frac{z_p m_{12}}{m_{33}T_Z}$$

$$c_3 = \frac{z_p m_{13}}{m_{33}} - \frac{z_p m_{11}T_X}{m_{33}T_Z} - \frac{z_p m_{12}T_Y}{m_{33}T_Z}$$

$$c_4 = \frac{m_{31}}{m_{33}T_Z} \qquad c_5 = \frac{m_{32}}{m_{33}T_Z} \qquad \text{(C36)}$$

$$c_6 = \frac{z_p m_{21}}{m_{33}T_Z} \qquad c_7 = \frac{z_p m_{22}}{m_{33}T_Z}$$

$$c_8 = \frac{z_p m_{23}T_Z}{m_{33}T_Z} - \frac{z_p m_{21}T_X}{m_{33}T_Z} - \frac{z_p m_{22}T_Y}{m_{33}T_Z}$$

The above equations are general and represent the projectivity between two planes. Thus, the reverse transformation, from photo points to road surface points, can also be expressed as:

$$X_P = \frac{c'_1 x_p + c'_2 y_p + c'_3}{c'_4 x_p + c'_5 y_p + 1}$$

$$Y_P = \frac{c'_6 x_p + c'_7 y_p + c'_8}{c'_4 x_p + c'_5 y_p + 1} \qquad \text{(C37)}$$

where

$$c'_1 = \frac{T_Z m_{11}}{m_{33}z_p} \qquad c'_2 = \frac{T_Z m_{21}}{m_{33}z_p}$$

$$c'_3 = \frac{T_Z m_{31}z_p + T_X}{m_{33}z_p}$$

$$c'_4 = \frac{m_{13}}{m_{33}z_p} \qquad c'_5 = \frac{m_{23}}{m_{33}z_p} \qquad \text{(C38)}$$

$$c'_6 = \frac{T_Z m_{12}}{m_{33}z_p} \qquad c'_7 = \frac{T_Z m_{22}}{m_{33}z_p}$$

$$c'_8 = \frac{T_Z m_{32}z_p + T_Y}{m_{33}z_p}$$

For 2D rectification there are eight constants and two equations per control point, therefore at least four control points are required for a solution. The projectivity equations can be written in matrix form and the eight constants can be solved directly. If more than four control points are used a least squares solution of the eight constants can be performed. The eight constants themselves are made up of seven independent unknowns.

- Three translations (T_X, T_Y, T_Z)
- Three rotations (ϕ, ω, κ)
- Camera focal length $(-z_p)$

PC-Rect makes some assumptions about the orientation of the camera which simplifies the solution

process. The optical axis is defined to be in the Y-Z plane, and the focal point is defined to be at a height T_z above the object plane origin such that:

T_X = 0

T_Y = 0

T_Z = Camera height

κ = Rotation about Z-axis = 0

Thus, in PC-Rect there are only four independent unknowns:

- Camera height (T_Z)
- Two rotations (ϕ, ω), defined as the camera inclination and rotation respectively
- Camera focal length ($-z_p$)

In PC-Rect the user inputs known distances between points on the road surface rather than the xy coordinates of points. Each known distance provides one equation.

$$L_i = \sqrt{(X_2 - X_1)^2 + (Y_2 - Y_1)^2} \qquad \text{(C39)}$$

where

L_i = known distance on object space

$X_2, Y_2, ..$ = end point coordinates of known distance on object space

Substituting for ($X_2, Y_2, ..$) with Equation C37, results in one equation for each known distance. Since there are four unknowns, PC-Rect requires four known distances for a solution. The equations are solved by varying the unknowns in an iterative process until the weighted total error is minimized. The weighted total error provides the user with an indication of the precision expected from the results.

The individual and weighted total errors are calculated in PC-Rect 2.4 as follows:

$$\text{Individual Weighted Error} = w_i \delta L_i \qquad \text{(C40)}$$

$$\text{Weighted Total Error} = \frac{\sqrt{\sum_i^n (w_i \delta L_i)^2}}{\sum_i^n w_i} \qquad \text{(C41)}$$

where

w_i = weighting of known distance, *i*

δL_i = error in known distance *i*

APPENDIX D

Images 15 to 18 were rectified at different resolutions from a 600 dpi bitmap of a 4" x 6" photograph print of Image 2a (original file size 8336 kB). The resolution and file size of each image are as specified below.

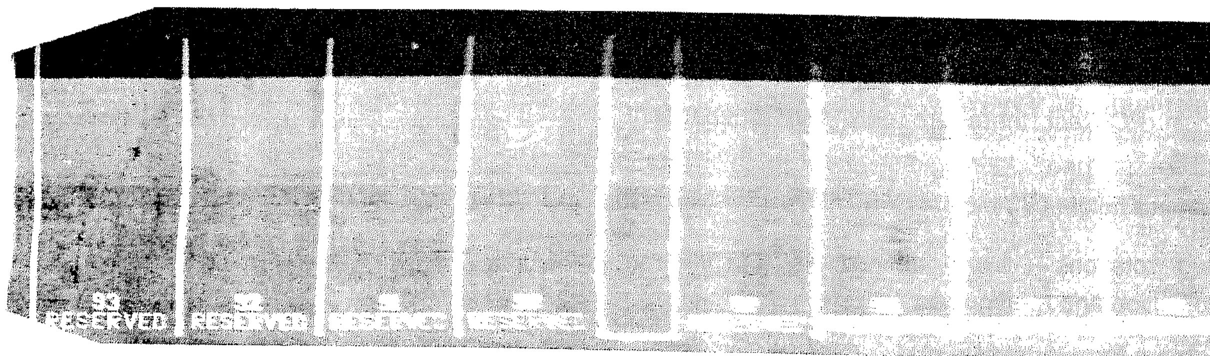

Image 15 - 600 dpi Original - 100 pixel/meter Rectification - Rectified file size 1442 kB

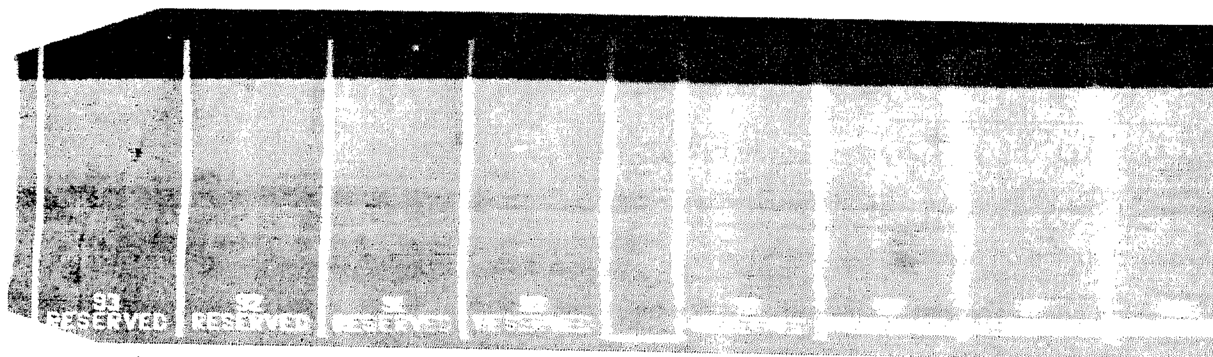

Image 16 - 600 dpi Original - 50 pixel/meter Rectification - Rectified file size 361 kB

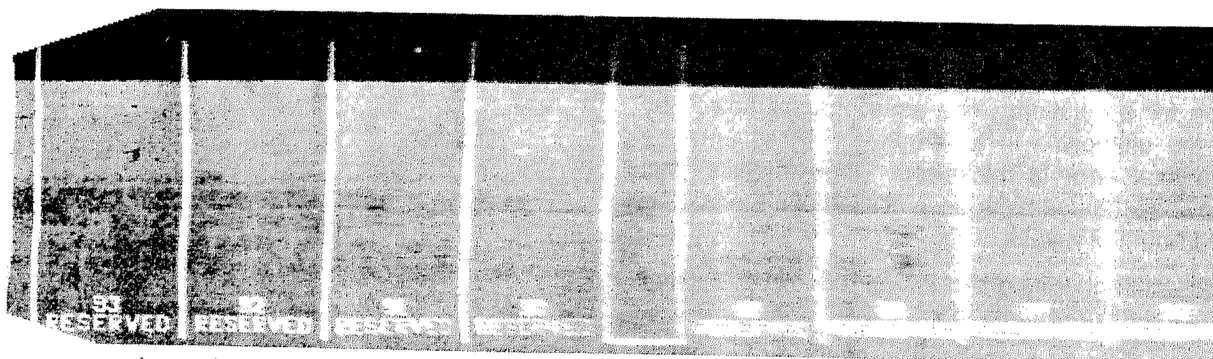

Image 17 - 600 dpi Original - 30 pixel/meter Rectification - Rectified file size 130 kB

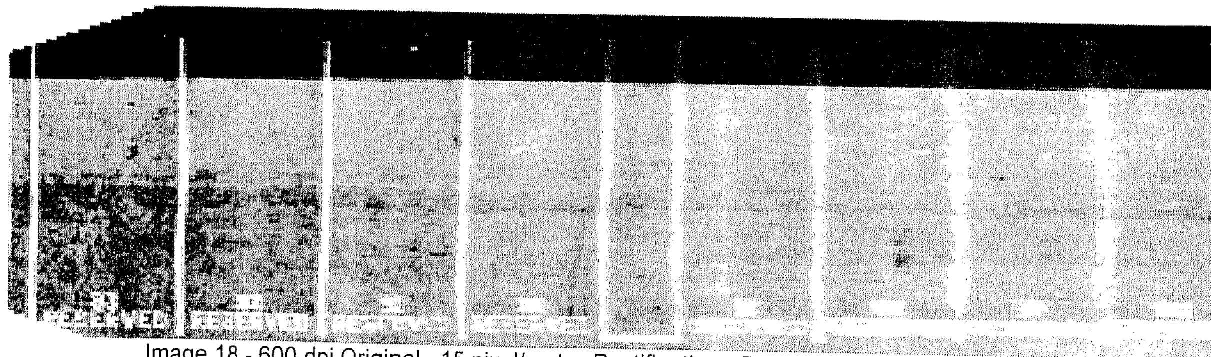

Image 18 - 600 dpi Original - 15 pixel/meter Rectification - Rectified file size 32 kB

Rectified images 19 to 22 were also based on a 4" x 6" photograph print of Image 2a. For these, however, the scanning resolution of the photograph print was varied and the rectification resolution was kept at 30 pixels/meter. This resulted in a file size of 130 kB for each rectified image. The original bitmap file size is given below each image.

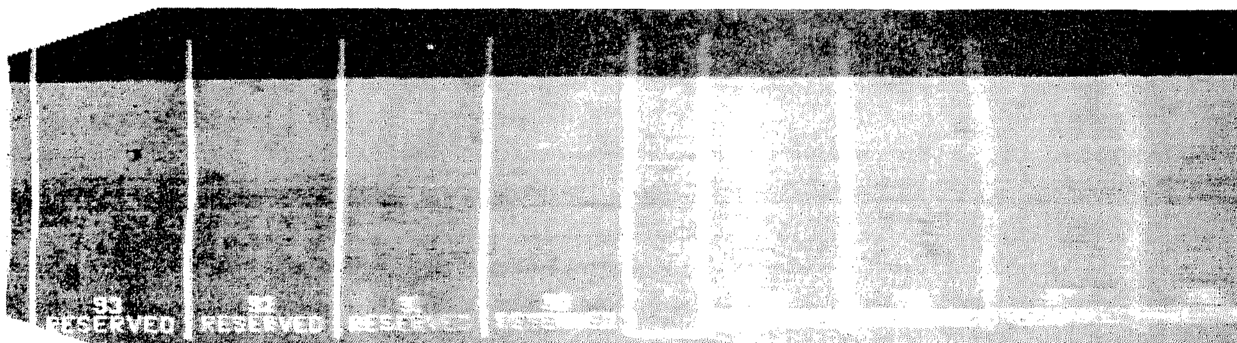

Image 19 - 600 dpi Original - 30 pixel/meter Rectification - Original file size 8336 kB

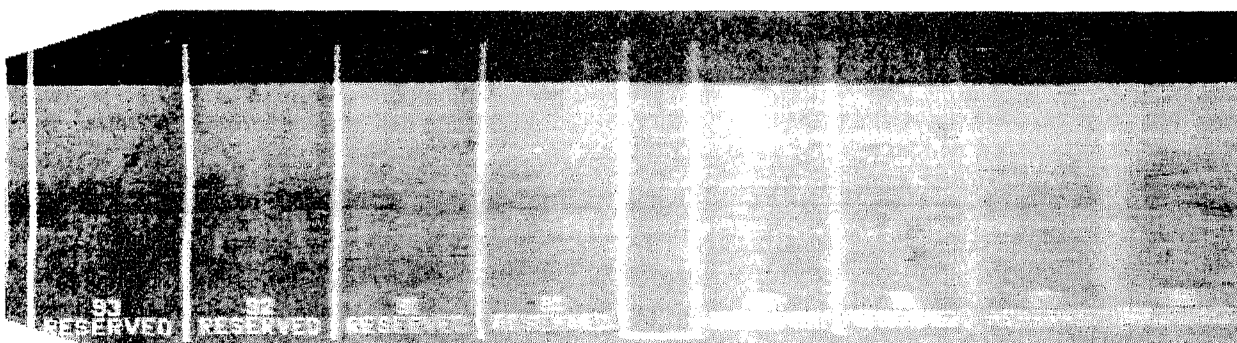

Image 20 - 300 dpi Original - 30 pixel/meter Rectification - Original file size 2088 kB

Image 21 - 150 dpi Original - 30 pixel/meter Rectification - Original file size 523 kB

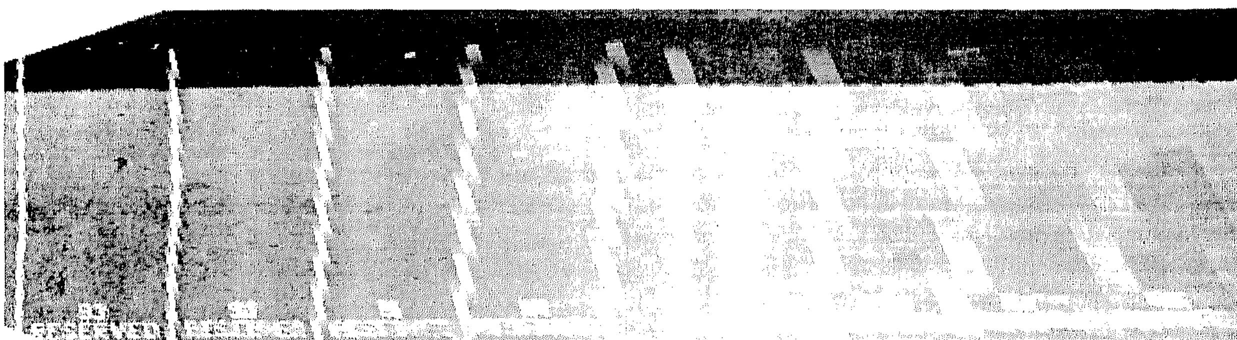

Image 22 - 75 dpi Original - 30 pixel/meter Rectification - Original file size 132 kB

Drag and Steering Effects of Under Inflated and Deflated Tires

Ric Robinette, Darrell Deering, and Richard J. Fay
Fay Engineering Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Under inflated or deflated tires are known to cause increased forward drag and lateral steering effects on vehicles. These effects are commonly suggested to be the cause of driver loss of control and subsequent vehicular accidents. The increased drag and steering effects of under inflated or deflated tires are frequently an issue in an accident reconstruction. This paper documents the results of a series of tests conducted to determine the magnitude and effects of under inflated or deflated tires on cars and light trucks. The test also establishes a method of testing that can be used to determine steering effects for other vehicles and speed conditions. Six vehicles ranging from a compact passenger car to a 3/4 ton pickup truck were tested. The test methodology was simple and produced repeatable test results up to the 45 mph speed defined as a limit for the tests.

The first phase of the tests involved the measurement of forward deceleration rates during a series of coast to stop tests with all of the vehicle tires initially inflated to the rated pressure. This was followed by tests at various under inflation pressures. The deceleration rates versus inflation pressures are documented and discussed. As anticipated all vehicles experienced an increase in the coast to stop deceleration rates at under inflated tire pressure conditions. However, the increase in the deceleration rates were not dramatic in magnitude. When all four tires on the test vehicles were deflated to 10 psi, the coast to stop deceleration rates still represented relatively small deceleration profiles.

The second phase of the tests was performed with a totally deflated tire on either the front or rear axle. The forward deceleration and lateral acceleration rates, and the corresponding dimensional lateral motion profiles were measured during the coast to stop tests with the deflated tires. The forward and lateral acceleration rates and the lateral offset travel distances are documented and discussed. During the test, the test driver was always able to easily maintain control of the test vehicles and steer them in either a straight path or curved path with either a deflated front or rear tire. The driver was always able to easily regain control and steer the test vehicles after initially releasing the steering wheel and allowing the vehicle to initiate lateral motion as a result of the deflated tires. This suggested that a blow-out single tire event can be a controllable condition.

These tests provided consistent results within the test speed ranges up to 45 mph. The results may not be similar at higher speeds and the results should not be randomly extrapolated to higher vehicle speeds without a valid basis. If higher speed affects are desired, the same test methology is considered to be a reasonable approach to gather data.

INTRODUCTION

The effects of under inflated or deflated tires are known to increase rolling resistance and to cause a steering effect wherein the vehicle tends to steer to the side of the vehicle with the deflated tire. This lateral steering effect after a tire blow-out has been alleged to be the cause of many accidents. A review of the literature provided limited objective data defining these lateral steer effects. Limpert (4) summarizes some lateral travel versus time data after a blow-out condition on the steering axle of a semi tractor-trailer combination. A series of tests were planned to produce subjective and objective results quantifying the forward and lateral acceleration rates and lateral motion with under inflated tires and deflated tires on either a front or rear axle. This paper documents the results of the first phases of the proposed test program. The tests were designed to be simple to perform with the minimum of test equipment so that the test could be easily repeated at a future date for any vehicle type that may be associated with a specific accident investigation or reconstruction issue. The tests were designed to permit the accumulation of a data base that can be utilized in conjunction with vehicle dynamic steering response simulator programs such as the Single Vehicle Simulator (SVS), HVOSM (5) or the Engineering Dynamics Corporation's EDSVS (6).

A range of vehicles was selected for the first phase of the testing program to include various sizes and types of passenger cars and light trucks. The vehicles were selected to include

front and rear wheel drive configurations. The test vehicles, tires and selected specification characteristics are listed in Table 1. All the vehicles were standard production vehicles. All of the tires used in the test were standard production tires with tread depths in excess of 6/32 inch.

TEST METHODOLOGY

The test were conducted on a dry asphalt air strip runway at the decommissioned Stapleton Airport in Denver, Colorado. The runway extended approximately 5000 feet in the north and south direction. The runway was 100 feet wide. The runway surface elevation profile was surveyed and was considered relatively level. To minimize any effects of grade and wind, all vehicles were subjected to repeated tests in the north and south directions and the results were arithmetically averaged. All of the test data presented in this paper is the arithmetic average of the repeated tests for each individual vehicle.

STRAIGHT LINE COAST TO STOP TESTS – The initial phase of the testing involved coast to stop tests that was designed to identify vehicle/tire deceleration characteristics at rated pressure and at lower tire pressure values. All of the coast to stop tests were conducted with the vehicles entering the deceleration test zone at a constant speed of 30 mph. Automatic transmission vehicles were driven in "D" drive gear and the four wheel drive vehicles were in two (rear) wheel drive mode. The initial test was conducted with all tires inflated at the rated tire pressure. Subsequent tests were then performed with all tire pressures reduced to 25 psi and 10 psi. The vehicles were driven at a constant 30 mph speed into the deceleration test zone and shifted into neutral and allowed to coast to a stop. The vehicle was then subjected to another similar coast down test while traveling in the opposite direction. It was decided to place all vehicles in neutral during the coast down test to minimize the potential differential effects of vehicle drive train braking and inertia that may be encountered with the different combination of manual and automatic transmission configurations that were being tested. Although there is still some drag on the vehicles from bearings and viscous friction, positioning the vehicles in neutral should minimize the mechanical friction and maximize the relative effects of variable tire inflation pressures. During the coast down tests in neutral, the driver continued to hold the steering wheel and guide the vehicle on a straight path.

During the coast to stop testing, the travel distance and time were recorded and utilized to independently calculate overall average deceleration rates. The deceleration rates from the coast to stop tests in opposite directions were compared for anomalies and individual tests were repeated if an anomaly was observed. The set of deceleration data were arithmetically averaged. Only the average values are presented in the paper and are used for comparison purposes.

DECELERATION AND LATERAL STEER TESTS WITH DEFLATED TIRES – The second phase of the testing involved coast to stop tests and lateral motion tests with totally deflated tires in order to simulate a tire blow-out condition. These tests were designed to define the forward and lateral deceleration rates and lateral travel distances with either a front axle or a rear axle deflated tire. Most tests were conducted with the vehicles entering the deceleration test zone at a constant speed of 30 mph with either a totally deflated front or rear tire. The same transmission and two wheel drive settings as the coast to stop tests were used. The test driver entered the test zone at a constant 30 mph with the required steering input to maintain travel along a straight line parallel to the edge of the asphalt runway. At the beginning of the deceleration test zone, the driver removed his hands from the steering wheel, removed his foot from the accelerator pedal, and simultaneously shifted into neutral (or depressed the clutch then shifted into neutral). The vehicle was thus allowed to coast and to freely respond to the deflated front or rear axle tire. It was decided to perform the test with the driver releasing the steering wheel to simulate a

scenario of an on road blow-out condition followed by no driver response or attempt to control the vehicle. The release of the steering wheel and allowing the vehicle to freely respond should produce the maximum lateral acceleration and lateral motions. Any reasonable attempts to control the vehicle by the driver would result in lesser lateral acceleration and lateral motion. The test driver was always able to drive all vehicles in a straight line and to steer the vehicles in either direction with either a deflated front or rear tire.

During the deflated tire tests the forward and lateral deceleration rates were recorded via a Valentine Research G-Analyst bi-axial accelerometer test instrument. The trajectory path of the vehicle was documented by means of a spray paint can mounted along passenger door area and operated by front seat passenger during the coast down. A less reliable method of defining the trajectory path was the deflated tire mark on the runway surface. This mark was not always clearly visible for all the vehicles. The forward and lateral motions were measured at predefined distances along the paint trail. The paint trail data was also useful in defining the changing radius of curvature of the trajectory path.

The numerical test results were obtained by applying the previously defined data averaging process for multiple tests in opposite directions. The intent for all the vehicle tests was to allow the vehicle to coast to a stop. However, in several tests the vehicle lateral travel exceeded the 100 feet width of the runway before the vehicle came to a stop. In those instances, the driver braked the vehicle to a stop at the opposite edge of the runway.

In order to have meaningful subjective test results, the same vehicle test driver was used for all of the deflated tire tests.

COAST TO STOP TESTS WITH RATED AND UNDER INFLATED TIRE PRESSURES

The results of the rolling resistance deceleration tests with rated and under inflated tire pressures are shown in Table 2 and graphically illustrated in Figure 2. At rated tire pressure conditions, the Mazda RX-7 exhibited the lowest overall deceleration and the Jeep had the highest deceleration rate. The aerodynamic drag resistance of the test vehicles may contribute somewhat to this trend as the Mazda is expected to have the lowest aerodynamic drag and the Jeep probably has the highest drag. In one test the Mazda RX-7 coasted over 3700 feet. At these deceleration levels, a small grade effect in the test surface can have a noticeable effect on the coast to stop distances.

FIGURE 2

DECELERATION RATES VS TIRE PRESSURE

Overall average deceleration rate calculations based upon the coast to stop distances were consistently about 5% higher then the overall average deceleration rates calculated from the elapsed times associated with the coast to stop tests. This slight difference was very repeatable and consistent throughout the tests.

Each individual vehicle exhibited an expected trend of increased deceleration rates with reducing tire inflation pressure. However, as a whole, the test group did not exhibit large increases in the deceleration rates. With the exception of the Mazda RX-7, the rates did not increase more than 200% between rated pressure and 10 psi. The absolute deceleration rates recorded for the Mazda at reduced tire pressures are similar to the other test vehicles. However, the percentage increases for the Mazda are larger because the baseline value at the rated tire pressure was lower.

The Ford F-250 pickup and the Jeep were equipped with tires with a higher load capacity rating relative to the actual tire loads associated with the vehicle weights. These higher load capacity tires probably have a stiffer side wall design then the tires on the test cars. The Ford pickup and Jeep tires exhibited less tire deflection than the car tires at the under inflated conditions. Inspite of this reduced side wall deflection characteristic, lower tire inflation pressures resulted in similar deceleration rates for the cars, the pickup truck and Jeep.

A subjective observation that was supported by the numerical test results was that the reduced tire pressure conditions were not always very perceptible to the driver in terms of vehicle handling. In contrast, the reduced pressure conditions were observable in the tire side wall contour at the lower pressures. Thus, a case could be made that handling and driveability characteristics may not alert a driver to an under inflated tire, and hence vehicle owners should regularly monitor their tire pressures to insure the tires are being maintained at the proper tire pressure.

SINGLE FRONT AND REAR DEFLATED TIRE TEST

Each vehicle was subjected to a series of tests with a deflated rear axle tire, and then the tests were repeated with a deflated front axle tire. Forward and lateral deceleration data was continuously recorded during these tests with a Valentine Research G-Analyst. Other dimensional data related to forward travel, lateral offset motions from the original straight line of travel, and radius of travel were recorded at 50 feet and 100 feet increments from the point of the initiation of the test.

The Jeep responses to the initial deflated tire tests were in conflict with the anticipated trends. At times Old Yeller (as the Jeep has affectionately become known) appeared to have a mind of its own and proceed in a repeatable but unanticipated direction. Subsequent testing determined that an improper steering alignment was resulting in a continuous lateral steer in one direction. Since the deflated tire lateral motion tests were skewed by the improper steering alignment, this test data was declared invalid and is not presented. However, the responses of the Jeep did provide some valuable subjective information that was consistent with other observation on the other vehicles. These will be discussed in a later section of the paper.

The forward deceleration rates with a totally deflated rear axle tire and with a totally deflated front axle tire are presented in Table 3 for travel distances of 50 feet and 100 feet after the initiation of the test. Section C in Table 3 illustrates the absolute and percentage increase of the forward deceleration rates relative to the tests with all tires at rated pressure. Figures 3-A and 3-B present these percentage increases graphically.

The following general observations were made. In general, all the vehicles exhibited the anticipated increase in forward deceleration with a deflated tire relative to the test with all tires at the rated tire pressure. Surprisingly, the Ford pickup did not exhibit any appreciable reduction with a deflated rear

axle tire. A front axle deflated tire did create an increase in the deceleration rate on the Ford. The Mazda RX-7 exhibited much higher percentage increases than the other test vehicles. Since the absolute deceleration values for the Mazda are similar to the other vehicles at the reduced tire pressure conditions, the differential percentage increase is once again a result of the relatively low Mazda deceleration rate with rated tire pressure. Another observation was that the vehicles that exhibited the smaller deceleration increases with a deflated rear tire also exhibited the smaller deceleration increases with a deflated front tire.

The lateral travel distances and lateral acceleration rates with deflated front and rear tires are shown in Tables 4 and 5. The lateral offset measurements relative to the initial straight line path are shown in Table 4 for forward travel distances of 50, 100, and 200 feet after the driver released the steering wheel and the vehicle was allowed to freely respond to the lateral accelerations associated with the deflated tires. These lateral travel distances would represent the maximum anticipated lateral travel distances a vehicle would experience with an on road blow-out if the driver provided no steering input or control at 30 mph. If the driver responded with any corrective steering input, the lateral travel would be reduced or potentially eliminated. For all tests performed, the test driver was always able to provide sufficient corrective steer to maintain the vehicle in a straight path or to steer the vehicle in either a right or left direction. These corrective steering maneuvers were accomplished with minor steering effort on the part of the test driver.

The data in Tables 3, 4 and 5 defining the deflated tire and lateral motion tests are presented in terms of forward travel distances, the data could have been developed in terms of time after start of the event. The following approximate times are provided for information purposes. The test vehicles

passed the 50 feet station between 1.1 and 1.2 seconds after the start of the test, and passed the 100 feet station between 2.25 and 2.45 seconds.

The primary observed trend of the data on Table 4 was that the magnitude of lateral travel was much greater with a front deflated tire then with a rear deflated tire. This was expected. The lateral offset of the Mazda with a deflated rear tire was much greater than any of the other vehicles. This trend with the Mazda was repeatable with addition tests runs, however, the reason for this trend was not identified.

Other general trends and observations were that vehicles with front steer/drive axles had less lateral offset motion then vehicles without a front drive axle during the deflated rear tire tests. This trend was not observed during deflated front tire tests. Another general trend was that shorter wheelbase vehicles had less lateral offset then longer wheelbase vehicles during both front and rear deflated tire tests. The large lateral offset distances recorded with the Mazda was the obvious exception to this trend. This trend was not expected because it was anticipated that the longer wheelbase vehicles with higher moments of inertia would not be as susceptible to higher lateral accelerations and travel distances.

The lateral acceleration rates with deflated tires are presented in Table 5. Figure 5-A and 5-B graphically present the lateral acceleration data at the time that the vehicles are 100 feet beyond the start of the tests. Table 5 also includes the results of attempts to calculate a lateral acceleration rate based upon the measured lateral offset dimensions shown in Table 4. The calculated results were developed by applying the lateral offset equations while traveling on an assumed constant radius. The assumption of a constant radius was not expected, and the results demonstrated that the vehicles did not follow a constant radius. However, the assumption of a constant radius for short portions of the first portion of the travel path provided reasonable agreement between the calculated and measured lateral acceleration values.

Basic motion equations of centrifugal acceleration were used to calculate the lateral acceleration from the offset distance data. Several sources provide a derivation of this type of analysis. One such derivation is included in Daily (7). He offers the following relationship for a lateral offset:

$$D = 0.366\ S\ \sqrt{(M/F)}$$

Where D = forward travel distance along the initial direction of travel, feet

S = speed, mph

M = lateral offset distance from initial direction of travel, feet

F = lateral acceleration rate, g's

As expected, the trends in Table 5 follow the data trends in Table 4. The lateral acceleration rates follow the pattern of the lateral offset travel distances. There were higher lateral acceleration rates with a deflated front tire compared to a rear tire.

Figures 5-A and 5-B illustrate the relationship between the calculated lateral accelerations based upon the lateral offset dimensions and the lateral acceleration rates measured with the G-Analyst. The trend of the calculated values followed the trend of the measured values, but the calculated values were consistently higher than the measured values.

The localized radius of curvature of the lateral travel path were analyzed at 100 feet travel distances for the front and rear deflated tire tests. The radius of curvature was clearly changing throughout the trajectory path. However, the trend of the change was somewhat unexpected. With a deflated rear tire, all of the vehicles experienced a continuously increasing radius after the first 50 to 100 feet of travel. With a deflated front tire, the majority of the vehicle tests exhibited a continuously decreasing radius, with the other vehicle tests having an increasing radius for the first 100-200 feet of travel, followed by the decreasing radius pattern.

PHOTOGRAPHIC ILLUSTRATIONS

Photographs 1 through 7 illustrate the deflated tire mark and paint trail for one of the deflated left rear tire tests with the Mazda RX-7. The deflated tire mark and the paint trail are highlighted with arrows.

GENERAL OBSERVATIONS

A few general observations are offered from the combined test results. The Mazda

RX-7 exhibited the lowest rolling resistance drag during the rated tire pressure coast to stop tests. The Jeep exhibited the highest rolling resistance during the same test. During the deflated tire tests, the Mazda RX-7 generally exhibited much higher lateral travel distances and acceleration rates than the other vehicles. Frequently, the Mazda lateral motion responses conflicted with the observed trends in the other vehicles. One proposed explanation is that there was a greater differential drag between the relatively low rolling resistance of the Mazda inflated tires versus the deflated tire. This greater differential apparently resulted in more lateral acceleration and displacement. In contrast, the Jeep exhibited much lower lateral responses to a deflated tire than any other vehicle. The higher rolling resistance of the inflated tires resulted in a smaller differential drag between the inflated tires and the deflated tire. This would correspond to the much lower lateral accelerations and displacement that was observed during the tests with the Jeep.

The detailed test data presented in this paper are all based upon a common initial speed of 30 mph. The Nissan Altima and the Oldsmobile Ciera were subjected to limited testing at 45 mph with deflated tires. The following subjective observations are made relative to these limited test. During all of the vehicle tests, the driver felt the harshest vibrations in the steering wheel at very low speeds. As the speeds were increased, the vibration levels tended to drop to a reduced level and then remain fairly constant as speeds increased. The driver perceived steering input torque and steer wheel rotation to maintain straight travel at speeds of 10, 30 and 45 mph were similar. This was supported by the G-Analyst data that illustrated a fairly constant lateral and forward deceleration rate for each individual vehicle during the coast to stop tests with a deflated tire. When the Nissan Altima was subjected to a deflated rear tire test at 45 mph, the magnitude of the lateral travel profile was not notably different than the characteristics at 30 mph.

There were some driver perceived differences in the required steering wheel input torque to maintain a vehicle on a straight path for deflated front versus rear tire conditions, particularly on the Ford pickup and the Oldsmobile. The Oldsmobile exhibited much greater vehicle and steering wheel vibration with either a deflated front or rear deflated tire than any other vehicle. It was unclear if this was a function of the tire construction or of the vehicle. Regardless of the cause, the driver had no difficulty maintaining the Oldsmobile on a straight path or achieving controlled lateral steering in either direction with a deflated tire.

The documented lateral acceleration rates during the deflated tire tests were all below 0.15 g's when the vehicles were allowed to respond freely without any restraint at the steering wheel. These lateral acceleration levels were all within easily attainable lateral steer capabilities of roadway vehicles and could be readily controlled by a fairly minor response from the test driver.

The tests results provided consistent results within the test speed ranges up to 45 mph. The results may not be similar at higher speeds and the results should not randomly extrapolated to higher vehicle speeds without a valid basis. If higher speed affects are desired, the same test methology is considered to be a reasonable approach to gather data.

ACKNOWLEDGMENTS

The authors wish to express our gratitude to Mr. Philip Hight and Mr. Donald Rudney for their review and input to the paper and to Mr. Mark Robinette, Mr. Kevin Robinette, and Mr. Bruce Birza who assisted with the testing activities. Special appreciation is extended to Mr. Mark Robinette and Mr. Kevin Robinette for contributing to the production of this paper.

SAE #970954
Reviewer's Discussion
by Philip V. Hight, P.E., Accident Research Santa Barbara
Drag and Steering Effects of Under Inflated and Deflated Tires
Richard J. Fay, Ric D. Robinette, Darrell Derring, Authors

This paper reports the results of automobile deceleration tests and lateral displacement experienced by vehicles with low tire pressure and also deflated tires. It describes clearly the methodology that was used. The findings generally were that the vehicles with deflated tires behaved in a mundane manner when it came to vehicles handling and control.

In the real world punctures occur more frequently to the rear tires than the front tires. Currently travel speeds may be well in excess of 88 km/h (55 mph) when tire deflation occurs. Although the authors have stated the tests speeds in their paper it is important for the researchers not to blindly extrapolate the findings to high speeds. Research has shown that when deflation occurs on curves it also increases the probability of vehicle handling difficulties for the driver. Even on a straight road with a minor uphill upgrade, a van driver, with cruise control engaged, can get into oversteering troubles when a rear tire explodes. At higher speeds the vehicles may still maintain static stability characteristics but with increased speed there is a change to the steady state path curvature stiffness. With increased speed the tire slip angle, force and moment assumptions may not remain linear. Other changes that occur at speed is that the circumference of the tires become slightly enlarged, more circular at the road contact location with less foot print length and change of contact patch geometry. When a rear puncture occurs the cornering stiffness at the rear of the vehicle is much reduced. Controlling an over steering vehicle at high speed is much more difficult than at lower speed.

When the front tire punctures then the trim changes due to aligning torque effects. The vehicle becomes more under steering but becomes poor for avoidance. Just because the vehicle is dynamically stable it does not mean that after the puncture its heading is correct. It would certainly be most helpful to have a follow up paper at much higher speeds and using a fifth wheel to obtain deceleration data. One would then not have to rely on the vehicle rolling at low deceleration values to a complete stop.

Drag and Steering Effects of Under Inflated and Deflated Tires
Richard J. Fay, Ric D. Robinette, Darrell Derring, Authors

Although this paper provides some useful data for use in accident reconstruction analysis, it best serves as a guide to establishing a test methodology. The variability encountered in the results suggests that if critical conclusions are relying on such data, independent testing should be conducted. The authors have provided good basic test procedures and baseline data for others to conduct their own individual tests with some confidence.

In the future it might be interesting to include testing of locked wheels totally deflated and with variable inflation pressure.

Project Y.A.M. (Yaw Analysis Methodology) Vehicle Testing and Findings - Victoria Police, Accident Investigation Section

Peter Bellion
Victoria Police

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A vehicle oversteered or cornering at excessive speed results in the tyres of the vehicle loosing traction with the road surface. As a result tyre yaw marks may be left on the road surface. Yaw marks are common at fatal collision sites.

Various methods are reported to estimate the speed of the vehicle that leaves yaw marks on a road surface. The difference in each method is how to determine the radius and whether the peak or average friction is used.

Tests were conducted with four different vehicles. Variations in tyre pressures, and driver inputs of acceleration, braking and steering over-correction were investigated. Yawing followed by emergency braking with and without ABS was further studied.

The radar speed of the vehicle for each test was compared with speed estimates from the yaw marks.

INTRODUCTION

Sliding of a tyre on a motor car on a road surface occurs not only when skidding during an emergency braking situation but also sometimes when steering. When a tyre on a car slides on the road in a steering situation the tyre mark that is left on the road surface is known as a tyre scuff mark, yaw mark or critical speed scuff mark. The tyre yaw marks are curved and will normally have striations angled across their width. Following Newton's Laws, a motor car once set in motion, tends to keep going in a straight line. When a driver turns the front wheels of the car at an angle, they would have to slide sideways if the car was to go straight ahead. Friction acting between the tyres and the road prevents such sliding and moves the front of the car in the direction it is steered, causing the car to follow a curved path. The faster the car travels, the more frictional force is needed to redirect the car into a curved path. If the speed of the vehicle is high enough, the force tending to keep the car going straight ahead (inertia) exceeds the friction acting between the tyres of the car and the road surface and as a result the tyre begins to slide sideways whilst still rotating. If the radius of the curved path of the car is known when the car started to slide out to the side and the friction (traction) force resisting slippage is also known it is possible to estimate the speed of the vehicle at which it commenced to sideslip. From the principles of circular motion the metric equation derived to calculate the speed at which side sliding occurs is shown in equation 1.

$$S = Sqrt[127R(f+e)] \dots (1)$$

where:

- S = Speed in kilometres per hour
- R = Radius of curved path of car in metres
- f = coefficient of friction
- e = grade or crossfall of road in direction of slippage of tyre in metre/metre.

*Note (e) is positive if grade/crossfall assists the car in passing around the curve and negative if it acts against the car.

In Accident Reconstruction the equation used to calculate radius from a chord (straight line intersecting two points on a curve) and middle ordinate (line which passes out at a right angle from centre of chord to the curve) is as follows in equation 2.

$$R = C^2/8m + m/2 \dots (2)$$

where:

- R = radius in metres
- C = chord measurement in metres
- m = middle ordinate measurement in metres

ASPECTS LOOKED AT DURING TESTING

Various measurement methods are reported in previous literature, [3,4,6,13,14,20], in respect to speed determination from yaw marks. To analyse various measurement methods to determine radius using equation (2) and whether the peak or average friction value should be used in conjunction with the determined radius to calculate speed, using equation (1), the Victoria Police, Accident Investigation Section conducted tests at Avalon Airport, Avalon, Victoria on the 13th, 14th, 15th and 28th of February, 1996. The tests incorporated 4 different test vehicles which were all examined by qualified police mechanical investigators attached to the Accident Investigation Section and found to be roadworthy prior to testing. The vehicles used were:-

- 1995 VR Holden Commodore sedan, 3.8 litre, 6 cylinder, automatic transmission, fitted with Goodyear Eagle GA tyres.
- 1995 ED Ford Falcon sedan, 4.0 litre, 6 cylinder, automatic transmission, fitted with Goodyear Eagle GA tyres.
- 1994 TR Mitsubishi Magna Executive sedan, V6 engine, automatic transmission, fitted with Goodyear Eagle GA tyres.
- 1995 Toyota Corolla Seca hatchback sedan, 4 cylinder, automatic transmission, fitted with Bridgestone RD-339 tyres.

Along with the various vehicles tested, tyre pressures were also varied from 26psi to 34 psi to see what effects this would have. Various inputs of acceleration, braking and steering over-correction were also looked at during testing. The effects of yawing and braking with and without anti-lock braking systems were also looked at during testing.

TEST NUMBERING, VEHICLE, MANOEUVRE, TYRE PRESSURE

Table (1) shows how the tests were numbered in respect to vehicle type, vehicle manoeuvre which led to the production of yaw marks on the road surface and the pressure in the tyres for that vehicle during the test. The test number is recorded in Column 1 of the result spreadsheets in Appendix 1.

Table 1 Test Numbering

Test No	Vehicle	Manoeuvre	Tyre Pressure
1-22	Commodore	straight->oversteer	28psi
23-36	Falcon	straight->oversteer	28psi
39-52	Magna	straight->oversteer	28psi
70-83	Corolla	straight->oversteer	28psi
53-57	Commodore	straight->oversteer, constant acceleration.	34psi
58-61	Commodore	straight->oversteer->50% brakes	34psi
62	Commodore	straight->oversteer->locked brakes	34psi
63-64	Commodore	straight->oversteer->accelerate	34psi
65-69	Commodore	straight->oversteer left then right	34psi
84-85	Falcon	straight->oversteer left then right	28psi
86-91	Falcon	straight->oversteer right	26psi
92-94	Falcon	straight->oversteer left then right	28psi
93ii-94ii	Commodore	corner at excessive speed	28psi
95	Commodore	corner at excessive speed, constant steer	28psi
96-98	Commodore	corner at excessive speed, accelerating	28psi
99	Falcon	corner at excessive speed, const. acc.	28psi
100-101	Falcon	corner at excessive speed, accelerating	28psi
102-103	Falcon	corner at excessive speed, const. acc.	28psi
104	Falcon	corner at excessive speed, accelerating	28psi
105	Falcon	corner ex. speed, braking with ABS	28psi
106	Falcon	corner ex. speed, brake to lock up.	28psi
107-110	Commodore	straight->oversteer, split friction surface	28psi

SPEED OF TEST VEHICLE COMING INTO STEERING MANOEUVRE

A Falcon hand held radar, speed measuring device was used to measure the speed of each test vehicle coming into the manoeuvre which led to the production of yaw marks. The radar was held at approximately 90 degrees to the front of the vehicle coming into the steering manoeuvre to minimise radar error. For most of the tests the speedometer reading of the vehicle was recorded for comparison with the radar reading. Columns 2,3 of test result spread sheets contained in Appendix 1 shows the radar speed and speedometer speed respectively. Tests were conducted from speeds of 40 kilometres per hour, incrementing by 10 kilometres per hour up to 100 kilometres per hour. Some of the cornering tests were conducted at speeds over 100 kilometres per hour.

CHORD & MIDDLE ORDINATE MEASUREMENTS AT TEST SITE

After each test 15, 20 and 30 metre chords were used to determine the radius of the front and rear, outside tyre yaw marks. Middle ordinate measurements taken from the mid point on each chord to the outer edge of both the front and rear outside tyres were then taken and recorded. Radius of curvature of the yaw marks were then calculated for each chord and middle ordinate measurement using Equation (2). " Tajima", 100 metre, "Symron" and "Engineer Super", yellow fibreglass tape and nylon-coated steel tapes, accurate between -40 degrees Celsius to 60 degrees Celsius were used for chord measuring, 3 police members ensuring tape is straight. Steel pocket tape measures were used for middle ordinate measurements. Photographs (1) and (2) show examples of the measuring sequence described above.

Photo 2, Middle Ordinate Measuring

DETERMINATION OF FRICTION INCLUDING GRADE/CROSSFALL DURING TESTING

A VS model Holden Commodore sedan was utilised for skid testing in direction of slippage of test vehicle tyres on each day of the testing. This vehicle was fitted with "Goodyear Eagle GA Tyres". Although this vehicle was different to the test vehicles, previous research and testing [28], indicated that the difference in drag factor would lead to negligible differences in speed results under dry conditions. Dry road surface conditions were encountered for the first 3 days of testing, however on the last day of testing slightly wet conditions were encountered, which led to lower drag factors. Skid tests were conducted on two or more occasions on each day of the testing. A VC2000PC, Portable Road Test, Dynamometer and Braking Test Computer giving output of time, speed, distance and peak/average friction at 1/100 second intervals was set up inside the skid test vehicle to record measurements for the skid tests. A "drag sled" device was also used, on occasions, to record drag factor measurements in order to compare results obtained with the VC2000PC.

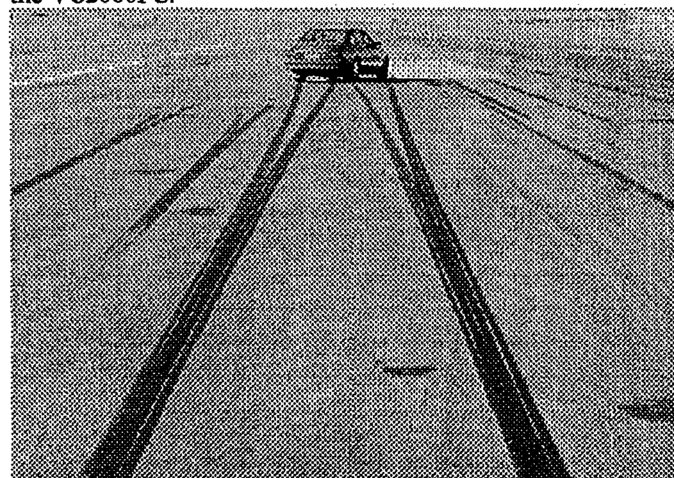

Photo 3, VS Commodore and Skid Marks.

The surfaces encountered during the testing were predominantly of an open graded, asphaltic concrete type, which had a smooth macro-texture and a rough micro-texture. This type of surface was consistent with a number of asphaltic concrete type surfaces found in the Melbourne, Metropolitan Area of Victoria, Australia.

The split friction tests were conducted on grass and a sealed taxiway surface. This sealed surface had a layer of liquid bitumen sprayed over its top which gave lower drag factors. The other type of sealed surface encountered was a Portland cement type concrete surface, which also had a smooth macro-texture with a rough micro-texture.

Photo 4, The VC2000.

Table 2, Drag Factors used in Speed Calculations

Day	Location	VC2000 Peak Factor	VC2000 Average Factor	c.f. Drag Sled
1	main runway north/south	0.95	0.78	0.78av.
1	taxiway split friction	0.67/0.61	0.46/0.45	
2	main runway north	0.93	0.77	0.84-0.93
2	main runway south	0.92	0.76	0.84-0.93
3	main runway north	0.93	0.78	
4	concrete taxiway (damp)	0.90	0.75	
4	cornering onto main runway	0.90	0.72	

RESULTS OF SPEED CALCULATIONS DETERMINED FROM CHORD AND MIDDLE ORDINATE MEASUREMENTS AT TEST SITE

The results of the speed calculations, determined from radius derived from chord and middle ordinate measurements, and the peak and average drag factors from the test site for each day are listed, in rows, starting with the test number on the spreadsheets in Appendix 1.

The second last column of data in the spreadsheets, Appendix 1, gives maximum percentage variation of calculated speed using peak drag factor from the radar speed. The maximum percentage variation relates to the chord measurement and tyre which gave the most deviation from the radar speed.

The last column shows for all chord lengths whether taken off the front or rear outside tyre, using the average drag factor, whether the calculated speed was less, equal or greater than the radar speed of the vehicle coming into the manoeuvre.

Line graphs of results have been prepared for the majority of the tests. Where prepared these are shown subsequent to the spreadsheet results also in Appendix 1.

PERCENTAGE ERRORS FROM SPEED RESULTS

The following tables show a summary of:-

- Sample number in each test group, for the given chord length used to determine radius,
- The percentage range for each test group, ie. the lowest to the highest percentage error from the radar speed for the speeds calculated from the given chord length measurements, eg. 15, 20 or 30 metre chord, off the front or rear tyre, and with either peak or average friction.
- The percentage of tests in the test group which gave a calculated speed, greater than radar speed, less than radar speed and equal to radar speed.

COMMENTS ON CHORD & MIDDLE ORDINATE SPEED RESULTS

Front Tyre, 15 metre chord, peak friction

More often than not the calculated speed was greater than the radar speed, especially for the flick steering tests, where the vehicle was being oversteered from one direction to the other. There was no test group using this method which always gave conservative results. The maximum range for all tests with this method was -15% to +38%.

Front Tyre, 15 metre chord, average friction

More often than not the calculated speed was less than the radar speed, however problems were encountered once again in respect to both the Commodore and Falcon

flick steer tests. In five (5) out of the (13) test groups where this method was able to be applied, 100% of the time the calculated speed was less than the radar speed. These were:

- Falcon, 26 psi, constant throttle
- Commodore, 34 psi, constant throttle
- Commodore, 34 psi, braking
- Commodore, 34 psi, accelerating
- Falcon, all cornering tests.

Maximum range for this method was -29% (Commodore, split friction) to +26.5% (Commodore, flick steering).

Front tyre, 20 metre chord, peak friction

More often than not the calculated speed was greater than the radar speed, exceptions were:

- Commodore, 34 psi, constant throttle
- Seca, 28 psi, constant throttle
- Falcon, 26 psi, constant throttle
- Commodore, split friction tests.

In one (1) split friction group, out of the (14) test groups, 100% of time, calculated speed was less than radar speed. The maximum range encountered for this method was -10.3% (Falcon cornering) to +19.8% (Commodore cornering).

Front tyre, 20 metre chord, average friction

More often than not the calculated speed was less than the radar speed. In ten (10) out of the (16) test groups this occurred 100% of the time. General exceptions to the rule were the Falcon cornering at speed whilst under acceleration and all flick steer tests, most likely due to the fact that the front tyre starts to follow a straighter path earlier than the rear tyre in these circumstances.

The maximum range encountered for this method was -26% (Commodore, split friction) to +9.2% (Falcon, 28 psi, constant throttle, oversteer).

Front tyre, 30 metre chord, peak friction

The 30 metre chord was restricted in it use as the yaw marks left from speeds of 60 to 70 kilometres per hour and below did not enable a 30 metre chord to be used because of the overall length of the yaw marks, however when used for speeds of approximately 60 kilometres per hour up to approximately 100 kilometres per hour the method gave good results. Five (5) out of the (16) test groups had calculated speeds less than the radar speed 100% of the time. Problems tests found with this method were:

- Commodore flicks
- Falcon flicks
- Commodore cornering at speed
- Falcon cornering at speed & accelerating.

Maximum ranges encountered for this method were -11.3% (Falcon cornering & braking) to +11% (Commodore flicks).

Front tyre, 30 metre chord, average friction

Most of the time, fifteen (15) out of sixteen (16) test groups, this method gave a calculated speed less than the radar speed, 100% of the time. The exception was the Commodore flick tests, however 80% of the time for these tests the calculated speed was less than the radar speed.

Maximum ranges encountered for these tests were -26% (Commodore split friction) to +1.1% (Commodore flicks).

Rear tyre, 15 metre chord, peak friction

More often than not the calculated speed was greater than the radar speed, except for Falcon, 26 psi tests and Commodore split friction tests.

Maximum range encountered for this method was -20.6% (Seca last test) to +18.5% (Commodore cornering).

Rear tyre, 15 metre chord, average friction

More often than not the calculated speed was less than the radar speed. In nine (9) out of the (13) test groups this was the case 100% of the time. Far better results were obtained in respect to the flick tests on the rear tyre than for the front tyre with a 15 metre chord and peak friction. Main exception group was the Commodore cornering at speed tests where 33% of the time the calculated speed was greater than the radar speed. For speeds less than 70 kilometres per hour this method generally always gave conservative speed results.

Maximum range encountered for this method was -29.9% (Seca last test) to +6.2% (Commodore cornering)

Rear tyre, 20 metre chord, peak friction

This method gave a fairly average spread of calculated speed results above and below the radar speed. Main problem tests were:

- Commodore flicks
- Falcon flicks
- Commodore cornering at speed
- Falcon cornering at speed, constant throttle
- Falcon cornering at speed & accelerating.

Maximum range encountered for this method was -20.6% (Seca last test) to +23.5% (Commodore cornering @ 80 km/h).

Rear tyre, 20 metre chord, average friction

In fourteen (14) out of the (16) test groups where this method was able to be used, the calculated speed, 100% of the time, was less than the radar speed. The problem groups were:

- Commodore cornering at speed
- Falcon cornering under acceleration.

Maximum range encountered for this method was -30.6% (Commodore split friction) to +9.9% (Commodore cornering @ 80 km/h).

Rear tyre, 30 metre chord, peak friction

Once again this method restricted in its use for reasons already mentioned above. More often than not the calculated speed was greater than the radar speed, main problem groups were the Falcon, flicks and cornering under acceleration.

Maximum range was -13.6% to +13.6% (Commodore cornering at speed).

Rear tyre, 30 metre chord, average friction

Where used, 99% of the time the calculated speed was less than the radar speed. For the 1% overestimate, calculated speed did not exceed radar speed by more than 1.2%.

Maximum range was -27% (Commodore split friction) to +1.2% (Commodore cornering @ 80 km/h).

RECOMMENDATIONS FOR CHORD & MIDDLE ORDINATE MEASUREMENTS, FRICTION.

After analysing the test data the following is recommended in order to obtain conservative speed results, ie., to establish beyond reasonable doubt, that the speed of the vehicle calculated from the yaw marks is a minimum.

1. Generally 15 metre chords on the outside, rear, tyre mark, should be used where the subject vehicles speed is believed to be 70 kilometres per hour or less. The chord should begin at the start of the visible tyre yaw mark from the outside rear tyre.
2. Generally 30 metre chords should be used on the outside, rear, tyre mark, where the subject vehicles speed is believed to be greater than 70 kilometres per hour.
3. The average coefficient of friction taken in the direction of slippage of the tyres should be used. If this cannot be measured in the direction of slippage of the tyres from the subject vehicle, this value will have to be corrected for grade and or crossfall of the carriageway.
4. Average coefficient of friction should be determined by way of a skid test or tests at the collision site on the same surface as, and adjacent to the subject vehicles tyre yaw marks. A VC2000 braking test computer is an acceptable device for determining average friction. If skid tests are unable to be performed at the collision site an alternative friction measuring device should be used to establish friction. This could be either a drag sled or drag tyre device, however one should use their experience in examining and testing road surfaces to ensure that the friction readings obtained from the sled or tyre device are comparable with what one would expect the average friction to be for the surface under inspection.
5. A vehicle fitted with an Anti-lock Braking System (ABS) that leaves yaw marks on a road surface can have its speed estimated using equation (1). This is expected to provide a calculated speed which is less than the actual speed of the vehicle.
6. Close examination, photography and sketching of striation marks angled across a yaw mark should be done. The striation pattern will show what input there has been from the vehicle driver in terms of acceleration or braking. Acceleration striations are generally closely spaced and angle out rearwards (opposite to direction of travel of vehicle), whereas, braking striations are more spread out and angle forwards.
7. Examination of the striation pattern within the tyre marks will indicate where a yaw mark changes from a yaw mark into a skid mark. The striation pattern will go from angling across the mark to running parallel with the mark. If this occurs it is also likely that the centre of mass path of the vehicle will change from a curved path to a straight path. Accident Investigators and Reconstructionists should be fully aware of this as this means that the chord length will be restricted by the yaw section of the marks and not go into the skidding section of the marks.
8. Where a vehicle goes into a yawing condition, leaving tyre scuff marks which originated from the vehicle having travelled over split frictional surfaces, eg. left side grass or gravel, right side sealed surface, a resultant drag factor calculated using 2/3 of left side friction plus 1/3 right side friction input into equation (1) should give a conservative estimate.
9. Where a vehicle is oversteered from one direction to another, chord measurements should not be taken on the outside front tyre mark for the initial oversteer, yaw marks, as this will more often than not result in an overestimate of the vehicles speed.

SURVEY OF SCUFF MARKS TO PREPARE VEHICLE CENTRE OF MASS PLOTS

In addition, to chord and middle ordinate measurements taken at the test site, on the tyre yaw marks

produced from the test vehicles, some of the test yaw marks were surveyed using Geodimeter 400 and 600 model, Total Survey Stations, accurate to +/- 5mm. The reason for this was that the majority of collision sites which the Accident Investigation Section attend are surveyed using the Geodimeter. On completion of each survey the measurements are downloaded onto a computer loaded with 'Geocomp,' engineering/surveying/drafting software. Utilising this software package it is possible to determine radius or lineal measurements of surveyed marks at the original scale as which they were measured on the road, ie. 1:1 scale. This is performed using commands within the software package.

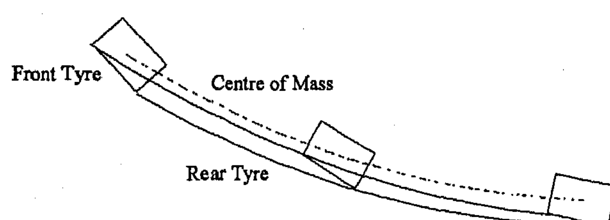

Diagram 1, An Example of Centre of Mass Plot, Falcon, Test No. 31.

RESULTS OF CENTRE OF MASS PLOTS

Wheelbase, track and centre of mass position diagrams of vehicles tested were plotted onto yaw marks surveyed, using the computer and 'Geocomp'. The centre of mass path plotted went from the commencement of the yaw marks where both the outside front and outside rear tyres coincided with the marks. Generally the centre of mass path did not exceed 30 metres in length. Utilising software commands the radius of the path followed by the centre of mass of the vehicle which left the marks was determined with the computer software tools. After the radius was determined, speeds were then calculated with both the peak and average friction using equation (1). Comparison of calculated speeds with peak/average friction was then made to radar speed. The results of this data analysis is contained in spreadsheet format in Appendix 2. Bar graphs have been prepared for illustration purposes, these are also contained in Appendix 2. Table 15 shows tests that were analysed with centre of mass plots.

Table 15, Tests Analysed by Centre of Mass

Vehicle	Manoeuvre	Tyre Pressure	Test Numbers
Commodore	straight then oversteer	28 psi	5,7,9,11,15,21
Falcon	straight then oversteer	28 psi	29,31,33,35
Magna	straight then oversteer	28 psi	48,49,51
Commodore	cornering at speed	28 psi	93,96,97,98
Falcon	cornering at speed	28 psi	99,101,102,103,104

COMMENTS ON CENTRE OF MASS RESULTS

Generally using this method gave more conservative speed results than for methods determined from chord and middle ordinate measurements taken off the front or rear outside tyre marks at the test site. This in fact should be the case as the centre of mass path should and did have a lower radius than that determined from the front or rear outside tyre mark.

Using the peak friction value the percentage error range for all 22 tests analysed using the centre of mass method was from -11% to +10%. 59% of the time the calculated speed was less than the radar speed, 14% of the time it was equal to the radar speed and 27% of the time it was greater than the radar speed.

Using the average friction value the percentage error range was from -20% to -1%, meaning 100% of the 22 tests analysed with this method had a calculated speed less than the radar speed.

Overall, although this method was not able to be applied to every test, it seems that conservative results would always be obtained if the average friction value is used.

If the peak friction value were used, in collisions cases, the actual speed of the vehicle would be expected to be within +/- 10% of the calculated speed.

SPEED COMPARED WITH RADIUS

The following is provided as a general rule or check for the accident investigator where a passenger car has left a set of yaw marks on a dry, asphaltic concrete or concrete surface.

Table 16, Speed km/h compared to Radius

Speed km/h	Approximate radius: yaw mark or centre of mass
60 km/h	25 metres
70 km/h	40 metres
80 km/h	50 to 60 metres
90 km/h	70 to 80 metres
100 km/h	80 to 90 metres
110 km/h	95 to 105 metres

MAXIMUM LATERAL ACCELERATION FACTOR

Maximum lateral acceleration factor was measured for the majority of the vehicle tests by VC2000PC which was mounted vertically on the centre interior of the vehicle windscreen. At the completion of each test the VC2000 was read and the maximum lateral acceleration factor was recorded. The average, maximum lateral acceleration factor was found to be slightly in excess of 1.0g.

CONCLUSION

In summary the testing carried out provided an extensive amount of experience for members of the Victoria Police, Accident Investigation Section. Estimating speed of passenger cars from yaw marks is a very useful tool for the Accident Investigator and Reconstructionist. Providing certain rules are followed the investigator can be reasonably confident that the estimate he is providing of the speed of a vehicle which has left a set of yaw marks at a collision site is a minimum. More often than not it is required for police to provide a minimum speed to the Court, especially in a criminal case where the standard of proof is beyond reasonable doubt.

ACKNOWLEDGEMENTS

All test work was carried out with the assistance of members of the Victoria Police, Accident Investigation Section all of which were dedicated to the task. The assistance of Inspector Neil O'Sullivan and Senior Sergeant Noel OSBORNE is appreciated in respect to organisation of the testing, coordinating legal indemnities and arranging for the troops to be fed during the four days. It is also correct to acknowledge former Acting Sergeant of Police, William KERAMIDAS who together with myself were the technical coordinators of the tests. Credit is further due to Mr. Rohan HARMAN of 'Drive Safe Australia' who was our driver for all tests. I would also like to thank, Acting Sergeant Cathy SMITH, of the Victoria Police, Policy and Education Section for her assistance in preparing the spread sheets contained in the appendices of this paper. I would also like to thank our sponsors, 'South Pacific Tyres' who provided money to pay for test location and facilities, and for providing 'Dunlop Monza 200 tyres' for ongoing testing as well as the Victoria Police, Transport Branch for arranging the test vehicles.

SAE #970955
Reviewer's Discussion
by Lynn B. Fricke, Fricke Cooper Engineering
Project Y.A.M. (Yaw Analysis Methodology), Vehicle Testing and Finding of Victoria Police Accident Investigation Section
Peter Bellion, Author

The author has summarized 110 tests that were done by four vehicles to create yaw marks. These data provide an excellent source of information that others may want to use in further research on the subject of speed estimates from yaw marks. The report gives guidelines that appear to be quite sound when estimates of speed are made from yaw marks. The results obtained by the author are similar to other data that has been collected by other researchers.

SAE #970955
Reviewer's Discussion
by Charles P. Dickerson, Collision Engineering Associates, Inc.
Project Y.A.M. (Yaw Analysis Methodology), Vehicle Testing and Finding of Victoria Police Accident Investigation Section
Peter Bellion, Author

The author presents the results of a large body of testing performed to test the validity of the Yaw Analysis Methodology (YAM) which is also referred to as the Critical Speed Formula. The speed at the beginning of the maneuver, throttle and brake application, tire pressure, and maneuver direction are presented. The magnitude or phasing of the steering input is not reported. It would be valuable if the slip angle of the vehicle during the maneuver was documented and presented.

The test results show that the analysis is sensitive to the coefficient of friction value.

In the series, the runs that resulted in the most error in the estimated speed were those in which a "flick" steering input is used. This maneuver is described as being more severe than others and the author states that none of the analysis methods rendered "conservative results". The results show that the calculation method tends to predict a value higher than the actual speed.

The reviewer would suggest that the problem with the "Flick" runs, is that the resulting vehicle slip angle is higher for these maneuvers. Testing performed as Arndt and Associates, Ltd. shows that at higher slip angles (>30 to 35 degrees), error increases in the calculated speed. This is a result of the force component that produces the curved path being less than the total force acting on the vehicle. It is important to determine the vehicle slip angle before applying this method.

The paper is rich in test data to support its discussions and conclusions.

Determination of Bumper Characteristics Using Prototype Moving Barriers

David J. King, James J. Bowler, and Stephen J. Ptucha
MacInnis Engineering Associates

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Accurate assessment of the severity of a low speed impact between two vehicles can sometimes only be accomplished through staged collisions with the actual or exemplar vehicles. However, the cost of obtaining, colliding, then repairing the vehicles often precludes this option.

For this paper, two prototype moving barriers were constructed to test three different bumper assemblies separate from their vehicles. Candidate bumper assemblies were mounted to the moving barriers for low speed impact testing with a stationary barrier and three other vehicles.

Forty three test series of 701 total impacts were done to compare bumper performance in moving barrier tests with their in-situ counterpart. Vehicle-to-fixed barrier, vehicle-to-vehicle, moving barrier-to-fixed barrier and moving barrier-to-vehicle tests were done using four different vehicles. The actual vehicle and moving barrier results were statistically compared.

The hypothesis that a moving barrier can be used in place of a motor vehicle in low speed impacts was tested.

INTRODUCTION

There has been increased research in assessing the severity of low speed collisions[1-7]. This paper focuses on the technique of reconstructing collision severity using a moving barrier in place of the vehicle.

The severity of a collision can be quantified in a number of ways[8]. In low-speed rear-end collisions, the velocity change (ΔV or delta-V) is the customary descriptor of severity. In this paper, velocity change and speed change are used interchangeably.

Without a doubt, the most accurate means of predicting collision severity is to recreate the collision using the actual or exemplar vehicles. This method will produce a virtually unassailable answer providing the tests were conducted properly.

When testing cannot be done, the accident reconstructionist must sometimes rely on empirical relationships such as ΔV versus average isolator compression, or energy change or absorption, and restitution versus isolator compression. The change in system energy for a collision is assumed to be the energy absorbed.

More theoretical, as opposed to empirical, methods have been pursued. Attempts to model the kinetics of bumper isolators[9] and other bumper constructions[10] have had little application in reconstruction. Some methods have shown promise, but their application requires not readily available knowledge of bumper properties. Acquiring those bumper properties requires the same testing that is required for application of the empirical methods outlined above.

The hypothesis of this study is that bumpers from our test vehicles attached to the prototype moving barriers will behave the same as if attached to the actual vehicles in low speed collisions.

MOVING BARRIER DESIGNS

MOVING BARRIER 1 (M1) - To achieve a wide variety of masses, mass centers, and mass moments of inertia, M1 was constructed mainly of rectangular aluminum tube stock with welded joints to be as light as possible. At a tare mass of 740 kg,

M1 is lighter than all but the lightest occupied vehicles. This allows in most cases for ballast to be added to duplicate the mass distribution and total mass for a specific vehicle. The center of mass position can be varied by altering the position of the ballast. The wheelbase was not made adjustable, so the center of mass to axle distance for both axles cannot be duplicated. It was determined that the suspension on the axle nearest the struck end would experience the bulk of the motion, so that having an adjustable wheelbase would not be of primary importance.

Load cells are attached to two vertical members at the front of the frame. The location of these load cells can be adjusted laterally and vertically by means of sliding tracks. Attached to the load cells is a hollow structural steel rectangular tube. To the front of this tube are attached laterally adjustable plates to which different bumper isolators can be attached. The portion of the isolator extending rearward of the isolator flange passes through slots in the steel tube.

Figure 1 shows the unladen M1. Table 1 lists the pertinent dimensions.

The M1 suspension consists of solid front and rear axles (both steerable) mounted on leaf springs attached to the barrier's main longitudinal members. The suspension stiffness can be adjusted by adding or subtracting leaves. The axles and spring assemblies were taken from the front end of two 1984 four wheel drive Suzuki SJ410's. Gas shocks were mounted vertically at the centers of all four leaf springs to provide suspension damping. The tires are P205/75/R15 on steel rims.

MOVING BARRIER 2 (M2) - The second moving barrier was made from a passenger car. A 1985 Chrysler LeBaron GTS four door was stripped of its engine (and associated components), transmission, fuel tank, rear hatch, rear doors, and interior structures. A plate was welded into the engine compartment for supporting ballast. This reduced the vehicle's mass from 1220 kg to 710 kg and likely did not significantly change the vehicle's front end stiffness for low speed purposes. The stock Chrysler suspension and wheels were not modified. The vehicle's front isolators were replaced by a pair of collapsed and welded isolators. These were used as mounts for the same load cells and rectangular steel tube structure used on M1. M2 is shown in Figure 2.

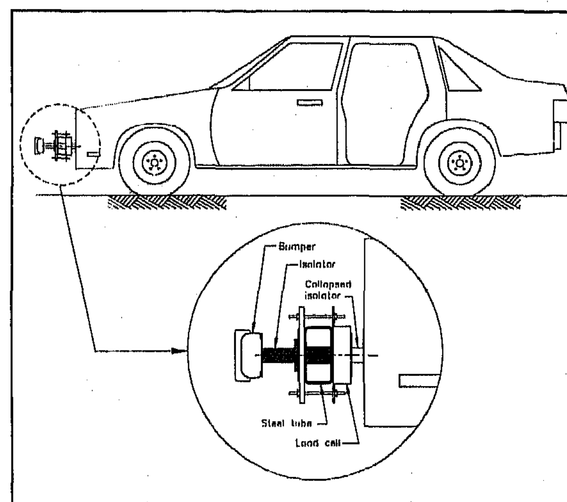

Figure 2. M2 and bumper detail.

TEST DESCRIPTION

EXPERIMENTAL METHOD - Forty three series of 701 total collisions were staged. Measured quantities were the vehicle mass, bumper isolator compression, pre-impact and post-impact speeds, and bumper force. Calculated quantities were speed change (ΔV), energy change (E), and coefficient of restitution (e).

The experimental procedure used for each test is described in detail elsewhere[2]. Briefly, the tests were staged on dry, level concrete and each vehicle was in neutral with the parking brake disengaged. A fine coat of Double*Glo Sno Spray™ was applied to each bumper isolator prior to each test in order to

distinguish isolator compression between tests. This procedure is necessary after the first few collisions since the paint on the isolator piston tubes, which leaves a good indication of compression distance, is scraped away. Tire air pressure was maintained according to the manufacturer's data placard except for M1. Its tire pressure was reduced to 20 psi from 32 psi to bring the rolling resistance in line with the other test vehicles.

VEHICLES - The four test vehicles are described in Table 2. The vehicles were weighed on a certified full-vehicle scale. Isolator data for each of the so-equipped vehicles is given in Table 2b. The approximate suspension stiffness in Table 2c was measured by placing known masses directly over the axle nearest to the impact surface and measuring the suspension deflection.

INSTRUMENTATION - Vehicle speed and force were measured in the x-direction. Speed data were acquired with an MEA 5th Wheel at 128 or 256 Hz for about 1 second before and 3 seconds after impact. Speed resolution in this sampling frequency range is about 0.01 m/s. Maximum isolator compression was measured to the nearest millimeter after each test.

Two Sensotec model 41 load cells were used to measure the impulse for most collisions. Each load cell's capacity was 44 480 N (10,000 lb.) and the total acquisition system resolution was ±30 N.

DATA INTERPRETATION - Figure 3a shows a sample of the MEA 5th Wheel and load cell output for one collision. Note that the target vehicle (Chevette) is stationary before impact. After impact, damped oscillation of both vehicles on their suspensions is seen in the traces. Long post-impact sampling durations were necessary to allow the oscillations of some vehicles to settle. For the collision shown in Figure 3a, the post-impact speeds were determined to be 0.24 m/s for the bullet vehicle (LeBaron) and 0.68 m/s for the target vehicle. The bullet vehicle's impact speed was 0.79 m/s.

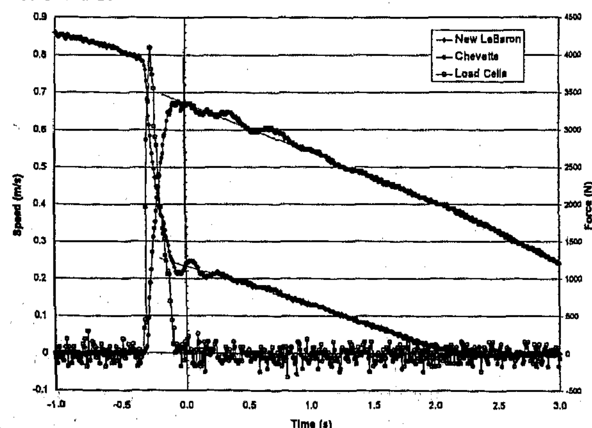

Figure 3a. Sample MEA 5th Wheel and force output.

Figure 3b shows a time-expanded view of the impact. The peak force was 4100 N and the collision duration was 0.25 s.

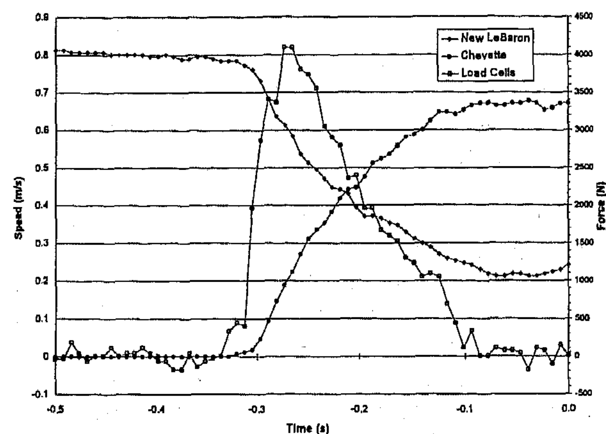

Figure 3b. Time-expanded view of collision interval.

ISOLATOR FAILURE - The performance of the LeBaron isolators became erratic after 330 tests (and a maximum speed change of 2.86 m/s). The average isolator stroke was 6 mm greater for a given speed change indicating an internal failure. The overall length of these isolators did not change. The relationship between isolator compression and speed change noted before the "failure" was observed with replacement isolators.

Static isolator compression tests results indicate that the initial compression force for the failed isolators was about 600 N lower than the replacement isolators. In addition, the force at full compression was 990 to 2311 N lower for the failed isolators. Sectioning of the failed isolators revealed that the metering pin was slightly bent to the outside of the annulus. General isolator descriptions are given in Reference 1. Both isolators exhibited the same behavior even though the static force at maximum compression for the left isolator was 1321 N greater than the right isolator. This is the only instance of isolator failure from repetitive testing that we have encountered in over 4000 tests.

BUMPER MOUNTING CONFIGURATION - It is important to mount candidate vehicle bumpers to the moving barrier in a manner as similar as possible to the actual vehicle. This requires that any significant load bearing points on the bumper that could transmit a collision force to the vehicle frame also have to be attached to the moving barrier face.

The front bumper from the Chrysler LeBaron is mounted on two hydraulic isolators and has a wrap-around cover. The ends of the cover are parallel to the vehicle's long axis and attach to the leading edge of the fenders. Insertion of load cells was necessary for force measurement in subsequent vehicle-to-vehicle tests. Figures 4 and 5 compare the results of front-to-barrier tests between the stock

Topaz	254	1150	79000
LeBaron	255	1220	67000

LeBaron front bumper and after load cell modification. Insertion of the load cells created a 4 cm gap between the wrap-around bumper cover and the fender leading edges. The gaps were spanned with aluminum channels to support the ends of the cover as when installed on the vehicle.

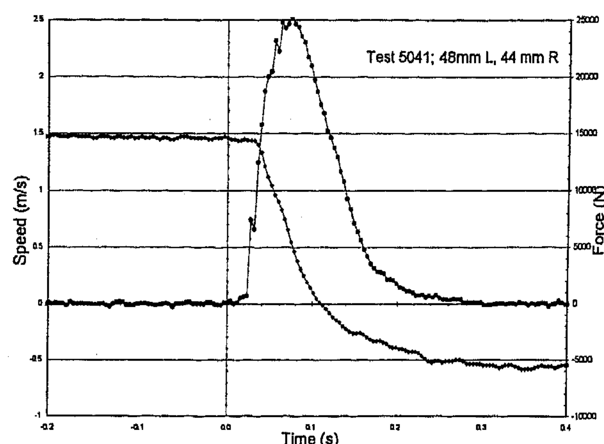

Figure 4(a). Force measured for entire bumper.

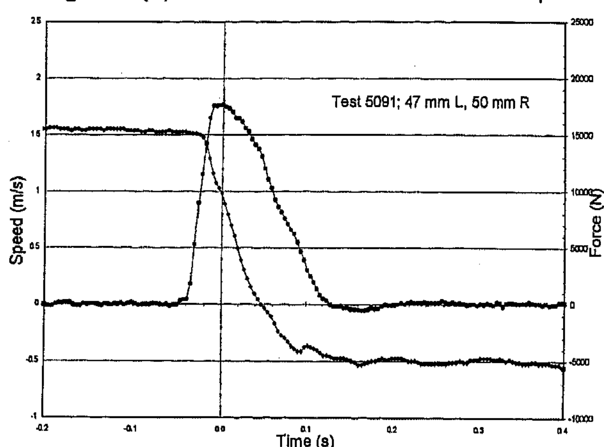

Figure 4(b). Force measured at isolators.

In Figure 4(a) the impact speed was 1.49 m/s and the peak load measured by the load cells, which is the load applied to the face of the bumper, was 25 kN. In Figure 4(b), the impact speed was 1.5 m/s. The load cells, between the isolators and the bumper, measured a peak force of only 17.6 kN. No other parameters were changed except that the load cells were inserted between the bumper bar and the isolators. With the load cells mounted to the bumper, they were not measuring the load applied through the wrap-around bumper cover to the fenders. Since the isolator compression and speed change were similar, the load cells did not alter the bumper performance. Comparison of these two tests shows that the wrap-around part of the bumper cover carried a peak load of approximately 7.4 kN, or about 30% of the collision force. Figures 5(a) and (b) show the same trend for a 0.6 m/s impact speed.

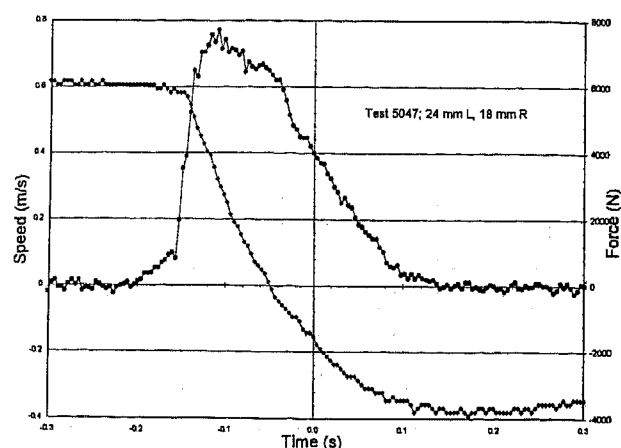

Figure 5(a). Force measured for entire bumper.

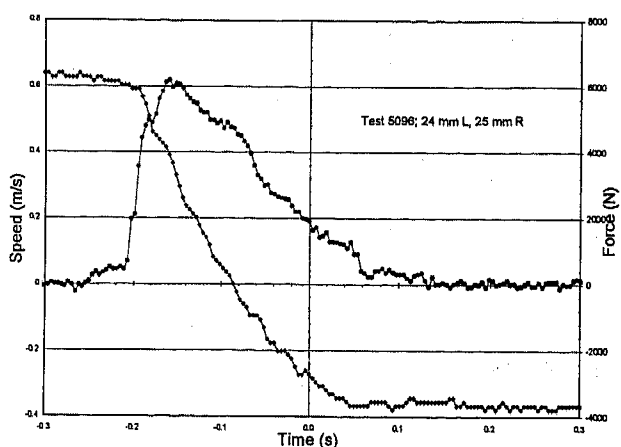

Figure 5(b). Force measured at isolators.

These tests highlight the concept that isolator compression is empirically correlated to speed change. While the isolators are not carrying all of the force, their compression can still be used to gauge impact severity. In addition, these tests demonstrate the importance of duplicating the bumper mounts to achieve comparable results. Had the spacers between the bumper wrap-around and fenders not been present, then more force would have been carried by the isolators and the correlation between isolator compression and severity would have been altered, giving more isolator compression for a given impact speed. The force comparison is shown in Figure 6.

RESULTS

TEST SUMMARY - The test data are shown in Figures 7 to 13, organized into the groups shown in Table 4.

STATISTICAL EVALUATION - The hypothesis of this study was tested statistically from the collected data.

For the test series where the actual test vehicles were used and not the moving barriers, a trend line was plotted through the speed change (ΔV), energy absorption (E), and coefficient of restitution (e) versus isolator compression

relationships. Each data point from the moving barrier tests was plotted against the value calculated from the actual vehicles' trend line. These plots have the actual vehicle on the x-axis and the moving barrier on the y-axis. The actual speed change was compared to the moving barrier speed change and a best-fit line was plotted as shown in Figures 14 to 20. Similar comparisons were made for the energy and restitution values. The dashed lines represent a confidence interval of 67% (± 1 standard deviation) about the best-fit line using the t-distribution. If the bumpers on M1 and M2 were behaving identically to the actual vehicle, the slope of the best fit line would be close to unity and the unity line shown on the graphs would be contained within the ±1 standard deviation confidence interval.

A simple scoring of each data set was used to assess the barrier performance. The performance scores are summarized in Table 5. The slope of the best-fit line was weighted between 0.9 and 1.1 based on the difference from unity. A slope of 1 is given a slope factor of 1, and slopes of 0.925 or 1.075 were given slope factors of 0.25, and so on. Slopes less than or equal to 0.9 or greater than or equal to 1.1 were given factors of zero. The fraction (0 to 1) of the confidence interval which contained the unity line was also calculated. The fraction is shown under the Unity heading in Table 5. The slope factor and the overlap fraction scores were summed to obtain a total score. A maximum score would be 2 for a best fit line lying on the unity line. A performance score greater than 1 is considered acceptable.

VEHICLE TO FIXED BARRIER TESTS

GROUP A - CHEVETTE BUMPER INTO FIXED BARRIER - Figure 14 compares the actual speed change, energy absorption, and coefficient of restitution for the Chevette into the fixed barrier with M1 and M2. The Chevette bumper was attached to M1 and M2 for the barrier impacts in the manner shown in Figures 1 and 2. The test data are shown in Figure 7.

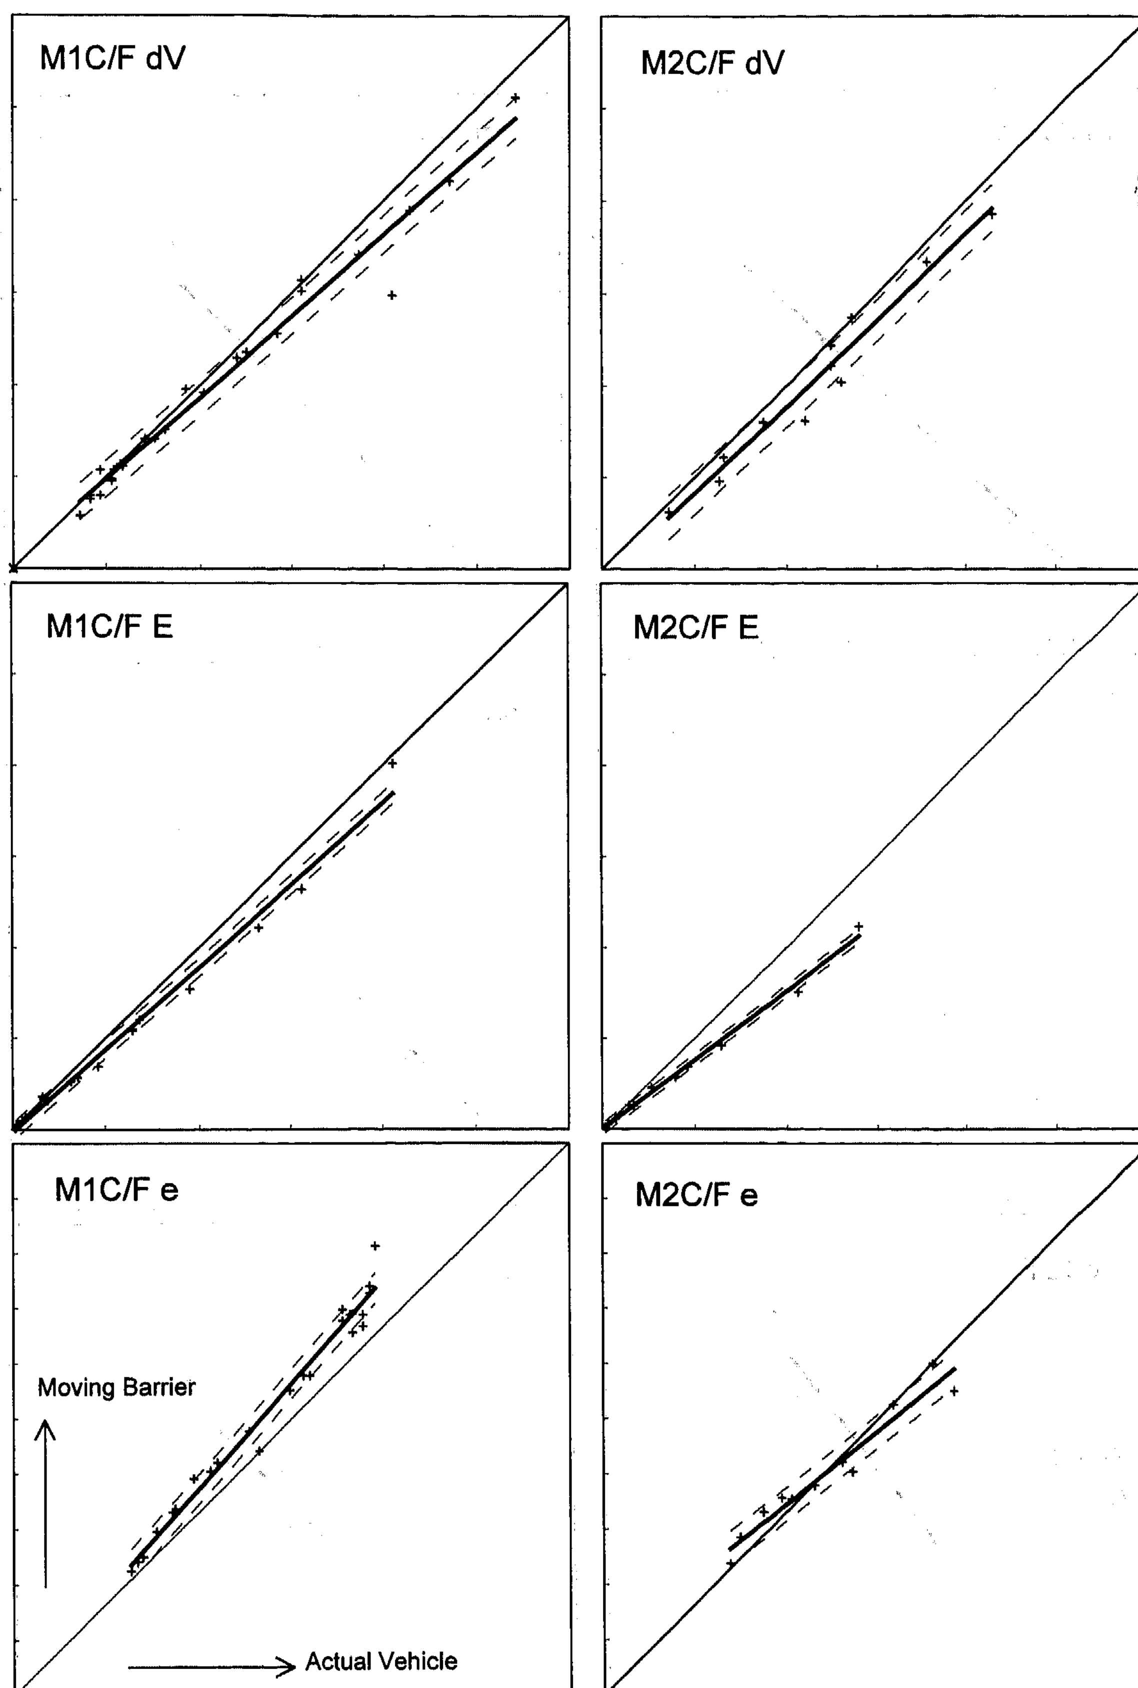

Figure 14. Group A Statistical Comparison- Chevette/Fixed Barrier (ΔV, E, and e).

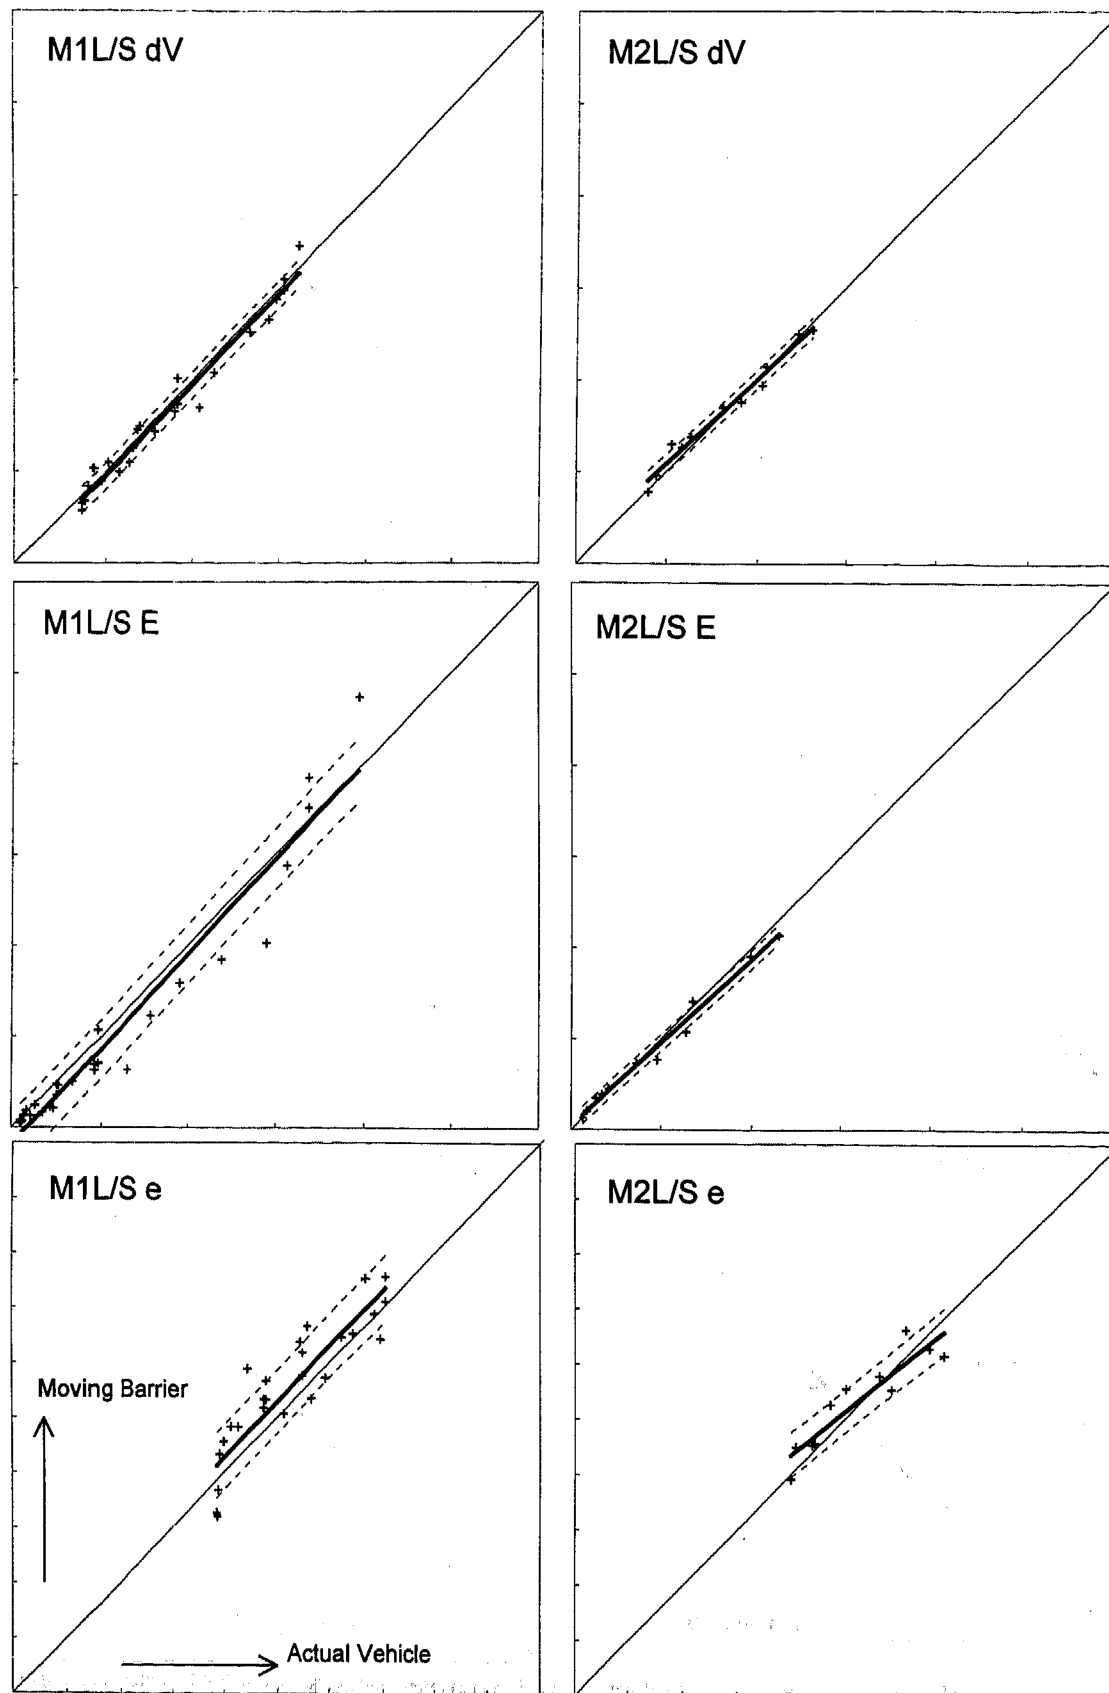

Figure 18. Group E Statistical Comparison -LeBaron / Sprint (ΔV, E, and e).

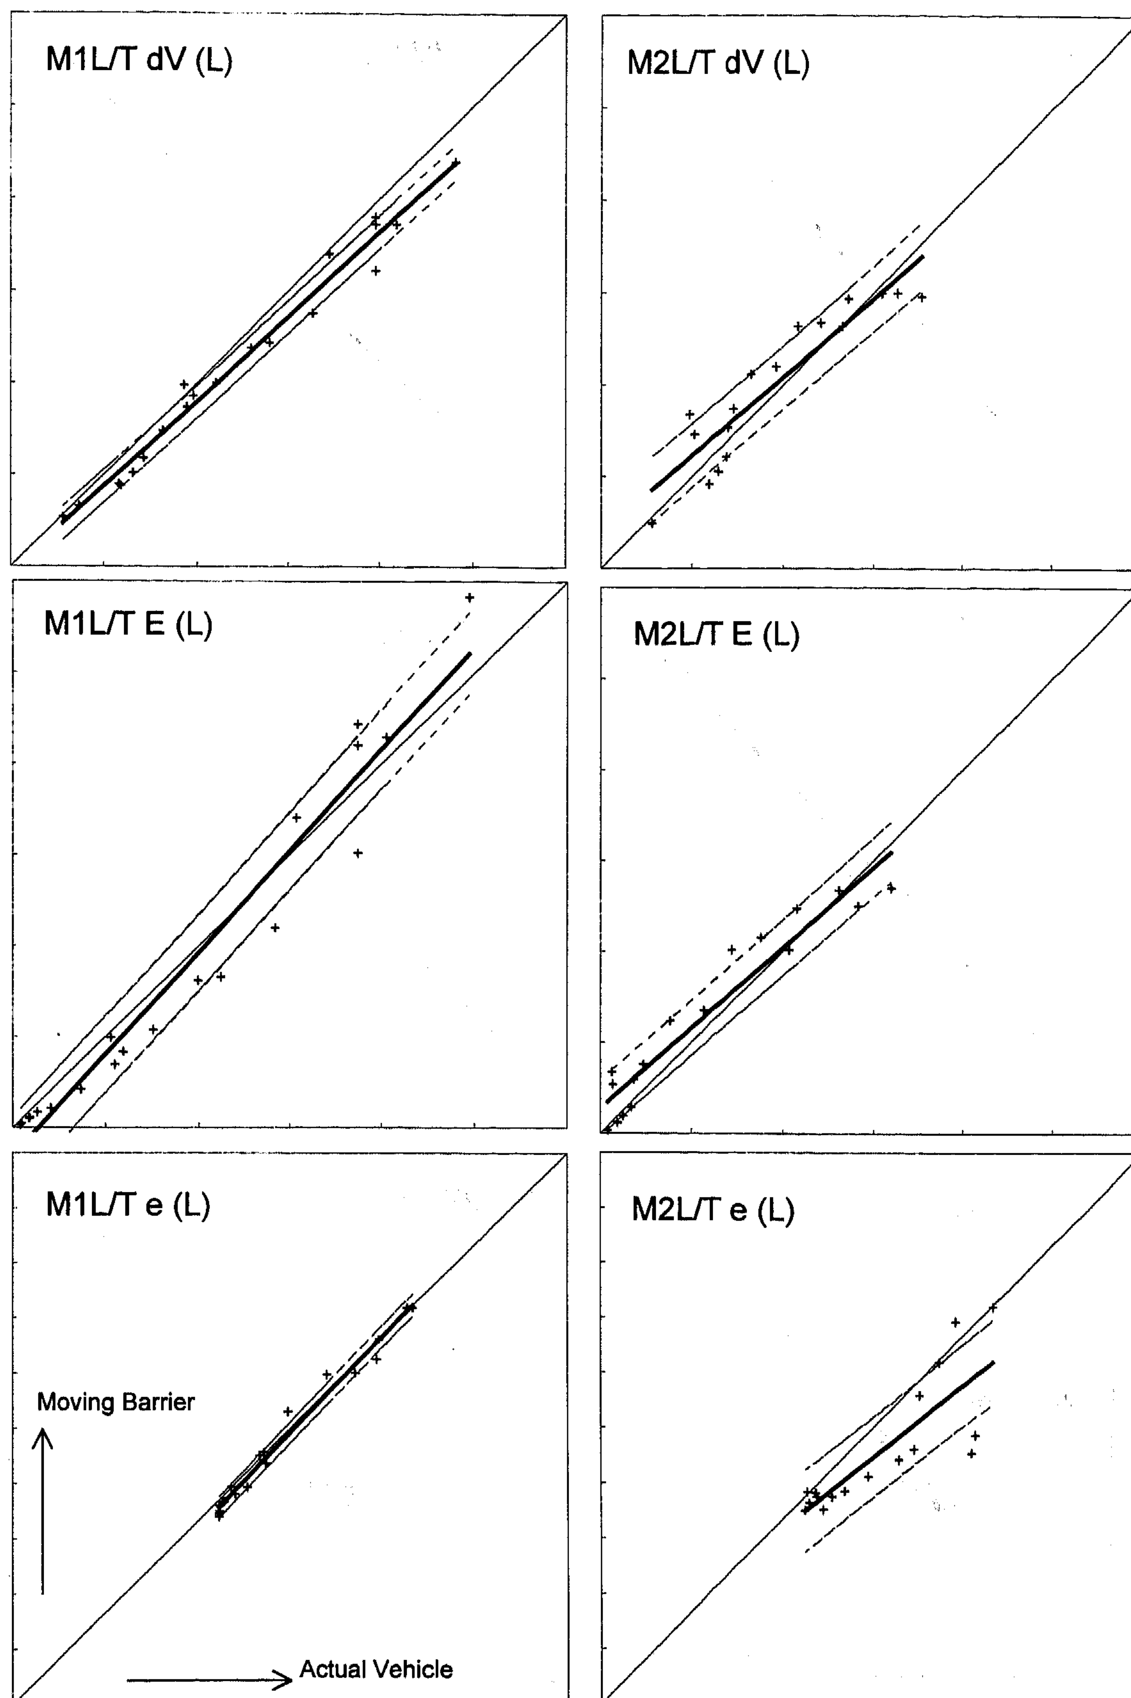

Figure 19a. Group F Statistical Comparison -LeBaron / Topaz (ΔV, E, and e) referenced to LeBaron.

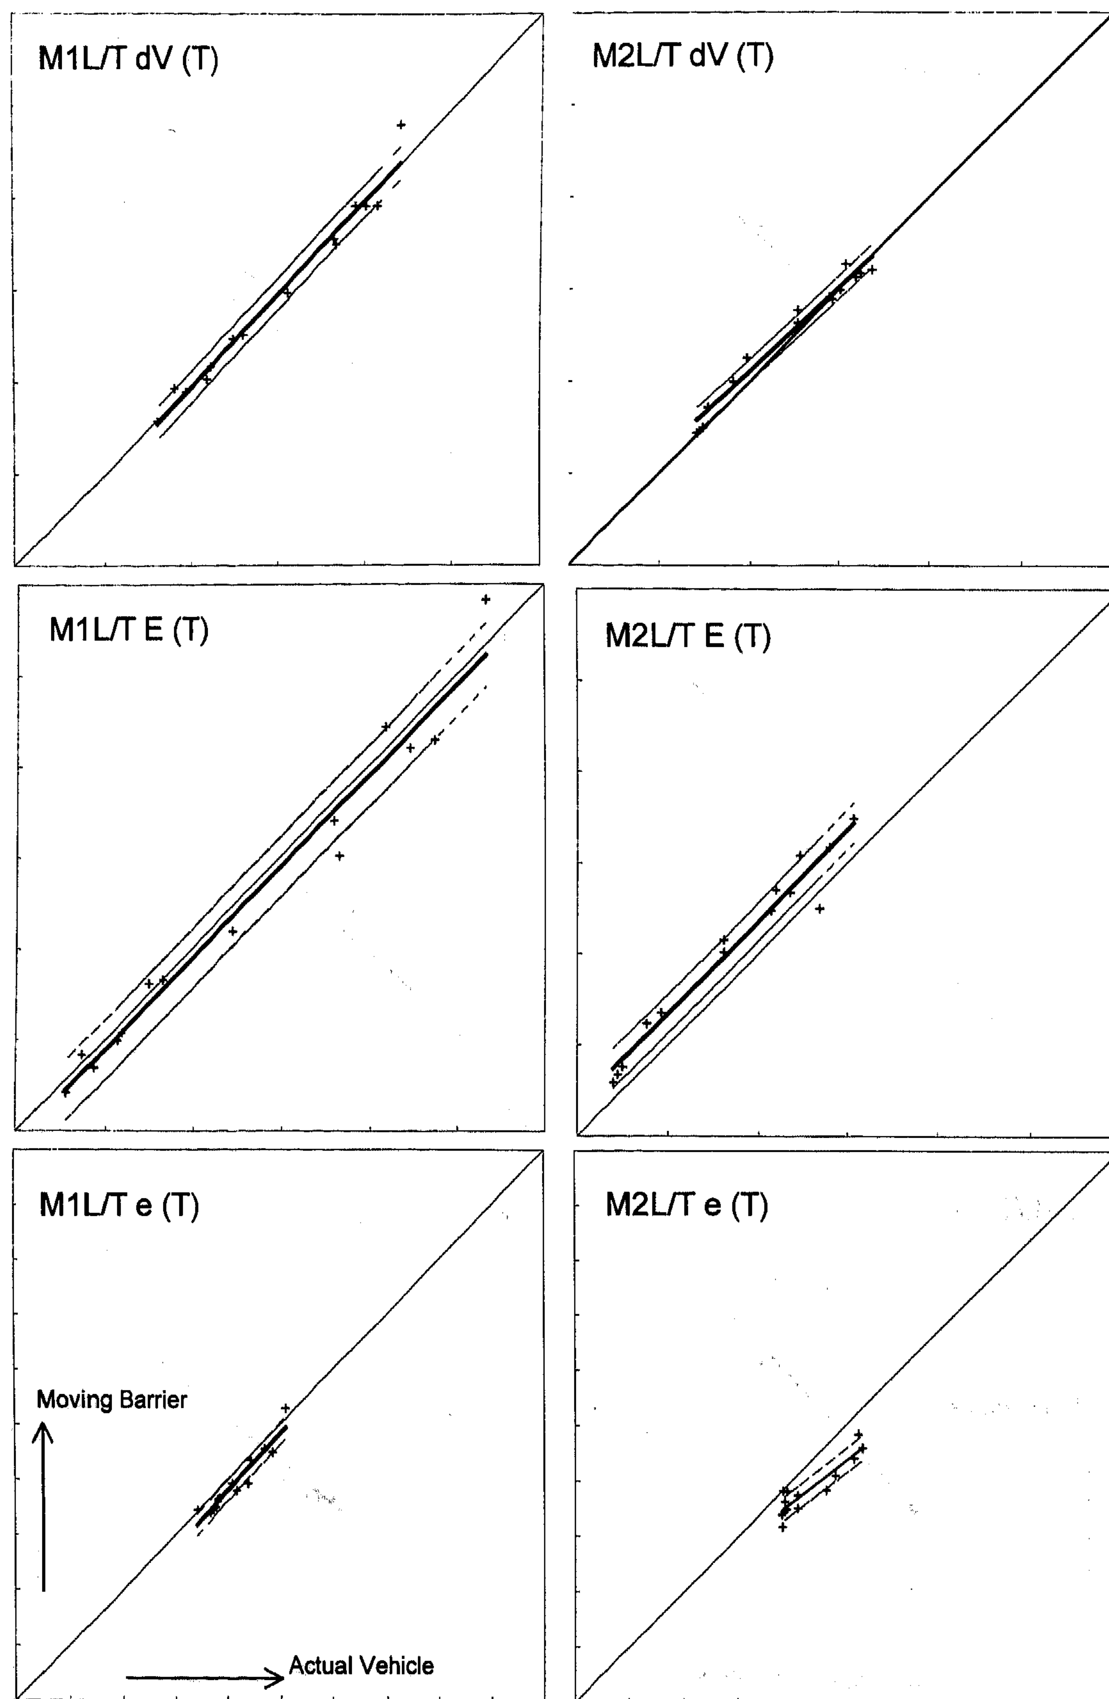

Figure 19b. Group F Statistical Comparison -LeBaron / Topaz (ΔV, E, and e) referenced to Topaz.

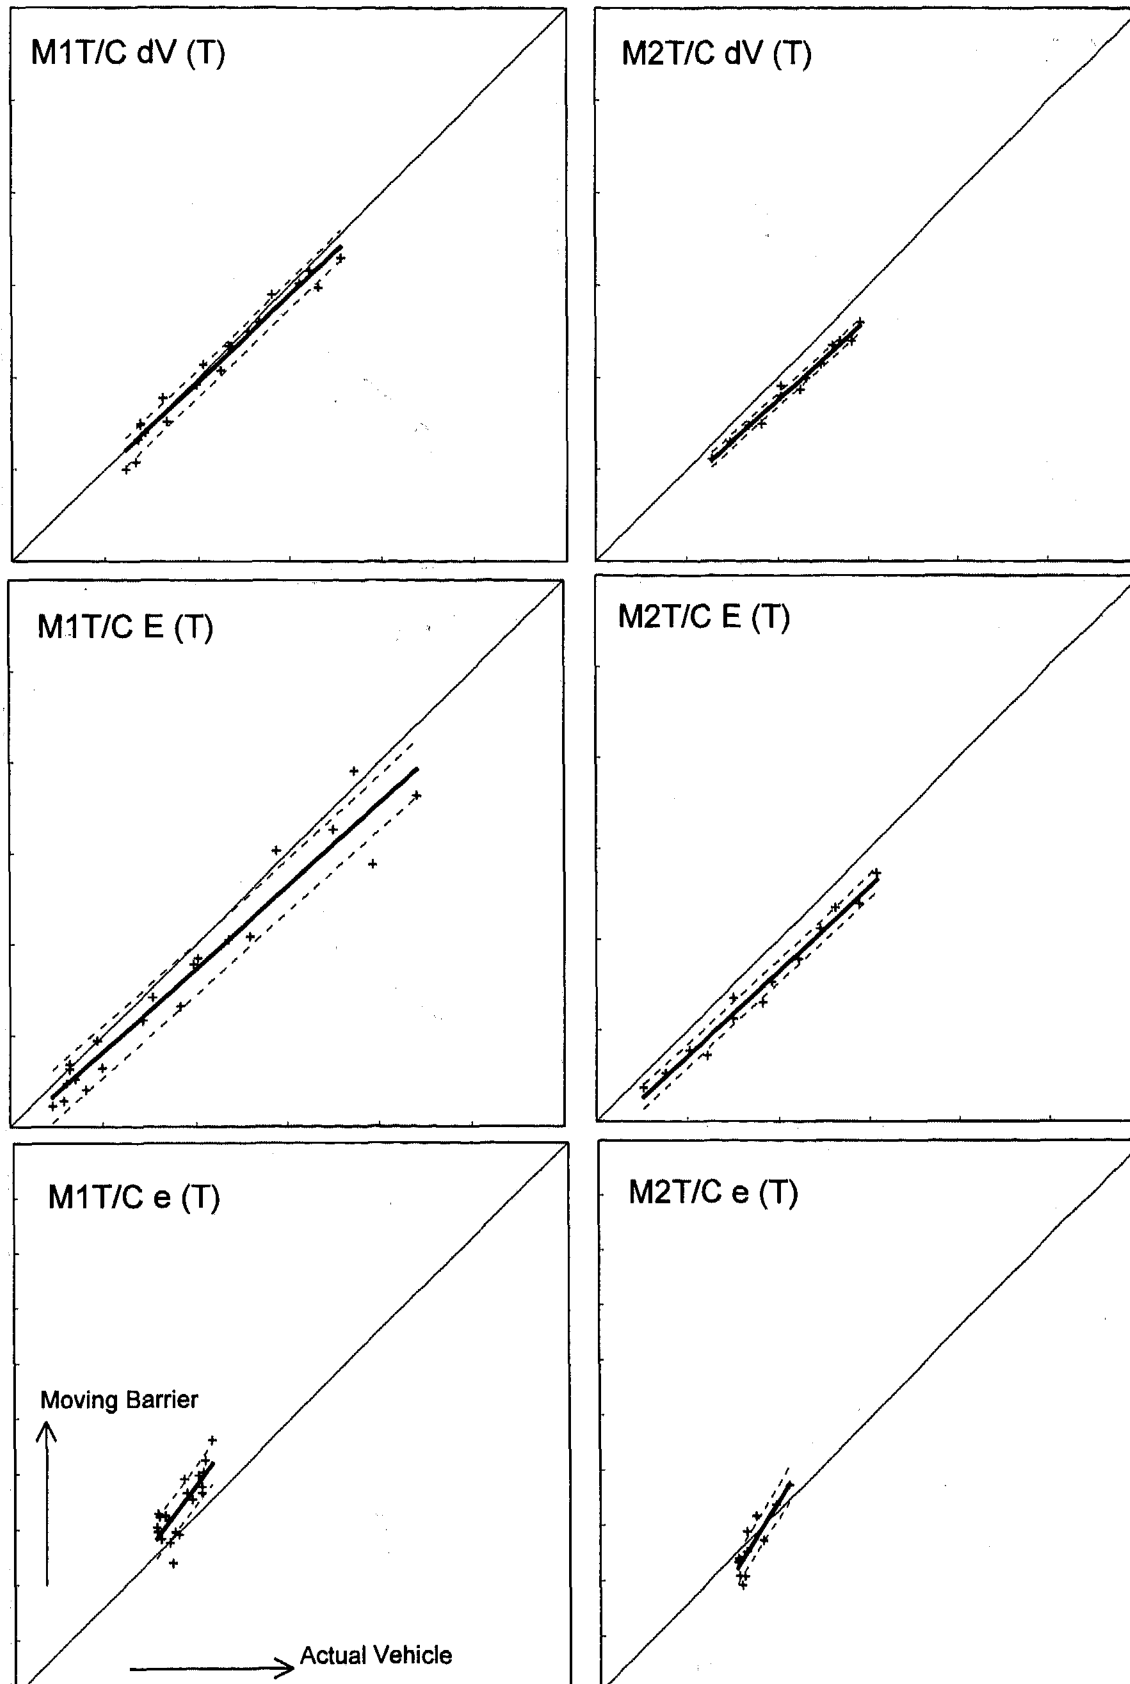

Figure 20a. Group G Statistical Comparison -Topaz/Chevette (ΔV, E, and e) referenced to Topaz.

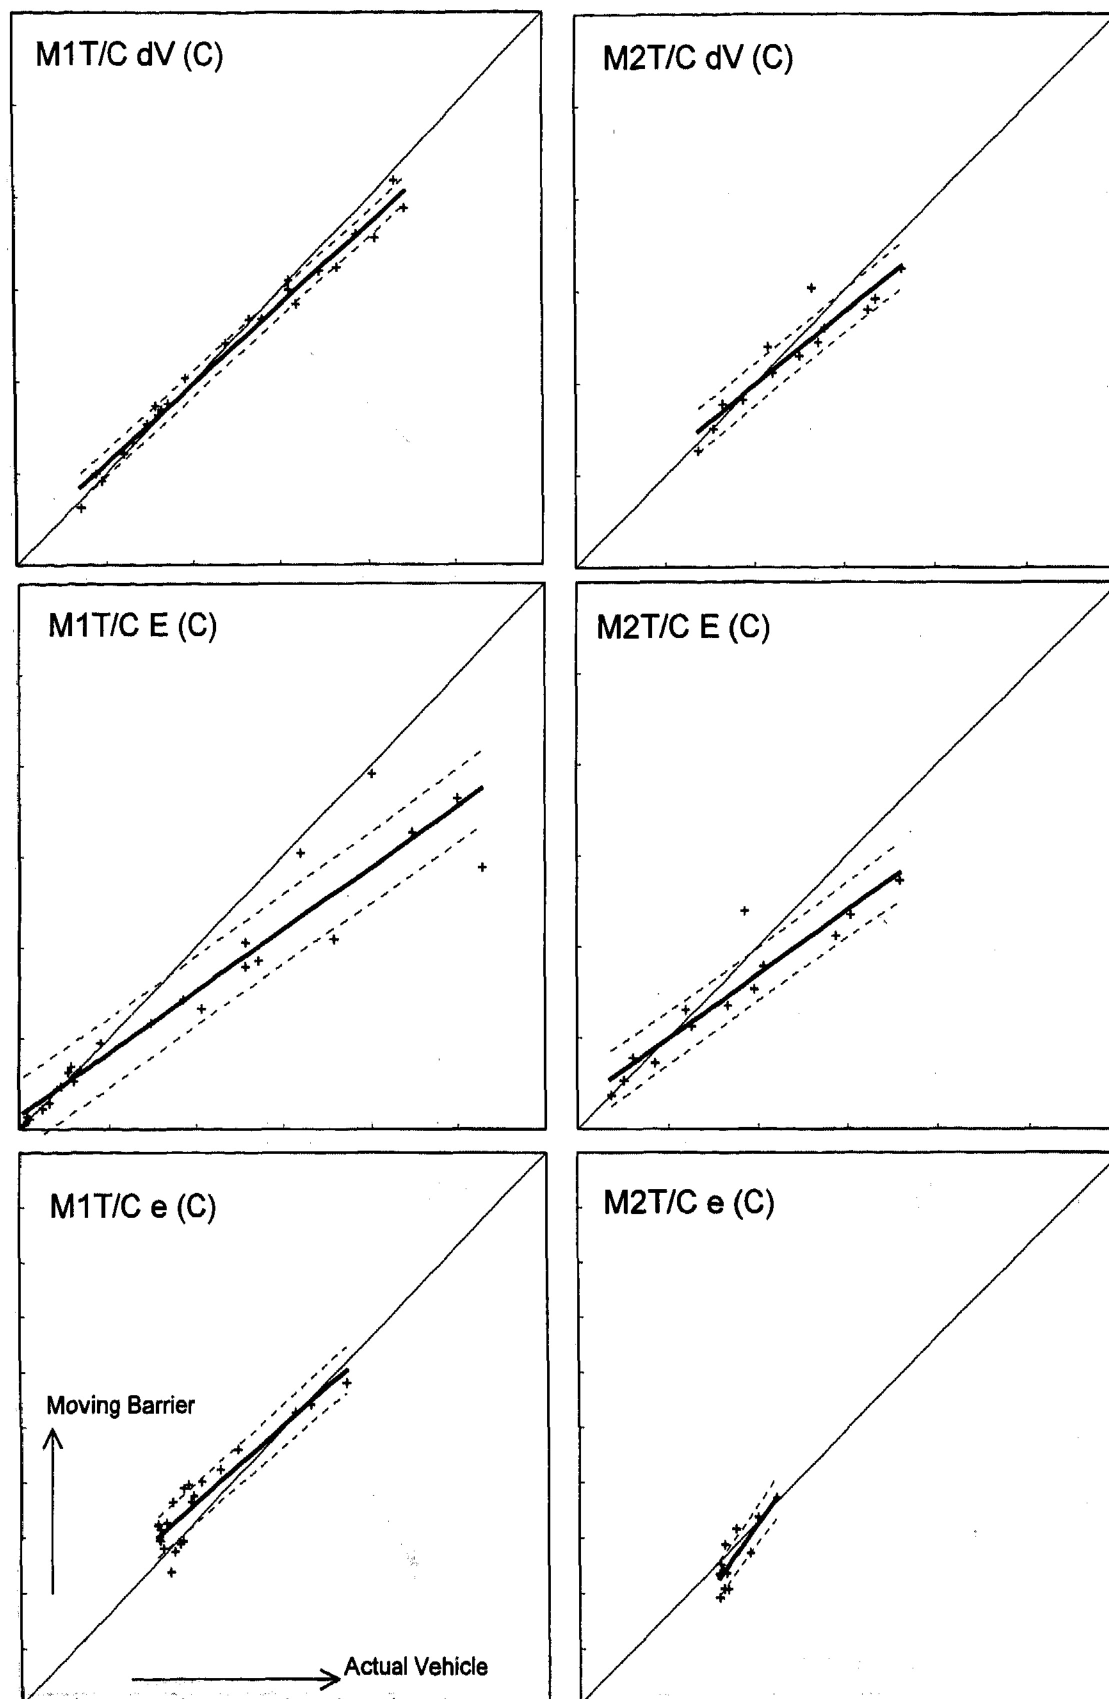

Figure 20b. Group G Statistical Comparison -Topaz/Chevette (ΔV, E, and e) referenced to Chevette.

The speed change comparison charts indicate that both M1 and M2 underestimated the actual Chevette tests except for very low speed changes.

The energy absorption comparison charts show that the energy absorbed in the M1 tests more closely resembles the actual Chevette tests than the M2 tests. However, both M1 and M2 underestimated the actual energy absorption. As the severity increased, the M1 and M2 results drifted further from the actual Chevette tests, more so with M2 than M1.

The coefficient of restitution comparison charts indicate that the M2 tests follow the actual tests slightly better than the M1 tests, which tend to overestimate the actual.

The highest performance scores were for M2's speed change and restitution comparisons, but all were less than 1.

GROUP B - LEBARON BUMPER INTO FIXED BARRIER - Figure 15 shows the comparison charts between the actual LeBaron into the fixed barrier and M1 and M2 with the LeBaron bumper into the fixed barrier. The test data are shown in Figure 8.

The M1 tests underestimated the speed change of the actual LeBaron tests except for speed changes below approximately 1 m/s.

The M1 tests slightly underestimated the energy absorption and overestimated the coefficient of restitution of the actual tests.

In the speed change, energy absorption, and coefficient of restitution comparison charts, M2 was much closer to the actual LeBaron into the fixed barrier than the M1 tests. This is expected since M2 was built from the LeBaron.

The performance scores for M2 were all acceptable.

GROUP C - TOPAZ BUMPER INTO FIXED BARRIER - The results of the fixed barrier impact comparisons for the Topaz, and M1 and M2 with the Topaz bumper attached are shown in Figure 16. The test data are shown in Figure 9.

The speed change from the M1 tests were closer to the actual Topaz at higher speed changes. Conversely, the M2 tests were further from the speed change of the actual Topaz at higher speed tests.

Both the M1 and the M2 tests overestimate the energy absorption compared with the actual Topaz except for the very low speed tests.

M1 and M2 both significantly underestimate the coefficient of restitution compared with the actual Topaz into the fixed barrier.

The highest performance score was for M1's speed change comparison, but at 0.67 the relation is unacceptable.

VEHICLE-TO-VEHICLE TESTS

In the vehicle-to-vehicle tests, two sets of comparison charts were examined. In the first set, the speed change, energy change, and coefficient of restitution of M1 and M2 were compared with that of the actual vehicles based on the isolator compression of the bullet vehicle. The second set of comparison charts were based on the isolator compressions of the target vehicle (if applicable).

GROUP D - LEBARON BUMPER INTO CHEVETTE - Figure 17 compares the actual LeBaron into the Chevette with M1 and M2 with the LeBaron bumper into the Chevette. The test data are shown in Figure 10.

The M1 tests underestimated the speed change compared to the actual LeBaron tests when the comparison was based on the LeBaron isolator compression. M1 compared closely to the actual when the comparison was based on the Chevette isolator compression. The speed change of the M2 tests slightly underestimated the speed change of the actual tests when the comparisons were based on the LeBaron or the Chevette isolator compression. In general the speed changes compared better in the M2 tests than the M1 tests.

The M1 and M2 tests underestimated the energy absorbed in the actual LeBaron tests based on the LeBaron isolator compression. However, M2 was closer to the actual LeBaron than M1. The comparison graphs referenced to the LeBaron isolator compression are shown in Figure 17a.

Based on the Chevette isolator compression, (Figure 17b) the energy absorption in the M1 tests was very close to the actual LeBaron tests and the M2 tests underestimated the energy absorption. This result is significantly different from the energy absorbed referenced to the LeBaron isolator compression.

The coefficient of restitution data from the M1 and the M2 tests were not significantly different than the actual LeBaron tests. This was the case whether the comparisons were based on the LeBaron isolator compression or the Chevette isolator compression.

The highest scores were for the M1 speed change, energy, and restitution comparisons referenced to the Chevette bumper isolator compression. These were all acceptable.

GROUP E - LEBARON BUMPER INTO SPRINT - Figure 18 shows the comparison charts between the actual LeBaron into the Sprint and M1 and M2 with the LeBaron bumper into the Sprint. The test data are shown in Figure 11.

The speed change and energy absorption charts in Figure 18 show that the M1 and M2 tests compare very closely with the actual LeBaron tests. The coefficient of restitution was slightly overestimated in the M1 tests.

The highest scores were for M1's speed change, energy, and restitution, all of which were acceptable.

GROUP F - LEBARON BUMPER INTO TOPAZ - Figure 19 shows the comparison charts between the actual LeBaron into the Chevette and M1 and M2 with the LeBaron bumper into the Chevette. The test data are shown in Figure 12.

M1 slightly underestimated the speed change when the comparison was based on the LeBaron isolator compression (Figure 19a). However, the speed change in the M1 tests closely resembled the actual LeBaron tests when the comparison was based on the Topaz isolator compression (Figure 19b). The speed change in the M2 tests was slightly overestimated at the low speeds and was closer to the actual at higher speeds. This relationship was approximately the same whether the comparison was based on the LeBaron isolator compression or the Topaz isolator compression.

The energy absorption in the M1 and M2 tests was close to the actual LeBaron when the comparison was based on the LeBaron's isolator compression. The energy absorbed in the M1 tests also closely resembled the actual LeBaron tests when the comparison was based on the Topaz isolator compression. However, the M2 tests overestimated the energy absorbed when the comparison was based on the Topaz isolator compression.

The coefficients of restitution for M1 were close to the actual LeBaron. However, the M2 tests underestimated the coefficient of restitution, especially at low speeds. A similar trend is observed for the Topaz referenced charts.

The highest scores were for the speed change and energy relations referenced to the Topaz. The only acceptable LeBaron-referenced group was the M1 restitution.

GROUP G - TOPAZ INTO CHEVETTE - Figure 20 compares the actual Topaz into the Chevette with M1 and M2 with the Topaz bumper into the Chevette. The test data are shown in Figure 13.

The speed change compared closely with the actual Topaz in the M1 tests referenced to the Topaz isolator compression. In the M2 tests the speed change was underestimated, especially when the comparison was based on the Topaz isolator compression. The comparison charts referenced to the Topaz are shown in Figure 20a. Figure 20b shows the test results referenced to the Chevette.

The energy absorption was underestimated using M1 and M2. However, M2 had slightly better results than M1 when the comparison was based on the Chevette isolator compression. M1 had slightly better results when the comparison was based on the Topaz isolator compression.

The coefficient of restitution was difficult to compare since there was little variance in restitution between low speed collisions and higher speed collisions. The M1 tests tend to overestimate the coefficient of restitution slightly. The M2 tests slightly underestimate restitution at the low end and overestimate at the high end.

The only acceptable score was for the M1 speed change referenced to the Topaz isolator compression.

DISCUSSION

The tests did not clearly distinguish one moving barrier over the other. M2 simulated the LeBaron into the fixed barrier better than M1, while M1 simulated the Topaz into the fixed barrier better than M2. Unexpectedly, M1 better simulated the LeBaron during LeBaron bumper into Topaz tests even though M2 was constructed from the LeBaron.

The bullet and target vehicle speed changes were consistently better approximated than the absorbed energy or the restitution. The restitution approximation was rarely acceptable.

The reason for the poor correlation of the collision restitution is unclear, although the two main factors are likely vehicle suspension and stiffness of the isolator mounting on the vehicle.

The absorbed energy of a collision is related to the collision restitution and varies proportionally as shown:

$$E \propto 1 - e^2 \qquad (1)$$

When the restitution was overestimated, the absorbed energy was an underestimate. This is shown in Figure 11 where M1 restitution values lie above the actual vehicle values, while the absorbed energy data points for M1 fall below the actual. The trend line for the absorbed energy data is below unity in Figure 18, and the trend line for restitution is above unity.

Although the data did not always correlate for all three of the collision characteristics (speed change, absorbed energy and restitution), the findings are encouraging. The speed change correlation was on average better than the energy and restitution. Since the energy change is proportional to restitution, modifying the moving barriers to better estimate the restitution of the actual vehicles should result in an overall improvement.

ADDITIONAL FINDINGS

Additional findings that were not the main focus of this paper were examined and are discussed.

SUSPENSION EFFECTS - Test series 22 consisted of 9 tests in which the Chrysler LeBaron with its suspension blocked struck the Chevrolet

Chevette. From the initial test of M1 with the LeBaron bumper into the Chevette, it was hypothesized that the difference in collision behavior between M1 and the actual LeBaron was related to M1's high suspension stiffness. It was noted that there was lower energy absorption and a higher isolator compression for a given speed change during collisions involving the LeBaron bumper mounted on M1. Additional tests were performed with the LeBaron suspension blocked, allowing it to behave more like M1. The results showed that with the modified suspension less energy was absorbed during the collision and the LeBaron had a higher isolator compression for a given speed change than with the suspension fully functional. Although the LeBaron with blocked suspension did not behave exactly like M1 during these collisions, it did show that vehicle suspension is a significant factor during collisions.

CHEVETTE BUMPER ON M1 - In test series 16, M1 with the LeBaron bumper struck the Chevette. In test series 21, M1 with the Chevette bumper struck the LeBaron. These two series were compared in order to determine if there would be differences in speed change, energy absorbed and restitution when the LeBaron bumper was mounted on M1 compared to when the Chevette bumper was mounted on M1. The correlation between isolator compression and speed change did not change between these two series. With the Chevette bumper mounted on M1, the collisions exhibited a lower restitution and a slightly higher energy absorption over the collisions in which the LeBaron bumper was mounted on M1.

MEA 5TH WHEEL AND CALCULATED ΔV COMPARISON - The MEA 5th Wheel speed change results were compared with the speed change calculated from the load cell data. In the x-direction the relation between the impact force and the speed change can be represented by the expression:

$$F\Delta t = m\Delta V \quad (2)$$

Load cell results from the actual vehicle-to-fixed barrier tests were used with this expression to compare the theoretical speed change with the MEA 5th Wheel result. From the load cell data, the term $F\Delta t$ (the average force times the duration) was calculated using the trapezoidal rule. As shown in Figure 21, there is good agreement between the 5th Wheel and load cell methods.

The slope of the best-fit line through the points in Figure 21 is 1.0268, and the r^2 is 0.9981.

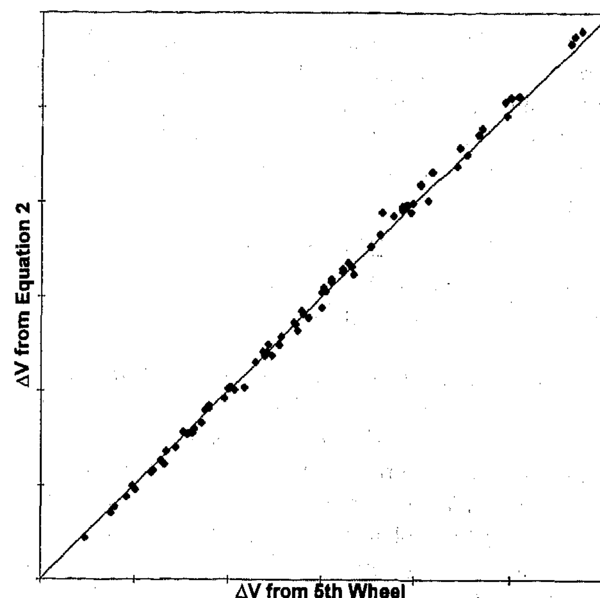

Figure 21. MEA 5th Wheel and Load Cell ΔV Comparison

BUMPER MOUNTING BEAM - Tests were conducted with M2 striking the fixed barrier without load cells and without the rectangular steel tube mounting beam attached. In these tests the bumper isolators were fitted into the frame rail ends at the front of M2 in the same manner as they would be on the actual vehicle. One test series used the LeBaron bumper and the other used the Topaz bumper.

There was no significant difference between the fixed barrier impacts with the LeBaron bumper on M2 with or without the load cells and mounting beam. These data also were not significantly different from the actual LeBaron, as shown in Figure 8.

The speed change versus isolator compression results for M2 with the Topaz bumper tests were approximately the same with or without the front mounting beam as shown in Figure 9. The energy absorption in the tests without the mounting beam were slightly lower and closer to the actual Topaz than the tests with the mounting beam. The coefficient of restitution was significantly higher in the tests without the beam than the tests with the beam but still lower than the actual Topaz.

CONCLUSIONS

FIXED BARRIER TESTS

1. M1 did not give acceptable results for speed change versus isolator compression. M2 gave acceptable results only when simulating the LeBaron.

2. M1 consistently overestimated the coefficient of restitution and underestimated the energy absorbed with the exception of the Topaz tests.

3. M2 tended to underestimate the coefficient of restitution except in the LeBaron tests. M2 also underestimated the Chevette energy change, accurately estimated the energy change in the LeBaron tests, and overestimated the Topaz energy change.

VEHICLE TO VEHICLE TESTS

1. The data presented indicate that for some vehicle pairs, a moving barrier can be an effective surrogate.

The best results were for tests between the LeBaron and Sprint. In these tests, the moving barrier results were similar to the actual LeBaron. It is not clear which Sprint parameters caused this test set to be different from the other tests with the LeBaron as the bullet vehicle. It may be due to the foam core bumper on the Sprint. The Sprint also had the softest suspension and was the lightest vehicle.

2. In most of the vehicle-to-vehicle tests the moving barrier speed change versus isolator compression results are similar to the actual vehicle tests.

3. A single conclusion cannot be made about the use of moving barriers because the data were dependent on which vehicle was being simulated as well as which vehicle was struck. For example, both moving barriers gave close results when simulating the LeBaron into the Sprint. However, M2 did not give acceptable results simulating the LeBaron into the Topaz even though M2 is a modified version of the actual LeBaron.

4. Blocking the suspension on the LeBaron caused it to behave more like M1. This suggests that part of the reason for the differences between M1 and the actual LeBaron was the high suspension stiffness of M1.

5. Care must be exercised when mounting candidate bumpers to the moving barrier in order to duplicate as closely as possible the actual bumper mounting conditions. In particular, bumper wrap-arounds may carry a significant portion of the bumper collision loads. Suspension characteristics, center of mass location, mass distribution, and axle to bumper distance may be influential variables in achieving fidelity between a vehicle and the vehicle's bumper mounted on the moving barrier.

RECOMMENDATIONS

1. The suspension on M1 should be redesigned so that its spring stiffness can be adjusted to closer resemble a passenger car suspension instead of the current truck-like suspension.
2. A new system for mounting bumpers to M2 should be developed to allow more vertical and horizontal adjustability. The new mounting system should not affect the front stiffness of M2.
3. A series of tests should be conducted to determine how well the moving barriers simulate pickup trucks, vans, and sport utility vehicles equipped with rigidly mounted steel beam bumpers.
4. Further research into the role played by the moving barrier suspension and the steel tube mounting beam is needed.

ACKNOWLEDGMENT

The authors wish to thank Mark Bailey, Colin Blair, Craig Brown, Robert Dyck, Michael Gardiner, Kurt Ising, John Miles, Gunter Siegmund, Robert Steves, David Switzer and the rest of the staff at MacInnis Engineering for their observations and assistance. Staging over 700 tests does not occur without the devotion and assistance of many individuals.

Determination of Bumper Characteristics Using Prototype Moving Barriers
David J. King, Mark Bailey, Authors

We use moving barriers in the study of side and rear-end collision studies at magnitudes where significant crush damages are induced. This paper examines the application of proposed moving barriers to low speed rear-end collisions. The authors present their proposed moving barriers and their applications to measure test vehicle bumper isolator compression in low speed rear end collisions.

While reasonable results relating to Delta V versus isolator compression were obtained by the authors, additional work is needed for the improvement of such systems.

One may also question the reasoning behind the development of a moving barrier system to study such low speed collisions, when using actual vehicles for such studies is most representative. The cost associated is only the replacement of the bumper or the bumper and the EA units will restore those vehicles to pre-test conditions.

Effects of Restitution in the Application of Crush Coefficients

Raymond R. McHenry and Brian G. McHenry

ABSTRACT

Effects of restitution on damage interpretations are compounded by the fact that restitution acts to reduce the amount of residual deformation, for a given maximum dynamic crush, while also acting to increase the total impact speed change. This paper presents a revised analytical procedure to include restitution effects for the CRASH program and refinements to the restitution modeling within the SMAC program. The conversion of vehicle impact test results into inputs for the two revised programs is also included. The effects of the refinements to the damage analysis procedures on reconstruction results are illustrated by direct comparisons with corresponding results produced by the original SMAC and CRASH programs and with measured data from full scale vehicle impact tests.

INTRODUCTION

During a motor vehicle collision, the maximum dynamic deformation generally exceeds the residual deformation. Subsequent to the peak dynamic deformation, the collision partners begin a restitution phase as the deformed structures restore kinetic energy, or "spring" back. The restitution force level and duration determine the impulse that acts on the collision partners during the restitution phase.

When an accident vehicle is examined, the residual, or permanent, deformation is observed and/or measured. The original form of damage analysis in CRASH does not include provisions for the effects of restitution. The original SMAC collision routine includes a simplified restitution model which is cumbersome to apply, can be sensitive to time increment size, and tends to over-predict the residual damage. The resulting effects on the accuracy of damage-based reconstructed values of ΔV, for the case of direct, central barrier collisions, ranges from approximately 10 to 30% underestimates, depending on properties of the specific vehicle and the extent of residual crush. For the case of oblique, non-central collisions, a similar range of effects is anticipated on the basis of indirect measures of corresponding restitution values [1, 2][1].

At the present time, crush coefficients for vehicle collision analysis are predominantly based on impact speeds and damage measurements from rigid, fixed barrier crash tests. The residual damage is correlated with the impact speed by means of fitted linear relationships. In general, there is no consideration given to the effects of restitution in applications of the fitted crush coefficients. However, the ignored effects of restitution on the total impact speed-change, corresponding to a given amount of residual crush, are compounded by the fact that restitution acts to reduce the amount of residual deformation, for a given maximum dynamic crush, while also acting to increase the total impact speed change. Thus, substantially different vehicles can share nearly equal slopes and intercepts in CRASH-type plots of the approach period speed-change as a function of residual crush. This can occur even though the actual exposure severity for a given residual crush may be significantly different.

The effects of restitution on damage interpretations became an important topic of interest in relation to recent efforts by McHenry Consultants, Inc. aimed at (a) reducing the sensitivity of restitution control in the original SMAC computer program [3] and (b) achieving significant improvements in the general accuracy level of damage interpretations. The related modifications of the SMAC and CRASH computer programs have retained the existing forms of the fitted crush coefficients. However, supplementary information regarding the restitution behavior of individual vehicles serves as the basis for refinements in the damage analysis aspects of the cited computer programs.

ANALYTICAL APPROACH

The analytical developments presented in this paper are based on limited test data that are available on the restitution behavior of automobiles in direct central collisions against rigid barriers. It is assumed herein that an analytical

1 Numbers in brackets [ ] indicate references at end of paper

model of the unit-width structural properties, in terms of the load-deflection characteristics during loading and unloading, that adequately correlates with the results of direct central collision tests, will also produce a reasonable approximation of restitution behavior in oblique, non-central collisions.

Direct measures of restitution in oblique, non-central collisions of automobiles are not known to be readily available. However, analytical procedures have been developed (e.g., Brach [1], Ishikawa [2]) to extract approximations of the effective coefficient of restitution from such test data. These approaches may provide a means of extending the current investigation to include comparisons with oblique, non-central collisions.

The assumed form of crush behavior, including restitution, is depicted in Figure 1A. The objective of the analytical developments has been to establish relationships among the variables depicted in Figure 1A and the existing CRASH coefficients A and B [4] that will **maintain the linear relationship depicted in Figure 1B**. On the basis of results of the analysis, it is concluded that the linear relationship depicted in Figure 1B can be maintained without changes in A and B, over wide ranges of properties of the form depicted in Figure 1A. Thus, the relationship of Figure 1B does not uniquely define a combination of crush and restitution properties. Restitution consists of two separate aspects: (1) a partial dimensional recovery and (2) a partial restoration of kinetic energy. The specific combination of the two restitution aspects is determined by three measures of restitution behavior from test data that serve as the basis for four fitted constants (K_1, K_2, ρ, Γ, see Appendices). The crush resistance during increasing loads, K_1, is determined by CRASH coefficients A and B and by the extent of dimensional recovery. The unit-width crush resistance during unloading, K_2, is determined by K_1 and the extent of restoration of kinetic energy. The nature and extent of effects on damage interpretations are outlined in the following paragraphs:

In Figures 2 and 3, full-frontal crush properties are depicted for two substantially different equal-width hypothetical vehicles which share identical crush coefficients (i.e., A and B in the CRASH format). Yet, at 20 inches of residual crush, the total impact speed-changes of the two vehicles differ by approximately 23% (i.e., approximately 7.3 MPH) as shown in Figure 4 and 5.

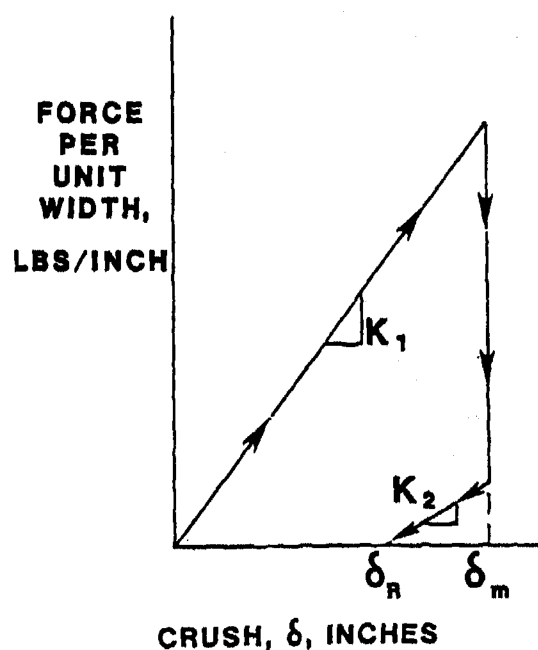

Figure 1A: Force v. Crush

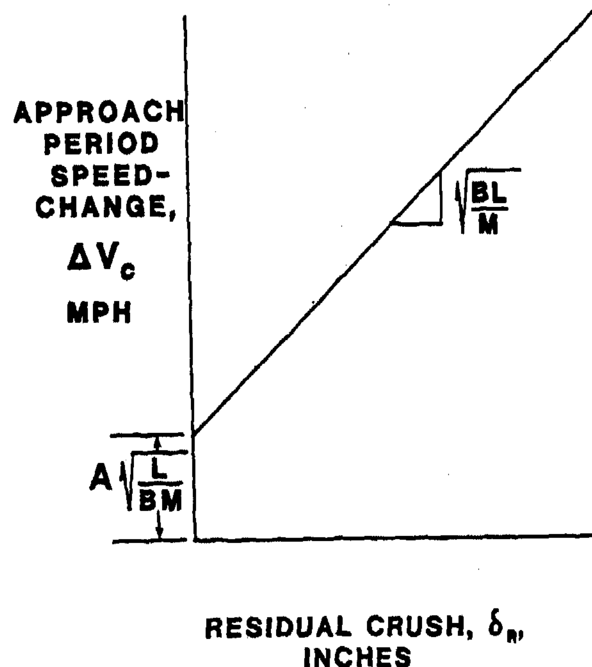

Figure 1B: Approach-Period Speed-Change vs. Residual Crush, Symmetrical Central Impacts

Figure 1 Assumed Form of Crush Behavior

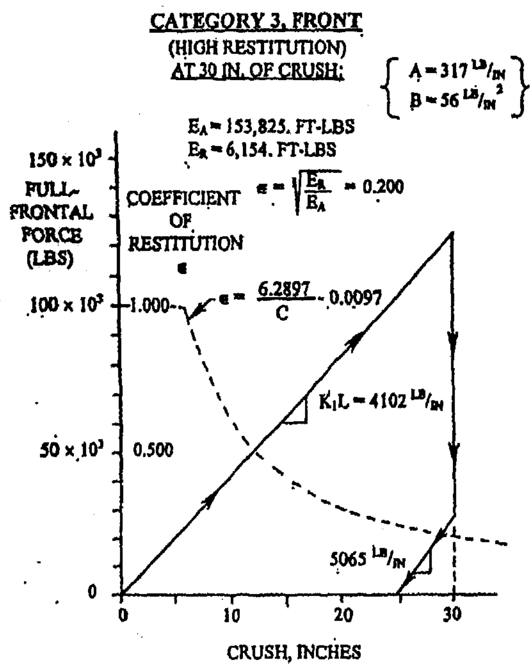

Figure 2 Full-Frontal Crush Properties

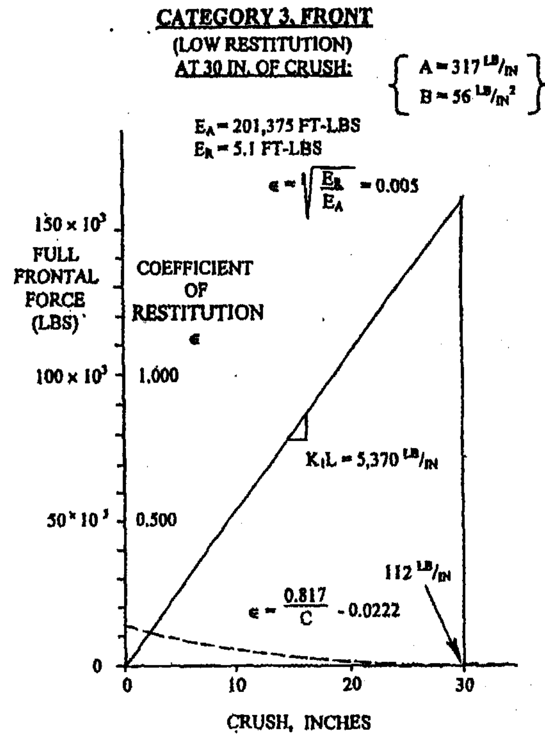

Figure 3 Full-Frontal Crush Properties

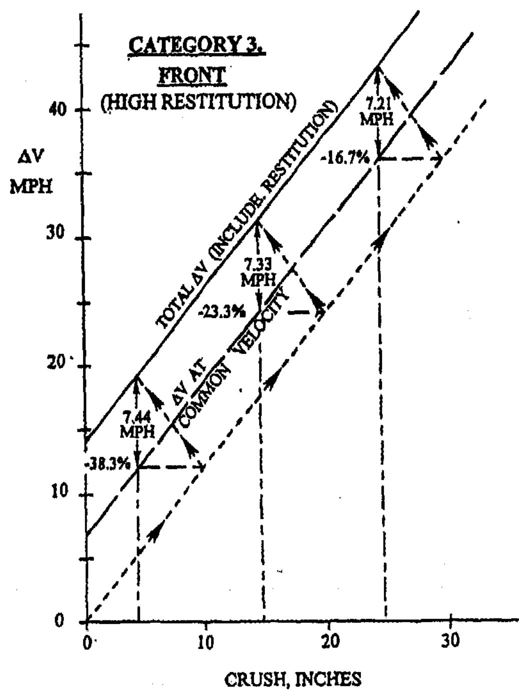

Figure 4 Impact Speed Change v. Crush, Category 3 Frontal, High Restitution

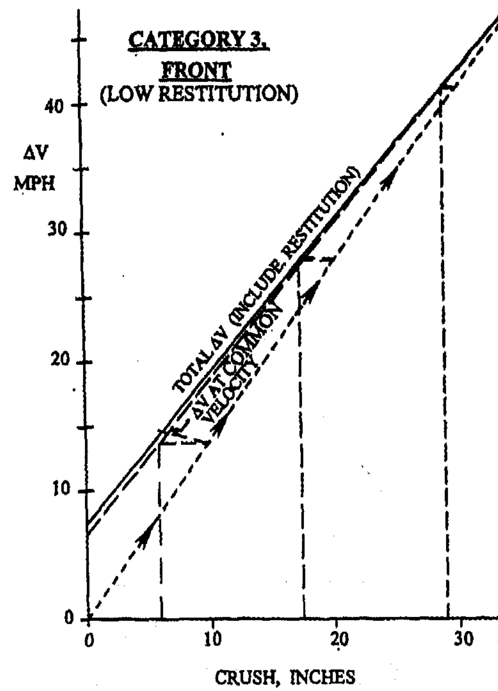

Figure 5 Impact Speed-Change v. Crush, Category 3 Frontal, Low Restitution

The vehicle properties depicted in Figures 2 and 3 are based on theoretical requirements to achieve a linear relationship between ΔV_o (i.e., the impact speed-change during the approach period) and the residual crush. To the extent that such a linear relationship constitutes a reasonable approximation of actual behavior, the underlying crush resistance and restitution definitions of Figures 2 and 3 are supported. It should be noted that the low-restitution vehicle of Figure 3 is approximately 31% stiffer than the high-restitution vehicle of Figure 2. Yet the crash behavior of each vehicle is defined by identical values of the current crush coefficients:

per reference [5]:

$$A = 317 \text{ LB/IN}$$

$$B = 56 \text{ LB/IN}^2$$

per reference [6]:

$$b_0 = 6.741 \text{ MPH}$$

$$b_1 = 1.191 \text{ MPH/IN}$$

In view of the significantly different values for the total ΔV at given values of residual crush as demonstrated in Figures 4 and 5, it is obvious that the current crush coefficients must be supplemented with restitution information. It should be noted that an absence of restitution throughout the entire range of deformation would produce zero values for the fitted coefficients A and b_0.

COMPARISON OF RESTITUTION IN ORIGINAL AND REVISED SMAC

At the time of development of the original SMAC computer program, (1972, Reference [3]) emphasis was on demonstration of the feasibility of the overall concept. The selected analytical approach to restitution at that time (presently retained in both original SMAC and EDSMAC) included the use of extensive simplifying assumptions aimed at reducing the requirements for associated computer memory and logic. In particular, identical load-deflection rates were applied for loading and unloading of the individual radial vectors, that define the collision interface, and the unloading was implemented at force levels close to the peak values [7]. As a part of the selected simulation approach, the "unloaded" lengths of the individual vectors were adjusted at each time increment during increases in loading. The associated coding thereby avoided any needs for logic to detect the end of loading at the individual radial vectors and for additional memory to store related information. The selected original approach permits reasonable control of restitution over a limited operating range about a given value of deformation for which restitution information is available. However, the high load level during restitution makes the simulation excessively sensitive to time-increment size. It is also cumbersome to apply and it tends to over-predict the residual damage.

Since the early 1990's the extent of limitations on logic and memory, that are imposed by readily available computers, are substantially reduced. Also, the available data on restitution behavior have been increased. Therefore, the collision routine of SMAC has been modified to achieve improvements in reconstruction accuracy. Results representative of the changes in restitution and in the ratio of residual to maximum dynamic crush, each as a function of the maximum dynamic crush and the residual crush, are depicted in Figures 6A and 6B, respectively

The ratio, δ_f/δ_m, clearly must vary from zero, at zero residual crush, to 1.000 at that value of residual crush where there is no further restitution. Figure 6B shows that original SMAC (EDSMAC) does not vary the ratio of δ_f/δ_m as a function of δ_f in a realistic manner.

It is obvious from Figures 6A and 6B that the ratio of (δ_f/δ_m) from the original SMAC program (or the equivalent ratio (C_R/C_T) in [8]) should not be used as a basis for determining the appropriate K_V value for the SMAC program corresponding to the fitted CRASH coefficients A and B. If a measured value of $(\delta_f/\delta_m)_1$ for a given maximum dynamic crush value, $(\delta_m)_1$ is available from a crash test, equation (8) in Appendix 1 can serve to define the appropriate K_v for given values of A and B.

Implementation of a revised damage analysis procedure, that includes restitution effects, was outlined for the CRASH computer program in [9]. A corresponding revision, which was recently incorporated in the SMAC computer program, has been applied to generate the responses presented on the following pages. Detailed analytical relationships are presented in the Appendices.

RESULTS

Damage-Based Reconstructions of Delta-V (ΔV)

In the following comparisons of (1) reconstruction results obtained with the original CRASH (EDCRASH) program and the revised CRASH program and also (2) reconstruction results obtained with the original SMAC (EDSMAC) program and the revised SMAC program, the differences in damage-based ΔV values are produced entirely by the inclusion of realistic restitution properties in a fully defined hypothetical vehicle. Neglect of restitution effects constitutes an analytical error since it involves the total omission of a significant aspect of the collision, particularly at impact speed changes below 30 mph.

In the application of any reconstruction technique to physical evidence there are many potential sources of error which must be properly taken into account. The presented comparisons isolate the changes in reconstruction results that are produced by effects of restitution.

It should be noted that meaningful direct comparisons of theoretical results with test data require that the accuracy and the repeatability of the test data be established. Also, such comparisons yield the total error from the combined sources.

A comparison of results obtained with the original CRASH program and the revised CRASH program for a defined hypothetical vehicle is presented in Figure 7. The figure illustrates the fact that an application of the original CRASH damage analysis procedure can produce ΔV errors (i.e., underestimates) in the range of 10-30%.

A comparison of results obtained with the NHTSA SMAC (EDSMAC) program and the revised SMAC program for the same hypothetical vehicle is presented in Figure 8. The figure illustrates the fact that an application of the NHTSA SMAC (EDSMAC) program for damage analysis purposes can also produce ΔV errors (i.e., underestimates) in the range of 10-30%.

The original form of restitution control in the SMAC program acts to return part of the absorbed energy but it does so with a less-than-actual dimensional recovery (Figure 9, Figure 10). As a result, a purely damage-based determination of ΔV by means of the original SMAC program tends to underestimate the true value of ΔV due to the fact that the residual damage for a given ΔV is overestimated. The cited error source in damage interpretations in original SMAC has led to some misguided adjustments in the crush stiffness (e.g., [10]) to achieve a match of predicted damage extent.

A comparison of the results obtained by the various versions of SMAC and CRASH are combined on Figure 11. It should be noted that the results for the revised versions of SMAC and CRASH are identical. The retention of an excessive amount of predicted residual damage by original SMAC makes the ΔV errors at low speeds somewhat greater than those of original CRASH.

Comparison of the Mathematical Model of Crush Behavior with Test Data

The lack of exact repeatability of full scale crash test results introduces "scatter" in comparisons of the detailed results of multiple tests. Measurements related to restitution behavior have been found to include an unusually large amount of scatter, particularly at low values of impact speed-changes. The effective coefficient of restitution can include significant effects of forces that are external to the two-body collision system. For example, in an SAE barrier crash, damaged running gear (e.g., jammed or impeded front wheels) can produce significant drag forces that act to reduce the rebound velocity, particularly at low levels of returned energy. Also, energy absorbers on bumpers can act to delay the return of a portion of the absorbed energy.

The mathematical model defined herein addresses the responses of the vehicle structure only. The magnitude of the effects of external forces on individual full-scale tests has not been measured. In the absence of special tests that measure the isolated responses of the structure only (e.g., tests run on casters), it is necessary to focus attention on correlation with the higher returned-energy end of the available measured responses.

While some comprehensive test data from individual tests are available, test series over a range of impact speeds with comprehensive reporting are still relatively rare.

In Figure 12, comprehensive test data from a series of four tests of '79 through '82 Ford LTDs [11] are compared with the fitted mathematical model. In Figure 13, test data for six '81-'85 Ford Escorts [12] which did not include reporting of the ratio of residual to maximum crush, are compared with the fitted mathematical model. In Figure 14, test data from a series of five tests on 1975-1979 VW Rabbits [13] which did not include reporting of the coefficient of restitution are compared with the fitted mathematical model.

Note that the measurements of different aspects of restitution behavior in crash tests that are presented in Figures 12, 13 and 14 include scatter produced at least in part by the previously cited effects.

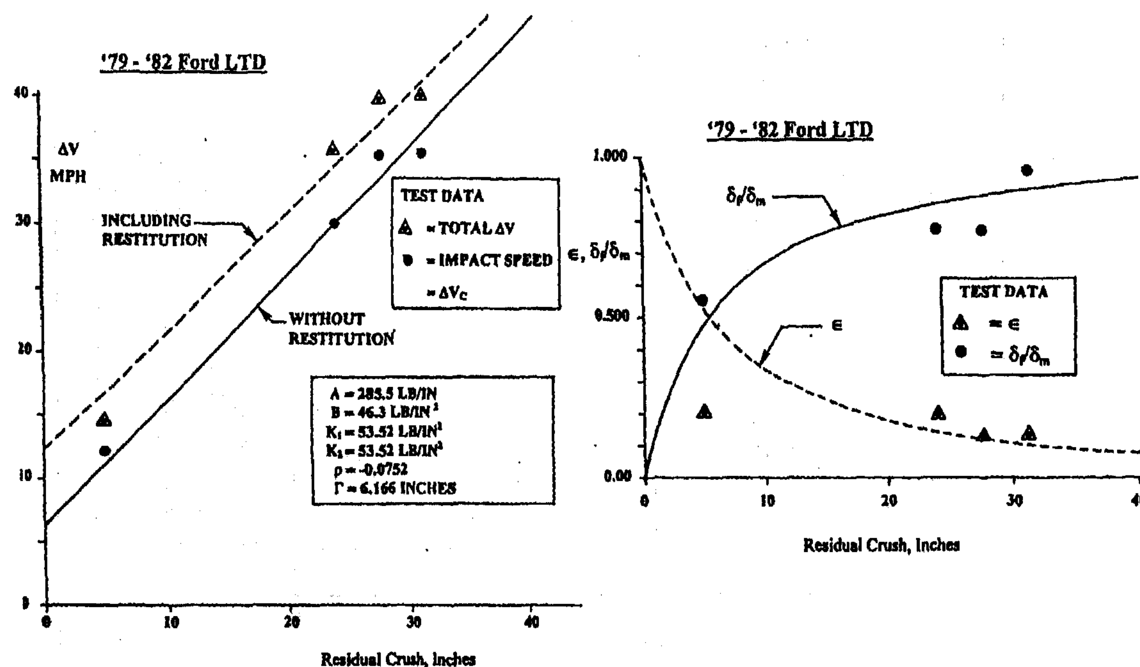

Figure 12 Comparison of Mathematical Model with Ford LTD Tests [11]

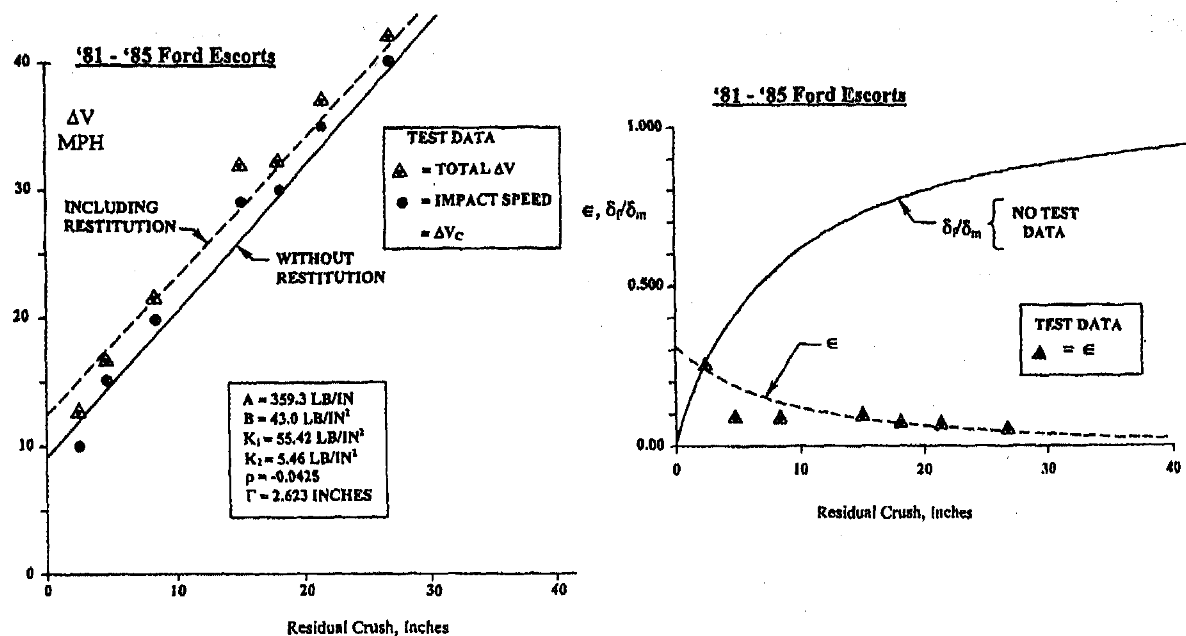

Figure 13 Comparison of Mathematical Model with Ford Escort Tests [12]

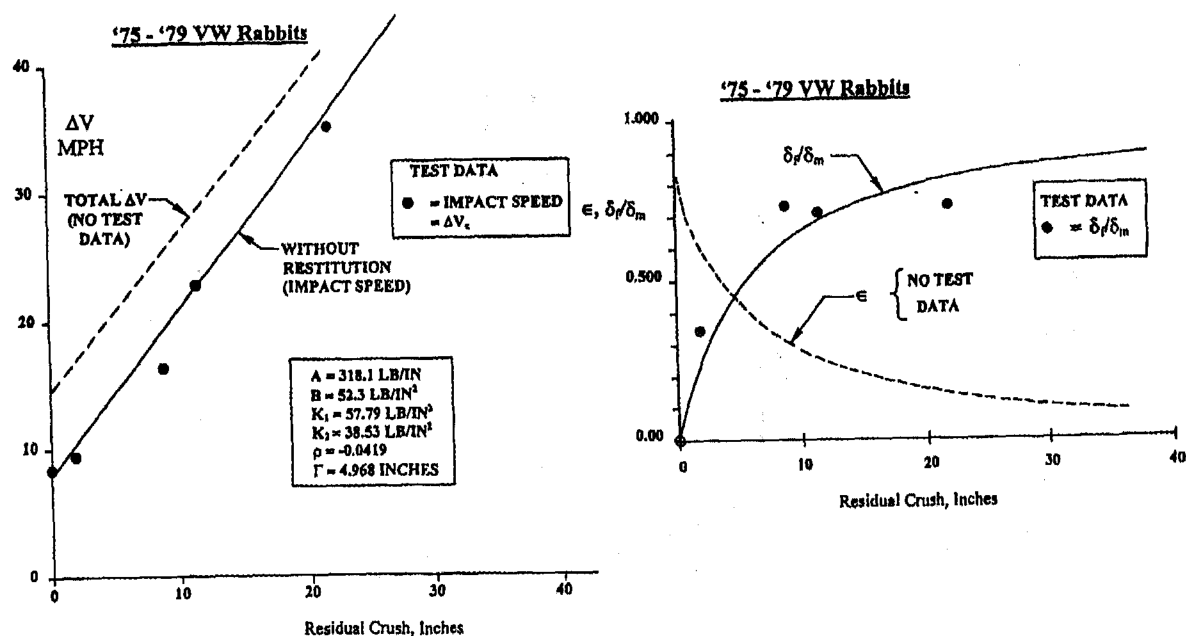

Figure 14 Comparison of Mathematical Model with VW Rabbit Tests [13]

Collisions between Vehicles with Different Restitution Properties

In Figure 15 the results of a 30 MPH head-on mirror image collision, simulated with the revised SMAC program, are displayed. Note that in the simulated collision of Figure 15, the restitution properties of the collision partners are identical. Figure 16 depicts the simulated results with the revised SMAC program of a head-on 27 MPH collision between a high restitution and a low restitution vehicle. Note that the effective restitution is an intermediate value.

In the SMAC implementation, force equilibrium is maintained between the interacting structures of the collision partners at all points within the contact zone throughout the unloading process. By this means, the two vehicles continue to interact during the unloading process until they each reach their residual values of crush at all contact points.

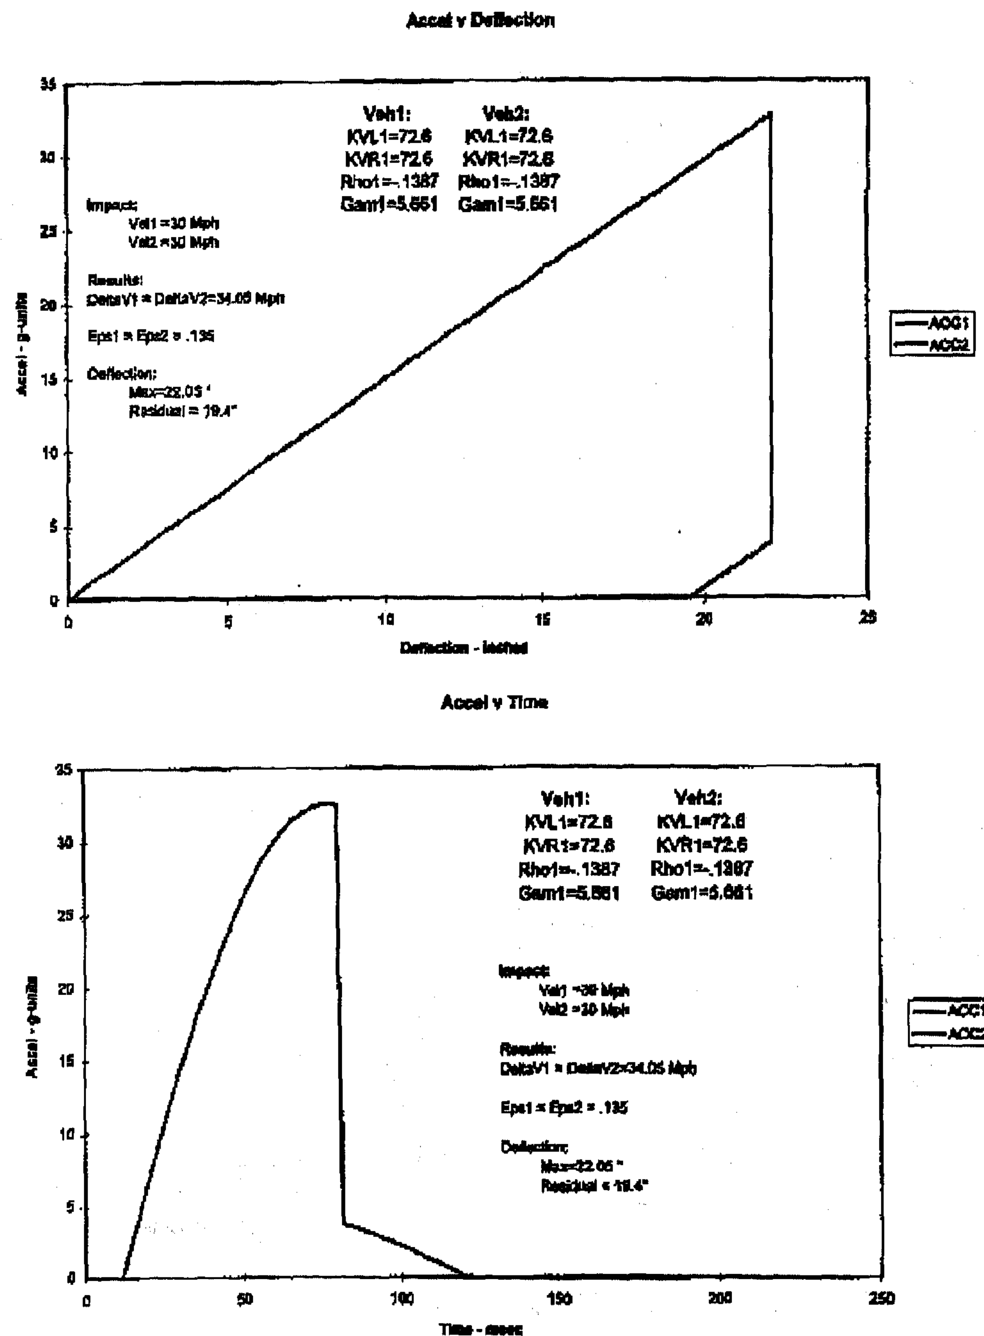

Figure 15 Example Response characteristics of revised SMAC collision routine, 30 MPH Head-On Mirror Image Vehicles

In the CRASH implementation [9], the restored energy for each of the collision partners is separately calculated by means of integrations across the damage interface. The resulting values are added together and then combined with the total absorbed energy for application in the calculation of ΔV_1 and ΔV_2.

In each form of implementation, the effective overall coefficient of restitution in a given collision includes effects of the width and location on each vehicle of the contact area, the detailed damage profiles, and the individual unit-width crush properties of the collision partners. This combination of effects is believed to constitute a realistic analytical representation of the actual physical system during the unloading process.

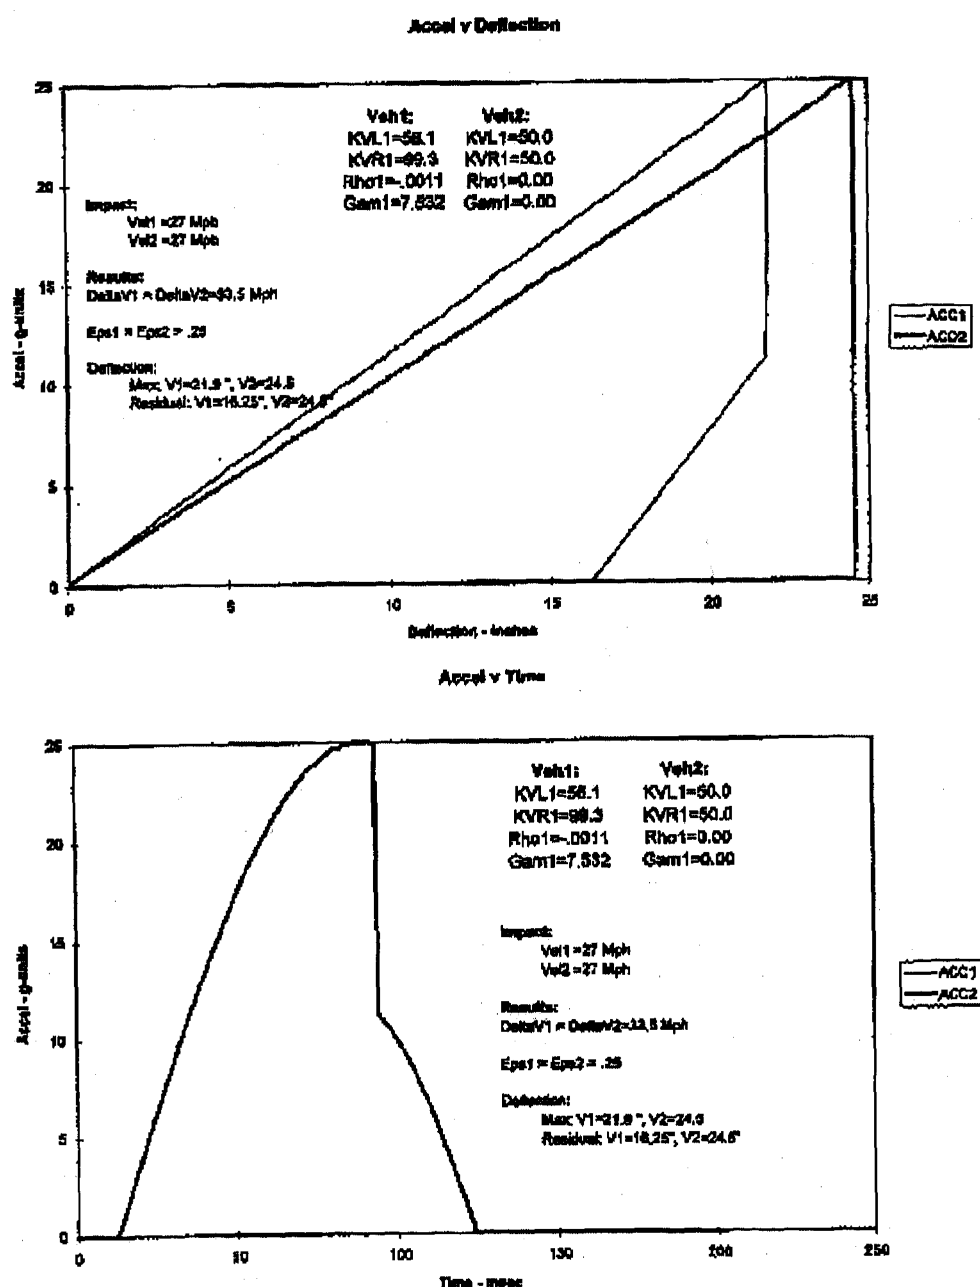

Figure 16 Example Response characteristics of revised SMAC collision routine, 27 MPH Head-On, High and Low Restitution Vehicles.

CONCLUSIONS AND RECOMMENDATIONS

1. Damage analyses which make use of either the original SMAC or CRASH programs produce lower-than-actual values for the impact speed-change, with the maximum errors occurring at low speeds where restitution is greatest. The original CRASH (EDCRASH) does not, of course, include restitution. The simplistic form of simulation of restitution in the original SMAC (EDSMAC), which restores a portion of the crush energy as needed in a time-history solution form, does so in a manner that retains an excessive amount of predicted residual damage. As a result, the error in a purely damage-based ΔV is somewhat greater for SMAC than CRASH at low speeds and somewhat less at high speeds.

2. The developed implementations for both SMAC and CRASH of a revised damage-based procedure that includes restitution have been shown to be capable of producing significant improvements in the accuracy of reconstruction results. They also can serve to insure compatibility of the inputs that define crush properties for the SMAC and the CRASH forms of analysis.

3. The revised damage analysis procedures for CRASH and SMAC provide a unique capability for entering separate definitions of the restitution properties of collision partners.

4. The limited comparisons of the mathematical model of crush behavior with test data that have been possible to date indicate a reasonable degree of correlation. The general form of the mathematical model is dictated by the assumption of a linear relationship between the Delta-V preceding restitution (i.e., to the point of a common velocity) and the residual crush. It should be noted that the specific analytical approach that is defined in Appendices 1 and 2 is not inherently limited to the case of a linear force-deflection characteristic. Modification of the modeled crush behavior to include a saturating force could be readily accomplished if corresponding test data were to become available.

5. The reported research results are considered to constitute an important demonstration of a means of achieving significant improvements in reconstruction accuracy. The restitution aspects of test data needed to fully utilize the described refinements are sometimes included in test reports. They should be made to be a routine part of crash test reports.

APPENDIX 1: Fitting of Crush Properties to Crash Test Data

Definition of Symbols:

CRASH3 Crush Coefficients, Ref. [5]:

A = Intercept, Lb./Inch

B = Slope, Lb./In^2

Campbell Coefficients, Ref. [6]:

b_o = Intercept, Miles per hour

b_1 = Slope, Miles per hour/inch

E_a = Absorbed energy, inch-lb.

E_r = Restored energy, inch-lb.

Figure A1:

F = Crush resistance force, Lb.

F' = Virtual crush resistance force, Lb.

K_1 = Crush resistance per unit width for increasing loads, lb./in^2

K_2 = Crush resistance per unit width for decreasing loads, lb./in^2

K_v = SMAC crush resistance, Lb./in^2 Ref. [3]

L = Contact width, inches

M = Mass, lb.-sec^2/in

V_c = Common velocity of contact regions at end of approach period of collision, inches/sec

V_o = Initial velocity, inches/sec.

V_f = Final (separation) velocity, inches/sec

ΔV_c = Impact speed-change during the approach period of the collision, inches/sec

ΔV = Total impact speed-change, inches/sec.

δ = Crush, inches.

δ_f = Residual crush, inches.

δ_m = Maximum dynamic crush, inches

Γ = Restitution constant.

ε = Coefficient of restitution

ρ = Restitution constant.

To the extent that the approach-period impact speed change, ΔV_c, can be reasonably approximated as a linear function of the residual crush, δ_f, the corresponding relationship between the coefficient of restitution, ε, and the maximum dynamic crush, δ_m, must be defined in the form:

$$\varepsilon = \frac{\Gamma}{\delta_m} + \rho \qquad (1)$$

$\{$ if $\varepsilon > 1.00$, $\varepsilon = 1.00$ $\}$

where ρ and Γ are fitted constants.

While the fitted A and B coefficients of CRASH are retained to define ΔV_c as a linear function of δ_f, those coefficients are supplemented by measures from crash tests of the restitution behavior. The combined crash test information is applied in the form of a total of four fitted constants:

K_1, K_2, ρ, Γ

The fitting procedure consists of following:

From measured data in crash tests, a test condition is selected at which the restitution behavior is to be matched. For that selected condition the maximum dynamic crush, $(\delta_m)_1$, the ratio of residual crush to maximum dynamic crush, $(\delta_f/\delta_m)_1$, and the corresponding coefficient of restitution, $(\varepsilon)_1$, are determined to supplement A and B. The four fitted constants are then calculated:

$$K_2/K_1 = \left\{\frac{(\varepsilon)_1}{1-\left(\delta_f/\delta_m\right)_1}\right\}^2 \qquad (2)$$

$$\Gamma = \frac{A}{B}\sqrt{\frac{K_2}{K_1}} \qquad (3)$$

$$\rho = (\varepsilon)_1 - \frac{\Gamma}{(\delta_m)_1} \qquad (4)$$

$$K_1 = B\left(1-\rho\sqrt{\frac{K_1}{K_2}}\right)^2 \text{ LB/IN}^2 \qquad (5)$$

$$K_2 = K_1\left(\frac{K_2}{K_1}\right) \text{ LB/IN}^2 \qquad (6)$$

The lack of exact repeatability of crash test results makes it clearly necessary to rely on multiple crash tests for a definition of crash behavior and to deal with the scatter of the results by means of statistical procedures. Measurements related to restitution behavior have been found to include an unusually large amount of scatter, particularly at low levels of returned energy (for example, see comparisons with test data elsewhere in this paper).

In view of the preceding, it is highly desirable to use regression analysis on multiple data points, to insure that the selected test condition is representative of the overall measurements of behavior. In the case of multiple data points, linear regression is first used to define the coefficients of equation (18) of Appendix 2, and, thereby, A and B. Next, the coefficient of δ_m in equation (9) of Appendix 1 is established by means of a fit to the reported values of δ_f and δ_m with an intercept at -A/B. A value for $(\delta_m)_1$ is selected and the corresponding values of $(\delta_f)_1$ and $(\delta_f/\delta_m)_1$ are calculated from the fitted equation (9). The measured value of $(\varepsilon)_1$, corresponding to $(\delta_m)_1$, is established and entered.

As more measurements of restitution behavior become available, it may become possible to establish patterns in the fitted constants for different vehicle types.

The physical significance of the fitted constants may be seen in Figures A1 and A2.

In Figure A1, it should be noted that the peak values of forces, F and F' are not identical. The plot of F' against deflection must be recognized to constitute a virtual force deflection, since the force and the deflection do not exist at the same time. It can be shown analytically that the ratio of the peak forces in Figure A1 is defined by the following:

$$\left(F/F'\right)_{PEAK\ \text{VALUES}} = \sqrt{\frac{K_1}{B}} \qquad (7)$$

The unit-width crush stiffness for increasing loads can also be established from the following relationship, which is independent of the extent of restored energy and, thereby, of the restitution coefficient:

$$K_1 = \frac{1}{B}\left\{\frac{A}{(\delta_m)_1} + B\left(\delta_f/\delta_m\right)_1\right\}^2 \quad \text{LB/IN}^2 \qquad (8)$$

Sample applications of equation (8) are presented in Fig. A3.

Further analytical relationships include the following:

$$\delta_f = \delta_m\sqrt{\frac{K_1}{B}} - \frac{A}{B} \quad \text{INCHES} \qquad (9)$$

$$\delta_f/\delta_m = \frac{\sqrt{K_1/B}}{\left(1+\frac{A}{B\,\delta_f}\right)} \qquad (10)$$

$$\rho = \sqrt{\frac{K_2}{K_1}}\left(1-\sqrt{\frac{K_1}{B}}\right) \qquad (11)$$

$$\varepsilon = \frac{\frac{A}{B}\sqrt{\frac{K_2}{B}}}{\left(\delta_f+\frac{A}{B}\right)} + \rho \qquad (12)$$

The relationship of the four fitted constants to A and B may be further defined:

$$B = \frac{K_1}{\left(1-\rho\sqrt{\frac{K_1}{K_2}}\right)^2} \quad \text{LB / IN}^2 \qquad (13)$$

$$A = B\Gamma\sqrt{\frac{K_1}{K_2}} \quad \text{LB / IN} \qquad (14)$$

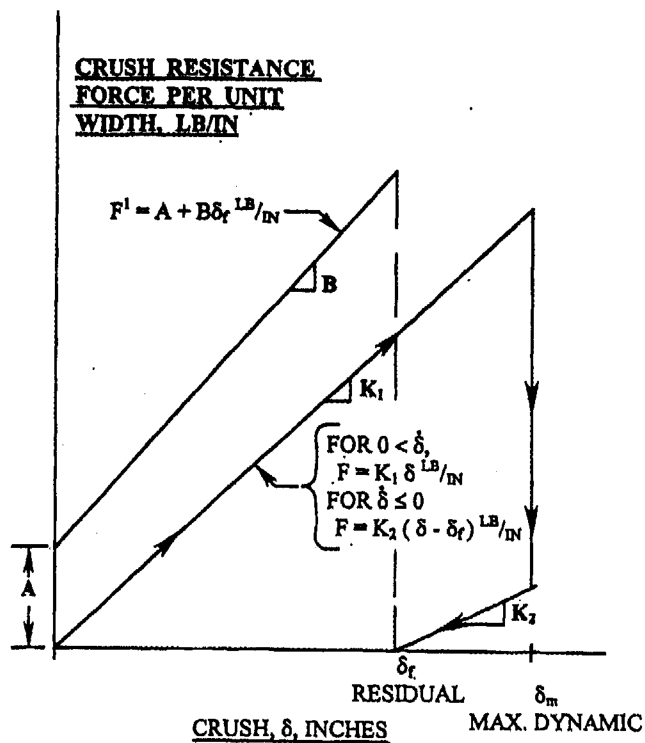

Figure A1: Crush Resistance Force Per Unit Width, Lb/In

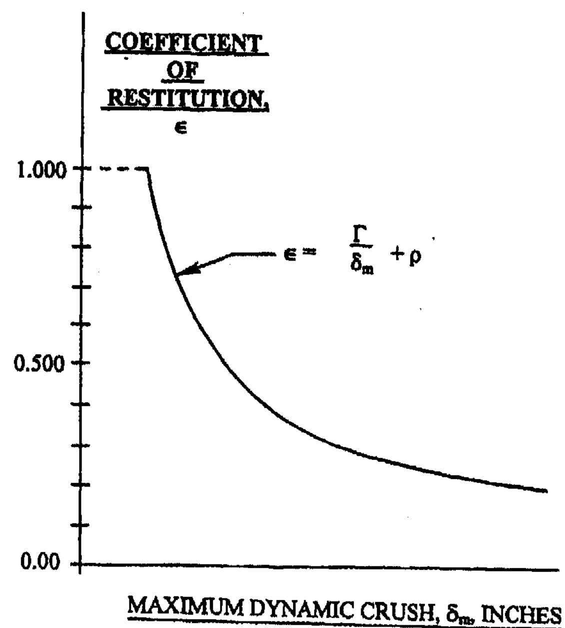

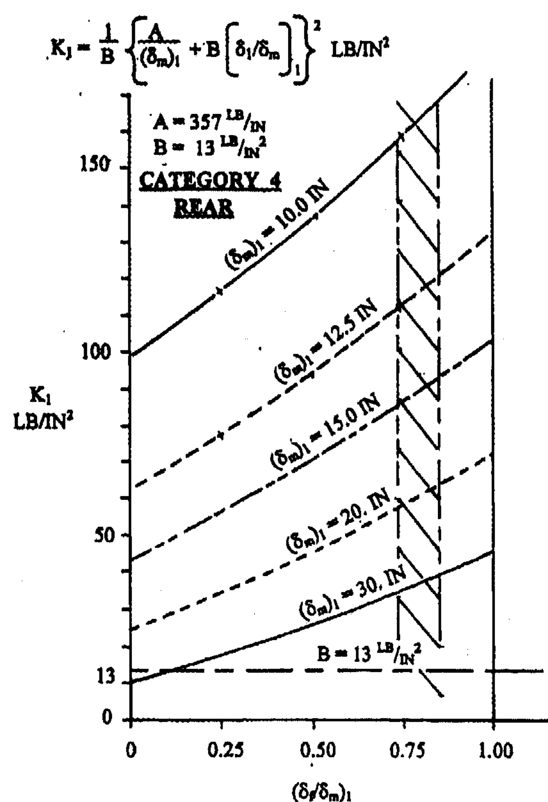

Figure A2: Coefficient of Restitution, ε

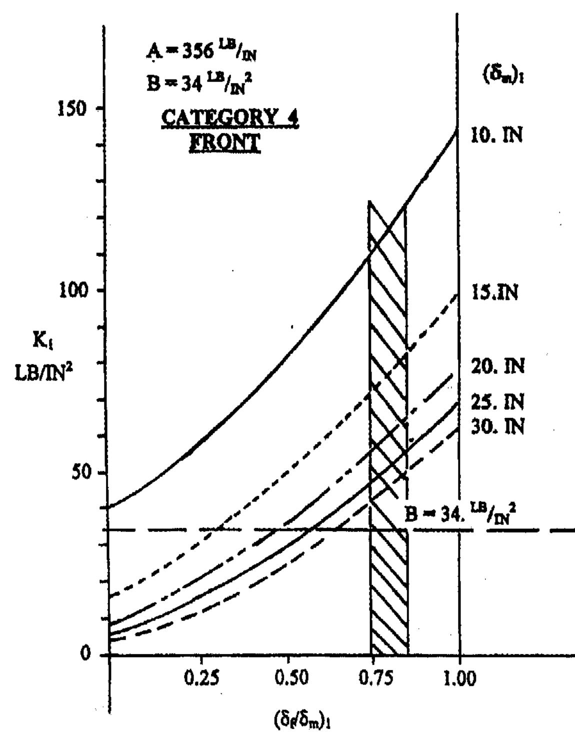

Figure A3: Loading Stiffness vs. Residual/Max Crush Ratio

APPENDIX 2: Derivation of Equations

From Figure A1, the ratio of returned to absorbed energy may be expressed:

$$\frac{E_R}{E_A} = \frac{K_2(\delta_m - \delta_f)^2}{K_1\delta_m^{\,2}} = \frac{K_2}{K_1}\left(1 - \frac{\delta_f}{\delta_m}\right)^2 \quad (15)$$

Since the coefficient of restitution is equal to the square root of the energy ratio,

$$\varepsilon = \sqrt{\frac{E_R}{E_A}} = \left(1 - \frac{\delta_f}{\delta_m}\right)\sqrt{\frac{K_2}{K_1}} \quad (16)$$

Solving (16) for δ_f,

$$\delta_f = \delta_m\left(1 - \varepsilon\sqrt{\frac{K_1}{K_2}}\right) \quad (17)$$

In order for ΔV_c at a given value of residual crush, δ_f, to be equal in the CRASH and SMAC forms of analysis (see Figure A1), the relationship between δ_f and δ_m must be defined by the following two equations:

$$\Delta V_c = A\sqrt{\frac{L}{BM}} + \delta_f\sqrt{\frac{BL}{M}} \quad (18)$$

$$\Delta V_c = \delta_m\sqrt{\frac{K_1 L}{M}} \quad (19)$$

From (18) and (19),

$$\delta_f = \delta_m\sqrt{\frac{K_1}{B}} - \frac{A}{B} \quad (20)$$

$$\frac{d\delta_f}{d\delta_m} = \sqrt{\frac{K_1}{B}} \quad (21)$$

From equation (17),

$$\frac{d\delta_f}{d\delta_m} = \frac{\delta_f}{\delta_m} - \delta_m\sqrt{\frac{K_1}{K_2}}\frac{d\varepsilon}{d\delta_m} \quad (22)$$

$$\frac{d^2\delta_f}{d\delta_m^2} = -\sqrt{\frac{K_1}{K_2}}\left(\delta_m\frac{d^2\varepsilon}{d\delta_m^2} + 2\frac{d\varepsilon}{d\delta_m}\right) \quad (23)$$

Since $\frac{d\delta_f}{d\delta_m}$ = constant, $\frac{d^2\delta_f}{d\delta_m^2} = 0$.

Solution of (23), for $\frac{d^2\delta_f}{d\delta_m^2} = 0$, yields:

$$\varepsilon = \frac{\Gamma}{\delta_m} + \rho \quad (24)$$

From (24), (22), and (21),

$$\frac{\delta_f}{\delta_m} + \frac{\Gamma}{\delta_m}\sqrt{\frac{K_1}{K_2}} = \sqrt{\frac{K_1}{B}} \quad (25)$$

From (20)

$$\frac{\delta_f}{\delta_m} = \sqrt{\frac{K_1}{B}} - \frac{A}{B\delta_m} \quad (26)$$

Substitution of (26) into (25) yields:

$$\Gamma = \frac{A}{B}\sqrt{\frac{K_2}{K_1}} \quad (27)$$

The ratio K_2/K_1 is defined on the basis of equation (16):

$$\frac{K_2}{K_1} = \left(\frac{\varepsilon_1}{1 - (\delta_f/\delta_m)_1}\right)^2 \quad (28)$$

where $(\varepsilon)_1$ and $(\delta_f/\delta_m)_1$ are obtained from crash test data for the specific vehicle for which crush properties are being defined.

From equation (24),

$$\rho = (\varepsilon)_1 - \frac{\Gamma}{(\delta_m)_1} \quad (29)$$

where $(\varepsilon)_1$ and $(\delta_m)_1$ are obtained from crash test data for the specific vehicle for which crush properties are being defined.

From equations (25), (17) and (24):

$$K_1 = B\left\{1 - \rho\sqrt{\frac{K_1}{K_2}}\right\}^2 \quad (30)$$

APPENDIX 3: Clarifications

The review process has revealed several points that may be confusing to some readers. The following is aimed at clarification of those aspects of the paper:

1. The existence of significant errors related to restitution that are present in both the original CRASH (EDCRASH) and original SMAC (EDSMAC) computer programs must be acknowledged. It is common knowledge that the original CRASH (EDCRASH) program underestimates the ΔV in barrier crashes by approximately 10 to 20% at 30 MPH and by a greater amount at lower speeds as a result of the fact that restitution is completely ignored. The original SMAC (EDSMAC) form of simulation of restitution is crude, with rarely changed inputs, and it cannot rationally be expected to produce reliable and accurate combinations of dimensional recovery and partial return of absorbed energy for all vehicles under all collision conditions. In fact, its under-prediction of structural recovery produces a similar range of underestimates of ΔV. Thus, the status quo regarding restitution effects in existing computer programs is very difficult to defend on a logical basis.
2. The ranges of errors (underestimates) indicated in the paper for damage-based ΔV values from the original CRASH and SMAC programs, that are produced either by a total neglect of restitution (CRASH) or by under-prediction of structural recovery (SMAC) are intended to provide the reader with approximate measures of the practical significance of the effects of restitution.
3. On the basis of Figures 2, 6A, and A2 as well as the closely related SAE 861894 it should be clear that ε is set to 1.000 whenever the calculated value exceeds 1.000. Therefore any concern about an "infinite limit" for ε is unfounded.
4. The modeled value of ε, at zero residual crush, is not necessarily equal to 1.000. Rather, it is defined by equation (16):

$$\varepsilon = \sqrt{\frac{E_R}{E_A}} = \left(1 - \frac{\delta_f}{\delta_m}\right)\sqrt{\frac{K_2}{K_1}}$$

   Results of applications of equation (16) to test data where the limiting value of ε was substantially less than 1.00 are shown in Figures 13 and 14. In Figure 13, the restitution coefficient for the Escort never exceeds 0.314. In calculations related to Figure 13 performed by one reviewer the value of ε was incorrectly set equal to 1.00.
5. Energy is absorbed whether or not a structure is elastic. It is the extent of return of the absorbed energy that distinguishes elastic from inelastic behavior.
6. The term "damage" in this paper is used to refer to the generally accepted residual crush, as opposed to any cosmetic disfigurement of "fragile body parts".
7. The general form of the A,B crush coefficients used in the CRASH(EDCRASH) program implies an effective elastic deformation range, in terms of full dimensional recovery, equal to A/B.
8. The lack of exact repeatability of individual measurements in crash tests that are performed under identical test conditions acts to produce ranges of measured responses rather than single values. For this reason, rigorous measures of reconstruction accuracy must be based on the mean experimental measurements for a given set of test conditions.
9. Available experimental measurements of restitution behavior over ranges of impact speed (e.g., Figures 12, 13, and 14) include only single measured values at the individual test conditions. Clearly, progress toward a rigorous and complete validation study is data-limited at the present time.

SAE #970960
Reviewer Discussion
by Raymond M. Brach, University of Notre Dame
Effects of Restitution in the Application of Crush Coefficients
Raymond G. McHenry, Brian G. McHenry, Authors

Many methods used by accident reconstructionists to estimate collision speeds assume that vehicle structures are perfectly plastic with insignificant rebound. For some collision configurations and for low speed collisions, this is not true. The authors present an approach to model the way in which restitution takes place within a vehicle structure during a collision. Restitution is viewed as the process of restoration of kinetic energy from strain energy following the maximum normal deformation. The model takes into account the variation of restitution with the severity of a collision by modeling it as a function of the maximum crush, using an equation with constants determined by crash test data. Restitution varies from location to location over a vehicle's periphery and varies from vehicle to vehicle. These variations are taken into account through suitable selection of test conditions. The model averages the restitution over the lateral extent of crush and ultimately yields refined values of crush coefficients for SMAC and CRASH.

The approach is interesting and forms a workable model of an extremely complex problem. Before being adapted for widespread use, the accuracy of the method needs to be verified more extensively than done in the paper, especially for low speed collisions. Additional issues may need to be investigated such as differences in restitution between car-to-barrier and car-to-car collisions. Another is the (potentially large) amount of experimental data needed to completely characterize a single vehicle.

Readers should note that the coefficient of restitution used in this paper is not the same as the one used in the impulse and momentum analysis of vehicle collisions. In this paper it is used to model the local behavior of the *structure*; in collision analysis it is used to represent the total energy loss of a *collision.*

SAE #970960
Reviewer's Discussion
by James A. Neptune, J_2 Engineering, Inc.
Effects of Restitution in the Application of Crush Coefficients
Raymond R. McHenry, Author

The authors' revised model for restitution takes a step in the right direction. The revised model, however, is not entirely realistic. As a result, it may not correctly represent a vehicle's crush response characteristics.

The revised model for restitution in figure 6A is a completely elastic crush response (ε=1.0) through the first several inches of dynamic crush. Completely elastic dynamic crush is a theoretical condition. In the real world, restitution may approach the theoretical magnitude of 1.0 but will never equal 1.0. Restitution is a mathematical "limit." The limit of the magnitude of restitution is 1.0 as dynamic crush approaches zero. Therefore, it is not realistic for the first several inches of dynamic crush to be completely elastic. In addition, the revised equation for restitution (appendix 1, equation 1) is an "infinite limit," or asymptote, where restitution (ε) becomes infinite as dynamic crush (δ_m) approaches zero. This equation is not realistic. If this model is implemented in a computer program, hopefully the program will provide the necessary limit not present in equation (1).

The crush response of the high restitution hypothetical vehicle in figure 2 is completely elastic through the first 6.2 inches of crush. A completely elastic crush response (ε=1.0) through the first 6.2 inches of crush is not realistic. Clearly front bumpers, with rare exception, do not extend 6.2 inches beyond easily damaged vehicle components such as the fenders and hood (note: any residual damage means $\varepsilon \neq 1.0$). Also "energy absorbing" bumpers that are present on vehicles "absorb energy" and, therefore, are not completely elastic. In addition, the vehicle in figure 2 would begin to develop residual crush (ε<1.0) after the first 5.6 inches of dynamic crush. This means that, between 5.6 inches and 6.2 inches of dynamic crush, the vehicle's crush response is partially plastic (ε<1.0) yet at the same time is completely elastic (ε=1.0). This is impossible.

Considering the above, the conclusions and graphs that are drawn from analyzing the hypothetical vehicles are subject to question (Analytical Approach section, figures 4 & 5). If the revised restitution model can produce a vehicle that could not exist in the real-world, can one be certain that the revised coefficients will correctly represent a vehicle's crush response characteristics when applied to a real-world vehicle?

Figure 2 Calculations:

Use equation (1), set ε=1.0 and solve for δ_m. $$\delta_m = \frac{6.2897}{1.0 + 0.0097} = 6.2 \text{ inches.}$$

Use $K_1 = \frac{4102}{72} = 57$ lb/in^2 & equation (9), set δ_f =0 and solve for δ_m. $$\delta_m = \frac{317}{56}\sqrt{\frac{56}{57}} = 5.6 \text{ inches.}$$

Or set equation (9)=equation (16), set δ_f =0 and solve for δ_m. $$\delta_m = \frac{6.2897}{\sqrt{\frac{5065}{4102} + 0.0097}} = 5.6 \text{ inches.}$$

The revised coefficients for 1979-82 Ford LTD's (figure 12) indicate that the first 5.7 inches of dynamic crush is completely elastic with no energy being absorbed by the vehicle's structure [use equation (1), set ε=1.0 and solve for δ_m]. Does this correctly represent this vehicle's crush response characteristics?

In figure 13 the revised coefficients for 1981-85 Ford Escort's would indicate the first 2.5 inches of dynamic crush is completely elastic [use equation (1), set ε=1.0 and solve for δ_m] and that a dynamic crush of 7.4 inches would occur before the onset of residual crush [use equation (9), set δ_f =0 and solve for δ_m]. Can this vehicle's front end structure flex rearward through 7.4 inches with no residual damage? Wouldn't the easily damaged vehicle parts such as the fenders and hood sustain significant damaged before 7.4 inches of dynamic crush occurs? Does this correctly represent this vehicle's crush response characteristics? [Note: Equations (1) & (16) can be used to evaluate the crush-restitution relationship in the range of crush that occurs after the onset of residual crush (δ_f >0). Equation (16), however, can not be used for the initial elastic-only portion of dynamic crush (before the onset of residual crush, δ_f) since the ratio δ_f/δ_m is zero. Equation (1), therefore, must be used to evaluate the crush-restitution relationship for the dynamic crush that occurs before the onset of residual crush.]

MacInnis Engineering (SAE Paper 940916) has tested a 1981 Ford Escort. Full stroke of the front bumper isolators is 57 mm (2.25 inches). Residual crush began at a dynamic crush of 55 mm (2.17 inches). Maximum restitution of 0.61 occurred at 0.5 mm of isolator stroking (dynamic crush). The MacInnis data contradicts the revised restitution model. Restitution is not equal to a constant value of 1.0 over the first 2.5 inches of dynamic crush. In addition, the onset of residual crush occurs at a dynamic crush of 2.17 inches rather than 7.4 inches. Analysis of the revised coefficients for the 1975-79 VW Rabbit (figure 14) when compared to data from SAE Paper 940916 produce similar contradictions.

The original CRASH/SMAC programs and the revised CRASH/SMAC programs were used to estimate ΔV for a hypothetical vehicle. The authors characterize the differences (10 to 30%) between the estimated ΔV's of the original versus revised CRASH/SMAC programs as "errors." Differences between the estimated ΔV's would be more accurately characterized as "potential improvements in accuracy" rather than "errors." A characterization of "error" should be limited to comparisons between estimated ΔV's and the actual ΔV's measured during the thorough testing of a real-world vehicle.

In the Introduction section of the paper, the authors state that the original SMAC program inaccurately estimates ΔV approximately 10 to 30% for the case of direct central barrier collisions. There is no reference to the source of this information/conclusion. Hopefully this conclusion is not based upon the above "error" analysis involving hypothetical vehicles. Also in appendix 3, the authors indicate that it is "common knowledge" that the original CRASH program "underestimates the ΔV in barrier crashes by approximately 10% to 20% at 30 MPH and by greater amounts at lower speeds." Stating this is "common knowledge" should not relieve the authors of the responsibility of providing the supporting evidence for this conclusion. The lack of supporting evidence raises questions regarding the accuracy of these numbers.

The authors' revised model for restitution, although a step in the right direction, is not completely realistic. The restitution model needs to be reconfigured such that restitution is less than, or equal to, the theoretical limit of 1.0 at zero dynamic crush ($\varepsilon_0 \leq 1.0$) and decreases from that point as dynamic crush increases.

RICSAC-97 - A Reevaluation of the Reference Set of Full Scale Crash Tests

Brian G. McHenry and Raymond R. McHenry
McHenry Consultants, Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Research performed in the 1970's revealed significant limitations in the available documentation of vehicle crush information and trajectory spinout information. As a result a series of full-scale crash tests were performed which became known as the Research Input for Computer Simulation of Automobile Collisions (RICSAC) crash tests.

Previous research using the RICSAC test results, particularly in relation to the validation of accident reconstruction computer programs, has varied widely in acceptance, interpretation and presentation of the RICSAC test results.

This paper presents a detailed review and decipherment in useable form of the original 12 crash tests that were performed within the RICSAC program. A new method of analyzing accelerometer data from arbitrary sensor positions, on the basis of discrete measures of the vehicle responses rather than complete time-histories, is defined. A discussion of previous research which included reference to the RICSAC test results as a measure of the validity of reconstruction computer programs is included.

INTRODUCTION

Research performed in the 1970's to "locate, review, decipher and place in useable form available experimental data on the structural crush properties of automobiles, and on the spinout trajectories produced by measured collision conditions" [1][1] revealed significant limitations in the available documentation of vehicle crush information and trajectory spinout information. As a result, an initial test matrix of 12 full-scale crash tests was performed in 1978 which became known as the Research Input for Computer Simulation of Automobile Collisions (RICSAC) crash tests [2].

For each of the RICSAC tests, a minimum of 13 accelerometers were mounted on-board each vehicle to record acceleration components at six to seven stations. At three locations triaxial (XYZ) packages were installed ("hard mounted") to provide coverage between the front and rear of the vehicle. The front steer angles were measured on each vehicle by a linear stroke potentiometer attached to the vehicle steering linkage. The time history of the change in vehicle yaw, pitch and roll angles and yaw rate were recorded by two-degree-of-freedom, free gyroscopes and a rate gyro.

For vehicle trajectory measurement, high-speed motion picture cameras were located overhead with supporting cameras at eye level height. Also, vehicle trajectory marker systems were designed and fabricated by Calspan to spray high pressure colored water trails (using very small amounts of liquid to avoid any effects of the water on the roadway coefficient) from several locations on each of the vehicles.

Plots of the full-scale test acceleration time-histories were generated by a computer program which also integrated the acceleration time histories (using a combination of Simpson's and Newton's 3/8 methods) in order to obtain velocity time history along each of the vehicle's three axes. For most of the reported results, the ΔV values reported for the vehicle CG were based on data collected by a Firewall mounted triaxial (XYZ) accelerometer.

The time of approximate separation reported in [3] was based on observation of the time histories of the acceleration. The time of separation was defined as "the point at which both of the involved vehicles' accelerations reapproached 0 g's". The authors of [3] noted that "the separation point was not always obvious in collisions in which the two vehicles spun out together".

The components of the vehicle's change in velocity (ΔV) were computed in [3] "by subtracting the initial velocity at impact from the velocity at the time of separation". The procedure was done for the X and Y velocity components separately.

The authors of [3] acknowledged that the "value for the separation velocity was contaminated by the effects of rotation of the vehicles between impact and separation". The problem was attributed to the post-processing integration software used for the tests which was primarily set up to integrate acceleration data for frontal collisions with barriers

1 numbers in brackets [] indicate references at end of paper

and therefore did not account for the rotation of the vehicle (the data reduction software assumed a constant direction cosine matrix). Errors which may occur in data collected from an accelerometer not at the center of gravity include the effects of rotation which are dependent on the magnitude of the offset of the accelerometer from the CG and the magnitudes of the vehicle's angular velocity and acceleration.

Table 1 contains best estimates of the actual accelerometer locations for the 12 RICSAC tests based on values reported by Jones [3]. Some of the locations have been corrected on the basis of a detailed review of the RICSAC test reports [2].

Table 2 contains a list of factors as reported in [3] which influenced the magnitude of effects of rotation on the RICSAC accelerometer data. Note that any differences in the accelerometer locations as listed in Tables 1 and 2 are due to the refinement in **Table 1** of some ambiguous dimensions reported in [2] and/or [3].

BACKGROUND

In 1980, Smith and Noga [4] created a summary of data associated with 16 full-scale crash tests (three more tests were performed as a part of RICSAC and reported in [5] and the other was from [6]). The authors "attempted to achieve corrections to acceleration and velocity data by approximating vehicle rotational velocity and rotation of the reference frame from it's orientation at impact, by making reference to multiple accelerometer outputs at different locations on the vehicles and by analysis of high speed photography." They also included an adjustment procedure for the ΔV's to insure that the momentum changes associated with the collision partners were equal and opposite (including consideration of tire forces). The adjustments were approximations to account for the effects of external tire-forces. They found that "cases number 10, 12 and 15 are believed to be in error" due to poor accelerometer data for one of the two involved vehicles. The determination of the separation velocity was not refined or presented.

In 1983, Brach [7] presented a table of refinements to the reported RICSAC separation velocities on the basis that: "Accelerometers used to record data on each vehicle were not located at the vehicle's center of gravity. Consequently, the final velocity data had to be corrected by the angular velocity at separation and the distance of the accelerometer from the mass center." The report does not include the specific equations and the values for distances of the accelerometers from the CG and other variables used in the adjustment process (The values from Jones reported in **Table 2** were the values probably used).

In 1985, Wooley, as a part of an attack on the CRASH3 analytical procedures [8] and as part of a presentation and testing of the "IMPAC" computer program [9], included a review and analysis of the RICSAC test results as reported by Smith and Noga [4]. In addition to agreeing with Smith & Noga that there were problems with tests 10, 12 and 15, tests 4 and 6 were identified as having either "a typing error or reporting error." A "Data Integrity Ranking" was calculated for the tests based on Newton's 3rd Law for equal and opposite forces and the law of conservation of linear momentum. The tests utilized the post-impact velocities (the separation velocities) which were the values as reported by Jones [3]. The testing procedures of [8] and [9] cited many instances where the "Data Integrity Ranking" calculations revealed cases with erroneous momentum *gains* and/or instances where the forces acting on the collision partners where not equal and opposite.

Also included in the reported results of [4] was a "velocity change" angle. The "velocity change" angle was calculated by finding the angle with tangent of the Δv (Y component) velocity change divided by the Δu (X component) velocity change. In [8], the "velocity change" angle reported in [4] was referred to as the Principal Direction of Force (PDOF).

IN 1989, as a part of a presentation of a comparison of EDCRASH program results with the RICSAC test results Day [10] concludes that "No general observations could be made using the RICSAC data analyzing the accuracy of the {computed} ΔV by any program because of measurement errors in the RICSAC test data." The report also states that "Previous program evaluations which used the RICSAC data as a means of validation for ΔV should be viewed as suspect."

Also in 1989, Cheng and Guenther [11] discussed the localized variations in speed-change (ΔV) due to rotational effects as applied to the speed-change experienced by the vehicle occupants. The paper included a discussion of the general differences in measurements produced by the various accelerometer locations in the RICSAC tests.

IN 1990, Day [12] as a part of a presentation of a comparison of the EDSMAC program results with the RICSAC test results included a Table of ΔV results for RICSAC which were obtained from [1-3] and "from personal correspondence from Dr. Russell A. Smith.". Some of the reported values are different from Smith and Noga [4] and may reflect refinements by Smith and Noga reported in [13]. The report conclusions include the observation: "The measured ΔVs were not of acceptable accuracy for use in a validation study because the motion transducers were placed at the vehicle's firewall, rather than the CG. This problem might be improved or eliminated by re-analyzing the original data with software which included a transformation matrix."

In 1996, as part of a validation effort of the PC-CRASH computer program, Cliff [14] used the RICSAC test results for the post-impact separation speeds as reported by Brach [7] for comparison "validation" purposes. They noted that "there appeared to be some error in a few of the reported post-impact speeds in [the Brach] paper when compared to the reported pre-impact speeds and vehicle weights."

Also in 1996, Bundorf [15] presented techniques for analysis of the CG ΔV from accelerometer data at locations other than the CG. He observed that "the potential for error is always present if yaw velocity is high and accelerometers are distant from the center of gravity." As an example, he presented a detailed analysis of RICSAC Test no. 9 (S&N Case 11).

RESEARCH APPROACH

The RICSAC tests [1-3] contain the most comprehensive collection of full-scale test results available to date. The test reports include objective information on the impact speeds, vehicle weights, dimensions, weight distributions, spinout trajectory and positions of rest. Some interpretation of the reported results is required, for example, to obtain speed-change (ΔV) and separation velocities from the accelerometer data. Also, some evaluations are required for the approximate extent of wheel drag and steer angles. The primary purpose of the research associated with this paper has been to develop and apply techniques for

interpretation of the crash phase of RICSAC and other full-scale tests. Of particular interest are the correct values for the impact speed-changes and separation velocities effective at the centers of gravity, which can be used as an obstacle course to evaluate and/or "validate" accident reconstruction techniques.

During full-scale testing, a hard-mounted accelerometer at the CG will record the correct acceleration *including* the effects of rotation. The time integral of the accelerometer data for the X and Y directions will produce the correct vehicle-fixed X and Y components of speed-changes. However, in the RICSAC tests and in many other full-scale tests, the ΔV calculations are complicated by accelerometer data for locations other than the vehicle center of gravity. The first task of interpretation was to develop generalized analytical techniques to transform the speed-change information from arbitrary accelerometer locations to the center of gravity. A secondary task was to use the calculated CG speed-change information to calculate the vehicle separation velocities. To correctly use the CG speed-change information to calculate the separation velocities, provisions must be included for the changes in the vehicle orientation.

The technique used by Jones [3] for calculation of the separation speeds for the RICSAC tests is in error, primarily due to the direct subtraction of the speed-change determined by integration of accelerometer data from the initial impact speed. The u and v speed-changes computed by integration of the accelerometer X and Y data cannot be directly subtracted from the initial vehicle velocities except for the case where no rotation occurs. A secondary source of error in the calculation of separation velocities reported in [3] is the assumption that the acceleration and velocity data from the firewall location are equivalent to those at the vehicle center of gravity.

CG-TRANSFORM

To provide a simple approximation of the RICSAC ΔV and separation velocities at the vehicle centers of gravity, an analytical procedure was developed for transformation of accelerometer data from accelerometers not located at the vehicle center of gravity on the basis of discrete measures of the responses rather than complete time-histories.

Bundorf [15] presented a procedure for determination of the speed-change (ΔV) at the vehicle center of gravity (CG) using accelerometer time histories from accelerometers not located at the vehicle CG combined with rate gyro data. The technique requires either the availability of the FM data recorder tapes or a manual digitization of the accelerometer and yaw velocity traces to determine the integral of yaw velocity squared and, thereby, the speed-change (ΔV). A drawback of the procedure is that it can be time consuming for the case where there are not FM data tapes and/or processing software available. Also, possible sources of errors can occur from integrating and synchronizing randomly sampled data (the accelerations were recorded with triaxial accelerometers, the angles and yaw rates were recorded with a pair of two-degree-of-freedom, free gyroscopes and a rate gyro).

The ***CG-Transform*** analytical procedure has input requirements listed in Table 3 (for a detailed definition of ***CG-Transform*** please see **Appendix 1**).

Table 3 Information required for *CG-Transform* analytical procedure

1. Accelerometer Location on vehicle, X, Y.
2. Impact speed and heading angle.
3. Integrated speed-change from accelerometer data.
4. Duration of crash pulse.
5. Separation angular (yaw) velocity and angle.

To permit initial testing and refinement of the ***CG-Transform***, the SMAC computer program was utilized to create a set of mathematically correct "test case" reconstructions. Extensions to the SMAC program developed for the present research include a provision to monitor the acceleration for any arbitrary position on the vehicle (e.g., **Figure 1**, **Figure 2**). ***CG-Transform*** was then used to transform the data from an arbitrary accelerometer location back to the CG. Since the CG data is a direct output of the SMAC program the procedure provided a detailed check of ***CG-Transform.***

The SMAC reconstructions used for this purpose were generalized reconstructions of the RICSAC test runs. The SMAC runs were based on preliminary refinements of the original RICSAC SMAC reconstructions presented by Jones [3] and more recently Day [16] in validation studies of the SMAC and EDSMAC computer programs. The refinements of some of the inputs were required due to the questionable nature of some of the SMAC inputs used in the "validation" reconstructions (e.g., some torque and steer values were arbitrarily varied). A more detailed discussion of the rationale for the changes to the SMAC inputs and suggestions for refinement of the inputs are to be presented as part of a separate research project [17].

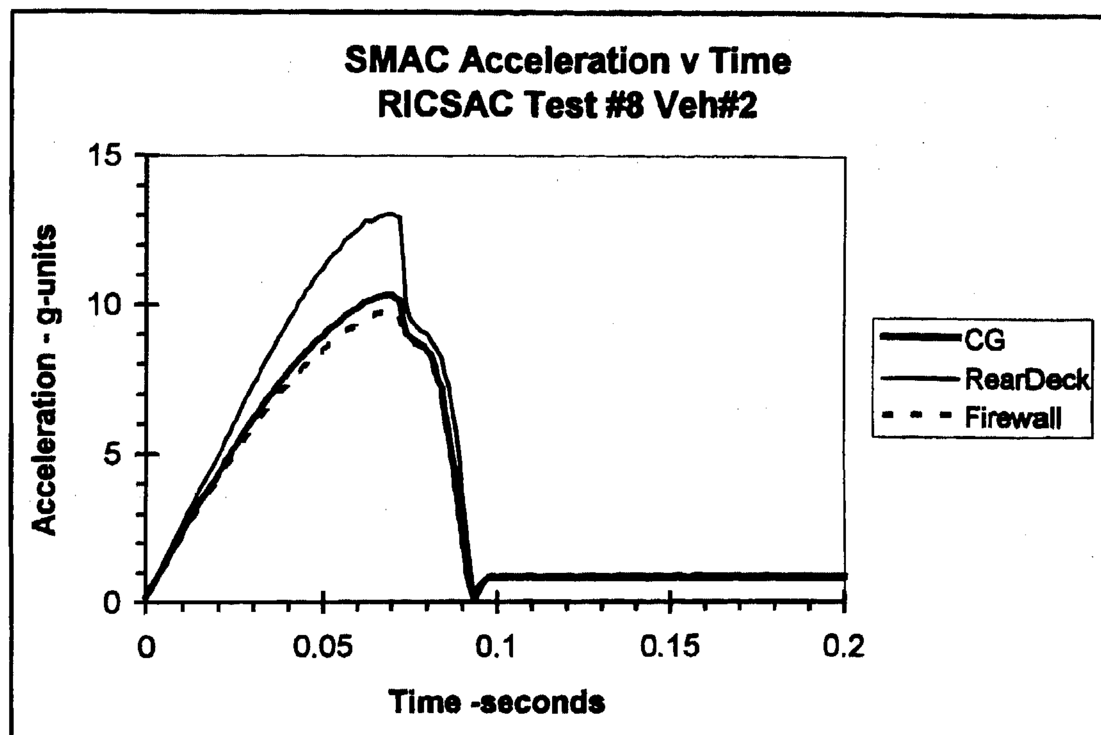

Figure 1 SMAC resultant acceleration time history at CG, Rear Deck and Firewall for RICSAC test No. 8, Vehicle No. 2

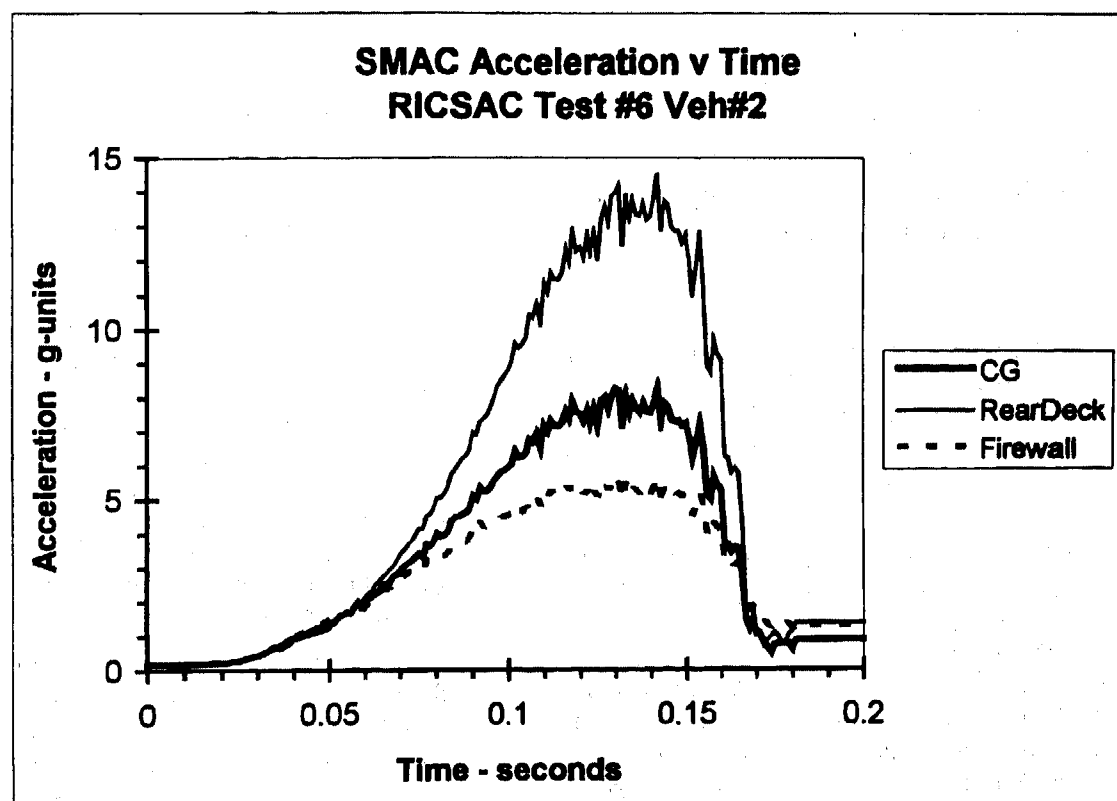

Figure 2 SMAC resultant acceleration time-history at CG, Firewall and RearDeck for RICSAC test No. 6, Vehicle No. 2

For each of the refined RICSAC SMAC runs, the acceleration was monitored for the Firewall (Cowl) and RearDeck locations as specified in the RICSAC reports. The installation locations for the Firewall and RearDeck accelerometers are included in **Table 1**. The acceleration at any given location, X_1, Y_1, can be expressed for a given time, t, as:

$$a_{xx} = \dot{u} - v * \dot{\psi} \quad (1)$$

$$a_{yy} = \dot{v} + u * \dot{\psi} \quad (2)$$

$$a_{xx1} = \dot{u} - v * \dot{\psi} - x_{a1} * \dot{\psi}^2 - y_{a1} * \ddot{\psi}^2 \quad (3)$$

$$a_{yy1} = \dot{v} + u * \dot{\psi} + x_{a1} * \ddot{\psi} - y_{a1} * \dot{\psi}^2 \quad (4)$$

$$u_{x1} = u - y_{a1} * \dot{\psi} \quad (5)$$

$$v_{x1} = v + x_{a1} * \dot{\psi} \quad (6)$$

Where, for a given time interval dt:

u, v = forward and lateral velocity componenets at cg
$\dot{u}, \dot{v}$ = change in forward and lateral velocity components at cg
a_{xx}, a_{yy} = acceleration components at cg
ψ = vehicle heading angle
$\dot{\psi}$ = yaw velocity
$\ddot{\psi}$ = yaw acceleration
x_{a1}, y_{a1} = location of accelerometer relative to cg
u_{x1}, v_{x1} = forward and lateral velocity components at x_{a1}, y_{a1}
a_{xx1}, a_{yy1} = x, y accelerations at location x_{a1}, y_{a1}

The SMAC generated acceleration time histories at the CG, Firewall and RearDeck were then integrated to determine the instantaneous velocities and resulting speed-changes. Two techniques were used to determine the impact speed-changes of the individual tests: ***Test Equivalent*** and ***SMAC Equivalent***.

TEST EQUIVALENT: For the reported RICSAC full-scale tests **[1-3]** the analysis of the accelerometer data to determine the vehicle speed-change consisted primarily of the integration of the vehicle a_x & a_y accelerometer traces to determine the time histories of velocities. The velocity time-history plots were then analyzed to determine the magnitude of the changes in the individual velocity components, ΔV_x and ΔV_y. The resultant speed-change and speed-change angle were determined by the following:

$$\Delta v_r = \sqrt{\Delta v_x^2 + \Delta v_y^2} \quad (7)$$

Where:

Δv_r = resultant speed change
Δv_x = speed change in the vehicle x direction
Δv_y = speed change in the vehicle y direction

$$\Delta V_{angle} = \text{atan2}^{-1}\left[\frac{\Delta v_y}{\Delta v_x}\right] \quad (8)$$

Where:

ΔV_{angle} = speed change angle
Δv_x = speed change in the vehicle x direction
Δv_y = speed change in the vehicle y direction

SMAC EQUIVALENT:In the original form of the SMAC computer program, the speed-change for a given acceleration exposure was determined by the integration of the *resultant* acceleration. For each time increment, a resultant acceleration was determined by the vector sum of the x and y components of the vehicle accelerations:

$$a_c = \sqrt{a_x^2 + a_y^2} \quad (9)$$

Where:

a_c = resultant acceleration, g-units

a_x = acceleration in the vehicle x direction, g-units

a_y = acceleration in the vehicle y direction, g-units

The resultant speed-change was determined by integration of the *resultant* acceleration from initial contact to separation. The initial contact is defined as the first instance where the resultant acceleration goes above 1 g-unit. The point of separation is defined as the first time that the acceleration again drops back below 1 g-unit. It was assumed that in general handling maneuvers and vehicle spinouts that the resultant acceleration would normally be below 1 g-unit (given that the nominal friction coefficient of roadways is normally less than 1 g-unit).

The Direction of Principle Force (DOPF) was determined for a given acceleration exposure in the SMAC program as the direction of the acceleration at the instance of peak *resultant* acceleration by:

$$DOPF = \text{atan2}^{-1}\left[\frac{a_y}{a_x}\right] \quad (10)$$

Where:

DOPF = direction of principal force

a_x = acceleration in the vehicle x direction

a_y = acceleration in the vehicle y direction

A summary of the steps required to create SMAC "full-scale test results" to be used for testing purposes of the ***CG-Transform*** analytical procedure was as follows:

1. A SMAC simulation was performed for each RICSAC test
2. Acceleration time histories were created for the CG and the reported Firewall and Rear Deck accelerometer locations for each vehicle of each test. **Table 1** is a list of the reported Firewall and Rear Deck accelerometer locations used in the SMAC tests.
3. The SMAC vehicle fixed X & Y acceleration time-histories were integrated for the CG, the firewall and the Rear Deck as follows:

    3.1. The individual speed-changes in the vehicle X and Y directions were determined by integration of the X and Y acceleration time-histories.

    3.2. A ***Test equivalent*** resultant speed-change was calculated.

    3.3. The ***SMAC equivalent*** resultant speed-change was also calculated by integration of the time-history of the resultant acceleration.

For some of the RICSAC tests the values for the ***Test equivalent*** speed-change was found to be less than the ***SMAC equivalent*** speed-change (ΔV) by as much as 10%-15%. The difference is due to the following:

When we use integration to find the velocity change produced by an acceleration curve, we are finding the equivalent velocity that is produced by the variation of the acceleration over a fixed interval of time. In full scale tests, the accelerometers measure the acceleration for the X and Y directions separately. Therefore, the integration of these acceleration time-histories produce separate velocities (areas) for the X and Y directions. The *resultant* speed-change velocity from full-scale tests is determined by finding the square root of the sum of the squares for the X and Y velocities. In the SMAC program, in addition to the separate X and Y acceleration time-histories, we also have available the resultant acceleration. Therefore, to determine the *resultant* speed-change we can integrate directly the resultant acceleration vs. time curve. In a motor vehicle full-scale test, the vehicle and occupants experience the resultant acceleration, not individually the X and Y components. The possibility of differences in the resultant speed-change by these two methods reveals a need for accident reconstruction simulation programs to individually calculate the speed-changes in the X and Y directions for comparisons with full-scale tests, while also calculating and reporting the resultant speed-change determined by integration of the resultant acceleration over time.

For testing and comparison purposes of the ***CG-Transform*** analytical technique, reconstructions were performed of the collision phase of the 12 RICSAC tests with the SMAC computer program. **Table 4** contains a summary of the RICSAC SMAC impact speed-change (ΔV) for the CG, Firewall and Rear Deck, **Table 5** contains the impact conditions, and **Table 6** contains the separation conditions.

The results of the SMAC reconstructions of the RICSAC tests were used in an evaluation of the ***CG-Transform*** analytical technique. The integrated speed-change for the Firewall and Rear Deck accelerometer locations were used with the other items per **Table 3** in an application of the ***CG-Transform*** analytical procedure to determine the speed-change at the center of gravity and the separation velocity. The results for the speed-change (ΔV) and separation velocity for each of the 12 RICSAC tests were calculated. For all cases the speed-change and separation velocity calculated for the CG based on the Firewall and Rear Deck accelerometer data was less then 1 mph maximum error, with an average error of ±0.1 MPH and a standard deviation of 0.30 MPH. The comparison gave a good indication that the ***CG-Transform*** analytical procedure properly approximates the CG speed-change and separation speed from speed-change data at arbitrary accelerometer locations combined with discrete measures of the yaw responses.

A dramatic demonstration of the positional differences in accelerations and therefore the corresponding differences in the integrated speed-change calculations is illustrated in **Figure 3** and **Table 7**. **Figure 3** is the resultant acceleration time-history for the CG, Firewall and RearDeck for the SMAC reconstruction for vehicle number 1 of RICSAC Test No. 10. The full scale test and the SMAC simulation of RICSAC 10 each contained a "sideslap" impact of the vehicles subsequent to the primary impact. In **Figure 3** there are two peaks in the acceleration time histories, particularly at the RearDeck location. **Table 7** contains the integrated speed-changes calculated for the primary impact, the side-slap and for the total duration. The speed-change calculated by components (***Test equivalent***) and based on the resultant acceleration (***SMAC equivalent***) for vehicle No. 1 illustrates a problem which can occur when integrating individual acceleration components. **Figure 4** is the X-Y acceleration components for vehicle number 1 of RICSAC Test No. 10. The X-acceleration for the RearDeck location in **Figure 4** reverses sign after the primary impact which acts to reduce and *reverse* the calculated X component of speed-change for the ***Test equivalent*** integration technique (The reported time-histories of the velocity components produced

by integration of the RICSAC accelerations contain this anomaly, e.g., p 16-41,[2]). Determining the speed-change based on the resultant acceleration per the ***SMAC equivalent*** technique eliminates the directional sensitivity.

The side-slap acceleration of RICSAC Test 10 also reveals a problem of determining which speed-change and/or separation velocity should be reported when a sideslap occurs. Note that the ***SMAC Equivalent*** resultant speed-change for the Rear Deck calculated from the initial impact through the end of the sideslap (from 0.50 to 0.862 sec.) is dramatically higher (63 mph) than the sum of the individual speed-changes for the primary impact (25.5 mph) and sideslap impact (17.5 mph). The difference is due to the integration of the acceleration (> 5 g's) which occurs at the RearDeck (due to it's offset from the center of gravity) during the rapid rotation of the vehicle between the primary and sideslap impact (approximately 0.20 seconds).

It is herein proposed that all test reports include provisions to indicate a "side-slap" impact. The post-processing analysis of the acceleration data should also integrate and report the speed-change for the primary and secondary impacts separately.

Large accelerations that can occur at locations other than the center of gravity, as demonstrated at the RearDeck for RICSAC Test 10 vehicle 1, should not be included in the speed-change calculations for the individual vehicles since the vehicles are not in contact during this time period. However, the additional accelerations due to offset from the center of gravity and rotational velocity may have dramatic effects on the magnitude of occupant exposure and consideration should be given to localized ΔV calculations as suggested in [11].

Table 4 **SMAC RICSAC reconstructions predicted ΔV's for CG, Firewall and Rear Deck accelerometer locations**

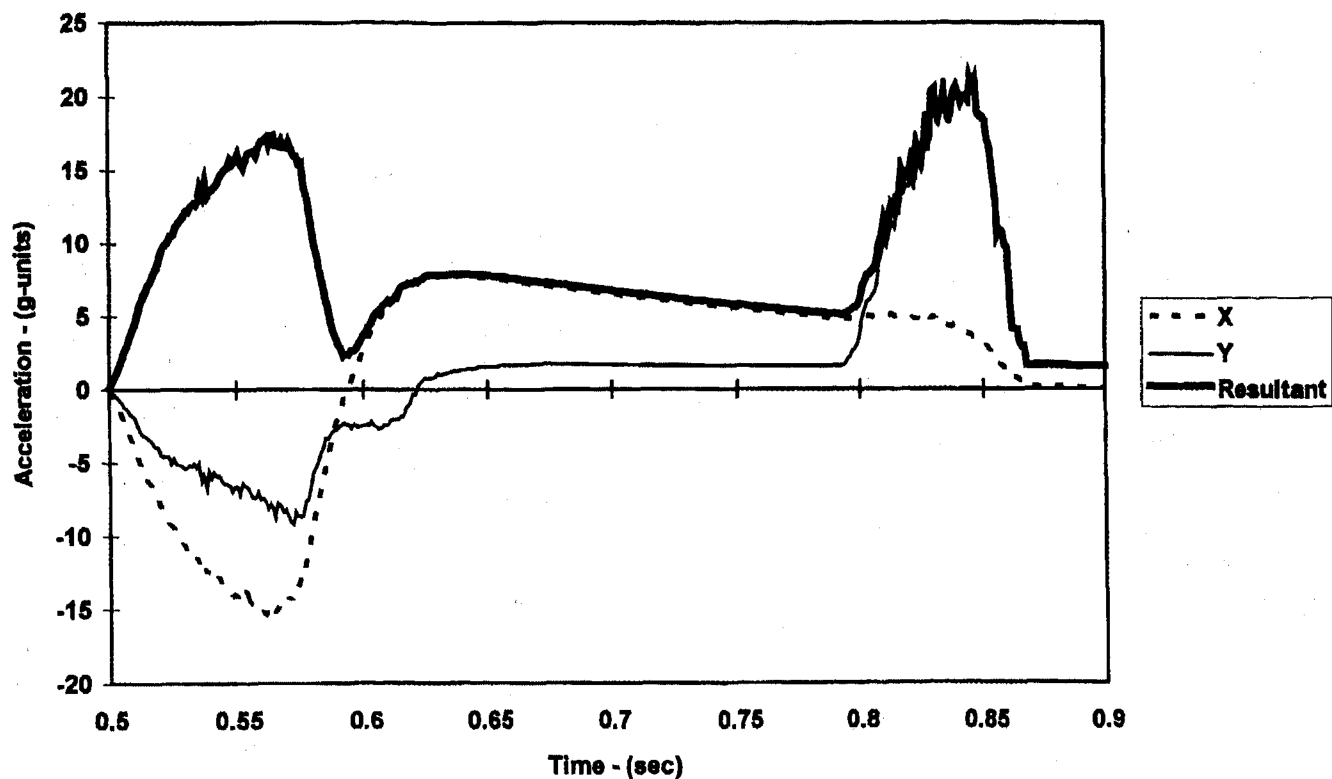

Figure 4 Acceleration components at RearDeck Location for RICSAC Test 10, Vehicle No. 1

Another check of the *CG-Transform* was to perform a comparison of the calculated results with results reported by Bundorf in [15]. Bundorf included a procedure for transformation of accelerometer information from locations other than the vehicle center of gravity to the CG. The procedure presented by Bundorf includes digitizing and analyzing the acceleration and angular velocity time-history data. The reported results by Bundorf were compared with results calculated with the *CG-Transform* procedure. The results of the comparison are contained in **Table 8**. The results of the *CG-Transform* procedure correlate well with the results of the Bundorf analysis procedure. The average result and standard deviation are nearly identical. Some small differences did occur between the different accelerometer locations.

The results of application of *CG-Transform* analytical procedure to the various locations tested demonstrate the ability of the *CG-Transform* procedure to accurately calculate the speed-change at the center of gravity for any arbitrary accelerometer location.

EVALUATION OF THE "RAW" RICSAC DATA

The task of evaluating and transforming the accelerometer data for the RICSAC full scale tests was undertaken to determine the CG speed-change and separation velocity for each test. A few possible problem areas which might affect the correlation are:

Source of Raw Data.

Acceleration Time-history Oscillations.

Excessive Collision Duration.

SOURCE OF RAW DATA: The raw ΔV values as reported in [3] were used for the comparison. A brief visual check of the time-history plots vs. the reported values was performed to check for any major differences. The reason the other reported refinements of the values could not be used was that the other reported values contained adjustments and corrections to transform the results from the Firewall accelerometer locations to the CG, the very task our ***CG-Transform*** is to perform.

ACCELERATION TIME-HISTORY OSCILLATIONS: Some of the acceleration time traces contained in the RICSAC reports [2] appear to have excessive oscillations (e.g., RICSAC Tests.Veh: 2.1,2.2,5.1,5.2,8.2,11) and some have resultant accelerations exceeding 40 g's (e.g., RICSAC Test.Veh: 10.1,12.1,7.2). These results may either reflect a possible problem with the accelerometers or with the choice in cutoff frequency filter. Sample oscillograph data from Mayor and Naab **[18]** contained in [19] illustrates the differences between unfiltered and filtered acceleration data for a 20 mph lateral impact. Peak accelerations vary from approximately 100 g's for unfiltered data to 40 g's for 50 Hz cutoff frequency to 28 g's for 25 Hz cutoff frequency. Also a dramatic reduction in the amount of oscillation occurs with increased filtering.

EXCESSIVE COLLISION DURATION: The collision contact duration reported by Jones (see **Table 2**) appears to be excessive. For example, Bundorf **[15]** determined the pulse duration for RICSAC Test 9 to be approximately 0.125 seconds whereas Jones reported the duration to be 0.200 seconds. Generally for car-to-car collisions, a normal range of pulse duration is 0.075 to 0.125. A review of the time-history accelerometer traces and the integrated velocity traces contained in the original RICSAC test reports also appears to indicate that the durations of the pulses reported by Jones are excessive. A comparison of the SMAC reconstruction pulse durations indicates that an average adjustment of the duration of approximately 0.090 seconds would be appropriate. For the purposes of this reported research, an approximate adjustment of 0.0825 was used (the average of .075 + .09).

RESULTS

The inputs for the reported raw RICSAC data [2, 3] which were used with the *CG-Transform* analytical technique are contained in ***Table 9***. A comparison of the *CG-Transform* calculated results with the speed-change at the CG as predicted by the SMAC program is contained in Table 10. A comparison of the *CG-Transform* calculated separation velocities with the separation velocities predicted by the SMAC program is contained in **Table 11**.

Given the possible variations and problems which can occur in full-scale test measurements the correlation of the ***CG-Transform*** calculated results and the SMAC results for most of the RICSAC tests appears very good. In all cases the cited correlation of ***CG-Transform*** with the mathematically correct SMAC results is within ±10% for ΔV and within ±13% for the separation velocity for at least one of the vehicles. This gives a good indication that properly interpreted results of all the tests are in complete agreement with Newton's Laws.

Some areas of difference can be explained as follows:

- For the ΔV values from the full-scale tests, differences in the individual components may be attributable to possible accelerometer calibration errors. Errors also can be caused by cross-coupling problems with gyros which can occur due to vehicle roll and pitch angles. Larger errors may be produced by problems with the individual accelerometers either in the crush zone or on components possibly affected by the impact configuration.
- For the separation velocity, differences in the individual components and resultant are produced by any of the following possibilities:
  - possible errors in determination of the time of separation in the full-scale tests
  - possible errors in the reported orientation of the vehicle at the time of separation
  - possible synchronization problems between the triaxle accelerometers and the gyros

CONCLUSIONS

1. The RICSAC data, when interpreted with the *CG-Transform* procedure, are reasonably accurate and are suitable for their intended purpose of testing the validity of reconstruction techniques.
2. Previously reported findings of gross errors and violations of Newton's laws in the reported RICSAC data are erroneous.
3. The SMAC program has been demonstrated to correlate well with properly analyzed full-scale test results

RECOMMENDATIONS

1. Future "validation" comparisons with the RICSAC full-scale tests should also give consideration to utilizing the mathematically correct SMAC results presented herein. Use of the SMAC program results for comparisons avoids the variability that normally occurs in full-scale tests. Without direct measures of the variability of experimental responses, by means of repeated runs of tests, the accuracy of analytical predictions cannot be properly evaluated.
2. Future full-scale tests should utilize a time-history simulation program like SMAC or a three-dimensional equivalent to permit a check of results and conversion procedures for data from accelerometers not located at the CG.
3. Any integration analysis of accelerometer data should include consideration for possible directional changes of individual components. This can be accomplished by direct analysis of the resultant acceleration to avoid the possibility of a reduction in the reported values for individual component velocities due to acceleration directional reversals.
4. Full-scale tests should include provisions for separately reporting and analyzing the occurrence of "side-slap" types of collisions
5. Full-scale test reporting and subsequent analysis should be in a coordinate system in conformity with standard SAE J670e

APPENDIX 1: *CG-TRANSFORM* PROCEDURE

In the following, a procedure is defined whereby accelerometer measurements taken at locations away from the CG are transformed into impact speed-changes at the center of gravity and into separation velocities on the basis of discrete measures of the vehicle responses rather than complete time-histories. The procedure, entitled ***CG-Transform***, is validated by means of applications to SMAC runs in which the outputs include acceleration components at selected locations on the simulated vehicles.

DEFINITION OF SYMBOLS

OXY =	Vehicle-fixed coordinate system with origin at the center of gravity.
O'X'Y'=	Space-fixed coordinate system.
ψ =	Heading angle of vehicle relative to space-fixed system.
u, v =	Components of velocity in the directions of the vehicle-fixed X and Y coordinates respectively, inches/second.
u', v' =	Components of velocity in the directions of the space-fixed X' and Y' coordinates respectively, inches/second.
x1, y1 =	Coordinates of accelerometer location in vehicle-fixed system, inches.
ax1, ay1 =	Components of acceleration at point 1 relative to the vehicle-fixed system, inches/sec^2.
a_x, a_y =	Components of acceleration at the center of gravity relative to the vehicle-fixed system, inches/sec^2.
Δu, Δv =	Changes in velocity in the directions of the vehicle-fixed X and Y coordinates respectively, inches/sec.

In the following pages, a dot over a symbol is used to indicate a time derivative.

The subletter **1** indicates the value of a variable at point **1**

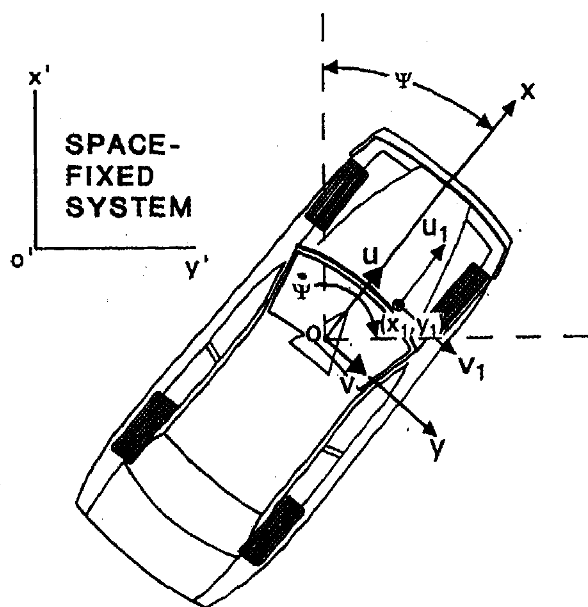

Figure 5 Velocity components of a Point on a vehicle

In ***Figure 5***, velocity components of point 1 relative to the vehicle-fixed coordinate system are defined by:

$$u_1 = u - y_1\dot{\psi} \qquad (11)$$

$$v_1 = v + x_1\dot{\psi} \qquad (12)$$

The velocity components of point P relative to the space-fixed coordinate system may be expressed as:

$$u_1' = u_1 \cos\psi - v_1 \sin\psi \qquad (13)$$

$$v_1' = u_1 \sin\psi + v_1 \cos\psi \qquad (14)$$

Substitution of (11) and (12) into (13) and (14) and differentiation of the resulting equations yields the following components of acceleration relative to the vehicle-fixed system:

$$a_{x1} = \dot{u} - v\dot{\psi} - y_1\ddot{\psi} - x_1\dot{\psi}^2 \qquad (15)$$

$$a_{y1} = \dot{v} + u\dot{\psi} + x_1\ddot{\psi} - y_1\dot{\psi}^2 \qquad (16)$$

From (15) and (16), the components of acceleration relative to the vehicle-fixed system at the center of gravity of the vehicle (i.e., $x_1 = y_1 = 0$) may be expressed:

$$a_x = \dot{u} - v\dot{\psi} \qquad (17)$$

$$a_y = \dot{v} + u\dot{\psi} \qquad (18)$$

Thus, the ΔV components at the center of gravity relative to the vehicle-fixed system, including rotational effects, may be obtained by integration of (15) and (16):

$$\int_o^t a_x dt = \int_o^t a_{x1} dt + y_1 \int_0^t \ddot{\psi} dt + x_1 \int_o^t \dot{\psi}^2 dt \qquad (19)$$

$$\int_o^t a_y dt = \int_o^t a_{y1} dt - x_1 \int_o^t \ddot{\psi} dt + y_1 \int_o^t \dot{\psi}^2 dt \qquad (20)$$

To obtain the components in the vehicle-fixed system, of the separation velocity (i.e., the velocity at the end of a period of acceleration) it is necessary to integrate (17) and (18) in the following manner:

$$u_f = u_o + \int_o^t \dot{u} dt = u_0 + \int_o^t a_x dt + \int_o^t v\dot{\psi} dt \qquad (21)$$

$$v_f = v_o + \int_o^t \dot{v} dt = v_o + \int_o^t a_y dt - \int_o^t u\dot{\psi} dt \qquad (22)$$

From the preceding, it may be seen that the following integrations are required to correct readings obtained from accelerometers at point 1:

$$\int_o^t \ddot{\psi} dt \qquad (23)$$

$$\int_o^t \dot{\psi}^2 dt \qquad (24)$$

$$\int_o^t v\dot{\psi} dt \qquad (25)$$

$$\int_o^t u\dot{\psi} dt \qquad (26)$$

Reasonable approximations of the values of the integrals listed as equations (23) through (26) can be obtained by the use of analytical functions fitted to test data:

$$\ddot{\psi} = Q_1 \sin \omega t - Q_2 \sin 3\omega t \quad (27)$$

$$u = u_f - (\Delta u) \cos \omega t \quad (28)$$

$$v = v_f - (\Delta v) \cos \omega t \quad (29)$$

Integration of equations (23) through (26) using the functional relationships defined by (27), (28) and (29) and application of the results to equations (19), (20), (21) and (22) yields the following relationships:

$$\omega = \frac{\pi}{2(\Delta t)} \quad (30)$$

$$Q_1 = \frac{3\omega}{4}\left[\frac{\pi}{2}\dot{\psi}_f + \frac{\Delta\dot{\psi}}{3} - \omega\Delta\psi\right] \quad (31)$$

$$Q_2 = 3\left[Q_1 - \omega\Delta\dot{\psi}\right] \quad (32)$$

$$A = \frac{1}{\omega}\left(\frac{\pi}{2}\dot{\psi}_f^{\,2} + \frac{Q_1}{\omega}\left[\frac{Q_1\pi}{4\omega} - 2\dot{\psi}_f\right] + \frac{Q_2}{9\omega}\left[\frac{Q_2\pi}{4\omega} - 2\dot{\psi}_f\right]\right) \quad (33)$$

$$\Delta V_x = \int_o^t a_x dt = \int_o^t a_{x1} dt + y_1\Delta\dot{\psi} + x_1 A \quad (34)$$

$$\Delta V_y = \int_o^t a_y dt = \int_o^t a_{y1} dt - x_1\Delta\dot{\psi} + y_1 A \quad (35)$$

$$B = \frac{1}{\omega}\left(\frac{\pi}{2}\dot{\psi}_f - \frac{Q_1}{\omega} - \frac{Q_2}{9\omega^2}\right) \quad (36)$$

$$C = \frac{1}{\omega}\left(\frac{\pi}{4}\frac{Q_1}{\omega} - \dot{\psi}_f\right) \quad (37)$$

$$D = \int_o^t a_x dt + B v_0 \quad (38)$$

$$E = \int_o^t a_y dt - B u_0 \quad (39)$$

$$delu = \Delta u = \left(\frac{D + (B+C)E}{1 + (B+C)^2}\right) \quad (40)$$

$$delv = \Delta v = \frac{\left(E - (B+C)D\right)}{\left(1 + (B+C)^2\right)} \quad (41)$$

$$u_f = u_0 + \Delta u \quad (42)$$

$$v_f = v_0 + \Delta v \quad (43)$$

RICSAC-97 - A Reevaluation of the Reference Set of Full Scale Crash Tests
Brian G. McHenry, Raymond R. McHenry, Authors

Although the RICSAC crash tests simulate only a narrow range of real-world impact conditions, they have long served as a tool for validation of vehicle collision simulation software as well as a body of data for the study of automobile impact dynamics. This paper discusses the RICSAC work along with some important limitations in its data.

Speed changes for the RICSAC crash tests were based on analysis of data from accelerometers. The results were affected to varying degrees by the placement of the accelerometers at locations other than the vehicle's CG. The authors present a sound new method for compensation of errors in the RICSAC results.

Velocity change (ΔV) during an instrumented crash test can be calculated through numerical integration of accelerometer data. The authors make insightful observations concerning potentially significant differences between common methods of reducing acceleration data to ΔV.

Reviewer's Discussion
by Terry D. Day
RICSAC-97 - A Reevaluation of the Reference Set of Full Scale Crash Tests
Brian G. McHenry, Raymond R. McHenry, Authors

This paper provides an important re-evaluation of the test data published in the original RICSAC study. Several previous authors reported the raw RICSAC data were in error because the Delta-Vs reported in the study were based on acceleration vs. time histories from accelerometers not mounted at the CG. This paper provides a solution to this "error" (the authors correctly point out the error is not with the raw data, but with the data *reduction*) by calculating the correct vehicle CG velocities using a simple transformation. In the future, researchers may ignore the Delta-Vs reported in the original RICSAC study, and use the Delta-Vs reported in the paper.

Avoiding the Emerging Pedestrian: A Mathematical Model

Rodney Vaughan
Rodney Vaughan & Associcates Pty. Ltd.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A common form of pedestrian accident involves the pedestrian emerging from behind a stopped vehicle, into the path of an oncoming car. A mathematical model ("EMERGE") has been developed for calculating the time available to the driver to see and avoid the pedestrian. It involves calculating in 2 dimensions the equations of motion of the vehicle and the pedestrian, together with the lines of sight of the driver and the pedestrian around the stopped vehicle. The sensitivity of the model to the different variables is demonstrated.

The model allows for deceleration of the car. For any given driver perception-reaction time and car deceleration rate, the model can be used to calculate the maximum speed of the car from which it would have been possible to have avoided the collision by braking to a stop. This can often demonstrate that the driver would only have been able to have avoided the collision if he had driven at an unreasonably low speed.

The model also has application in some vehicle-to-vehicle and bicycle-to-vehicle collisions where vehicles are hidden from each other until just before the collision.

INTRODUCTION

A common form of pedestrian accident involves the pedestrian suddenly emerging from behind a parked vehicle into the path of a passing car: Figure 1 illustrates the general problem. Such collisions very often involve young children and result in severe injuries. For example, in a study of pedestrian accidents in Australia, 388 of 3109 pedestrians killed or injured (or 1 in 8 pedestrian casualties) involved the pedestrian emerging from behind a stationary vehicle. Half (190) of the emerging pedestrians were less than 17 years of age; one quarter of the 758 pedestrian casualties under the age of 17 years suddenly emerged from behind parked vehicles (Road Safety & Traffic Management Directorate 1996).

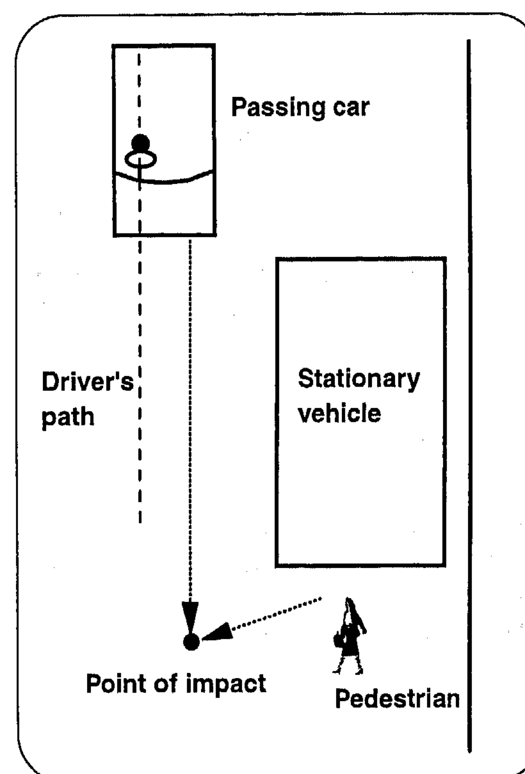

Fig. 1: The general problem of the emerging pedestrian

The time available to the driver of the car from when the pedestrian first came into view, to the point of impact, is an important consideration in apportioning

liability for the collision: could the driver have avoided the collision? The courts often see the driver as having the ultimate responsibility for driving at a speed and in a manner so as to be able to see and avoid pedestrians appearing in their paths. A collision with a pedestrian is very often seen to have at least partially resulted from the driver travelling at a speed which he should have known was too fast for the prevailing traffic conditions.

This paper is about a mathematical model ("EMERGE") which can be used to readily calculate the time available to the driver under various combinations of variables.

Graphical methods have been used to determine the time available to the driver in these types of crashes. The method typically involves establishing the paths followed by the pedestrian and the vehicle to the point of impact, and, starting from the point of impact, working backwards along the paths to establish the line of sight between the two at various times prior to impact. When the line of sight drawn on the diagram intersects the stationary vehicle, the time to impact can then be found. Figure 2 illustrates a typical graphical analysis.

One of the assumptions usually made in such analyses is that the pedestrian and the vehicle move at constant speeds. The assumption can in many (possibly most) cases be justified by statements to the effect *"it happened so fast - I didn't see him before I hit him"* (by the driver) and *"I never saw the car"* (by the pedestrian).

Graphical methods are tedious and prone to error. Where the speed is not constant (for example, where the driver commences braking) the process becomes even more tedious and time consuming as well as increasing the chance of error. If a range of speeds and/or positions/paths followed by the vehicle and pedestrian and positions of impact also have to be considered, the problems of the process are compounded.

For simpler cases, the graphical method is straightforward and easily understood. However, if a range of variables has to be considered and/or speeds are not constant during the crash sequence, the process is much less useful.

EMERGE

In principle, the mathematical model "EMERGE" is not dissimilar to the graphical method. The position of the stationary vehicle or other visual obstruction is established in relation to the paths of the vehicle and of the pedestrian. The point of impact is established in relation to the stationary vehicle and on the car striking the pedestrian. Once again, the analysis commences at the point of impact and works backwards to the time at which the pedestrian would have first come into the field of view of the driver. In the basic EMERGE, the speeds of the pedestrian and the car are assumed to be constant (that is, the pedestrian does not pause and the car driver does not brake before impact).

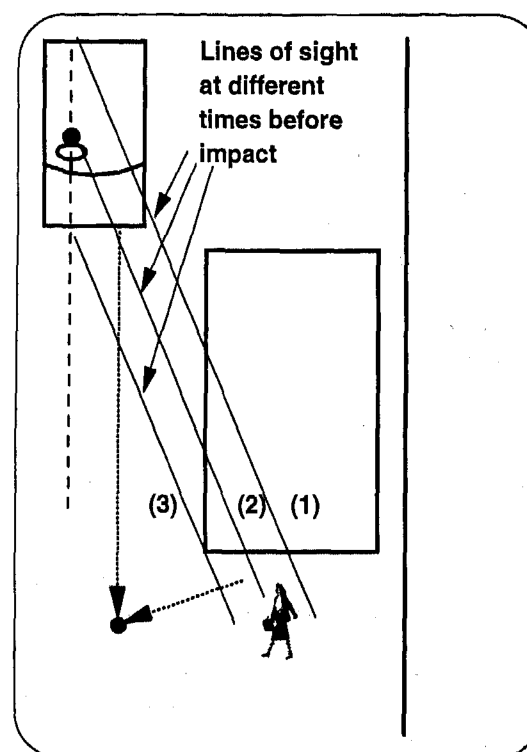

Fig. 2: The graphical method of establishing the theoretical lines of sight between the driver and the pedestrian at different times before impact. The line which first clears the stationary vehicle establishes how long before impact the pedestrian would be in the driver's field of view. For example, lines (1) and (2) are obscured by the stationary vehicle; line (3) establishes when the pedestrian is first in the driver's field of view.

The edge of the stationary vehicle beyond which the pedestrian comes into view is generally a corner of the vehicle and in EMERGE is denoted as the *"critical corner"*. At time t before impact, the lines of sight from the driver to the critical corner and from the pedestrian to the critical corner are calculated. The angle of each line of sight at time t before impact can thus be readily calculated: when the angles are

such that the two lines of sight are collinear, the pedestrian is first in the field of view of the car driver (Figure 3). The calculations involved are derived from simple two dimensional geometry.

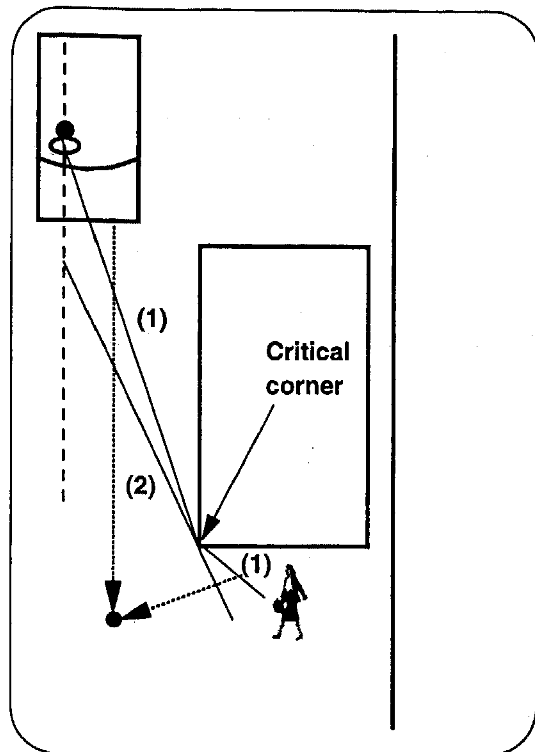

Fig. 3: The principle of EMERGE. The angles of the lines of sight at time t before impact between (a) the driver and the "critical corner" of the stationary vehicle and (b) the pedestrian and the "critical corner" are calculated. The time before impact when the pedestrian would be first in the driver's field of view is established when the two lines of sight are collinear. For example, lines of sight (1) are not collinear and hence the pedestrian is still hidden from the driver. Lines of sight (2) are collinear and the pedestrian is just in the driver's field of view.

Variables used in the basic EMERGE are

u_c speed of the car (assumed to be constant)

u_p speed of the pedestrian (assumed to be constant)

θ the angle between the paths of the pedestrian and the car

s_{lat} the lateral distance from the point of impact on the car to the driver

s_{long} the longitudinal distance from the point of impact on the car to the driver

y_{crit} the lateral distance from the "critical corner" on the stationary vehicle to the point of impact on the road

x_{crit} the longitudinal distance from the "critical corner" on the stationary vehicle to the point of impact on the road

t_{see} the time before impact when the driver can first see the pedestrian

The physical variables are illustrated in Figure 4.

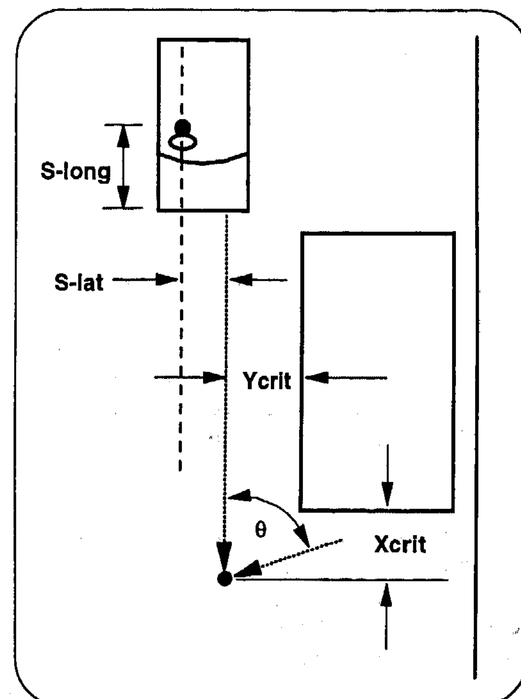

Fig. 4: Variables used in the basic EMERGE.

The analysis is based on Cartesian (or rectangular) coordinates, with the point of impact as the origin (Figure 5). At time t, the pedestrian is at position A and the driver at position E. The coordinates of A are $(u_p*t*\cos\theta,\ u_p*t*\sin\theta)$; the coordinates of E are $(u_c*t + s_{long},\ - s_{lat})$.

Within triangle ABC, angle BAC = α
$= \mathrm{atan}((x_{crit} - u_p*t*\cos\theta) / (u_p*t*\sin\theta - y_{crit}))$ ....(1)

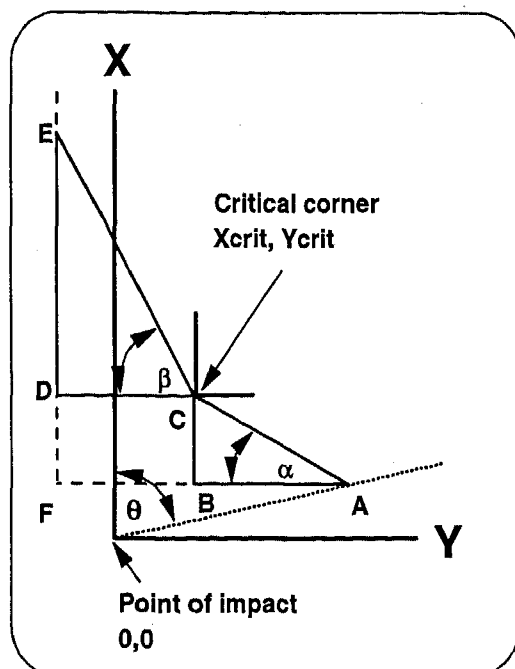

Fig. 5: The geometry of the basic EMERGE: when $\alpha = \beta$, the pedestrian is first in the field of view of the driver.

Within triangle CDE, angle DCE = β
$= \text{atan}((u_c{*}t + s_{long} - x_{crit}) / (s_{lat} + y_{crit}))$ ....(2)

When $\alpha = \beta$, the pedestrian is first in the field of view of the driver: hence the value can be established of the time available to the driver from when the pedestrian first came into his field of view to the point of impact.

Once the time available to the driver from when the pedestrian first came into his field of view to the point of impact (t_{see}) has been established for a given set of conditions (or range of conditions), that time can be compared with perception-reaction time data to assess whether the driver should have been able to have taken evasive action.

At time t_{see}, the line ACE in Figure 5 is straight, forming the hypotenuse of the right angle triangle AEF. The dimension AE is the sight distance when the driver and pedestrian could first see each other. The coordinates of A and E are as indicated above. The coordinates of F are ($u_p{*}t_{see}{*}\cos\theta$, $-s_{lat}$). From Pythagoras' Theorem,

$$AE^2 = EF^2 + AF^2$$
$$= (u_c{*}t_{see} + s_{long} - u_p{*}t_{see}{*}\cos\theta)^2 + (s_{lat} + u_p{*}t_{see}{*}\sin\theta)^2$$

and hence the value of the sight distance can be calculated.

THE INFLUENCE OF DIFFERENT VARIABLES ON THE TIME AVAILABLE TO THE DRIVER

Each of the variables involved has different effects in the calculation of the time before impact when the driver can first see the pedestrian (time t_{see}): this is illustrated by altering individual variables in a basic example.

The basic example involves a Toyota Camry car travelling at 40 km/h (about 25 mph), passing a large stationary vehicle with a clearance of 1.2 m (about 47 inches), and striking a pedestrian who is crossing at a speed of 3 m/s (about 10 fps) at right angles 1 m (about 39 inches) in front of the stationary vehicle. The pedestrian is struck by the nearside (car passenger's side) headlight: the lateral distance from the stationary vehicle to the point of impact is 1.55 m (about 61 inches). The longitudinal and lateral distances from the point of impact on the car to the driver are 2.4 m (about 94 inches) and 0.9 m (about 35 inches) respectively. Solving the equations indicates that the pedestrian would have first come into the driver's field of view about 0.62 seconds before impact. At that time, the sight distance between the driver and the pedestrian would have been about 9.6 m.

The time available to the driver from when the pedestrian first came into his field of view to the point of impact can now be compared with perception-reaction time data to assess whether the driver should have been able to have taken evasive action.

Often the speeds of the car and the pedestrian are only known within ranges. How critical are the speeds? Figure 6 illustrates the effect on the time available to our driver from the basic example, by considering pedestrian speeds of 1.5 m/s (within the range of young adult walking speeds), 3 m/s (within the range of young adult jogging speeds) and 4.5 m/s (within the range of primary or elementary school student running speeds) against car speeds of 10 km/h to 70 km/h (about 6 mph to 43 mph). For a given pedestrian speed, the speed of the car in this example makes very little difference to the time available to the driver: above a car speed of about 20 km/h, the time values in this example rapidly become asymptotic.

To illustrate the effect of a less sudden emergence from behind the stationary vehicle, the analysis shown in Figure 6 is repeated in Figure 7, but in this latter case, the car and the pedestrian have

double the clearance from the stationary vehicle. The car in this case passed the stationary vehicle with a clearance of about 2.4 m and the pedestrian crossed 2 m in front of the stationary vehicle: the impact was with the Camry's nearside headlight, and thus the point of impact was about 2.75 m laterally from the stationary vehicle. While the time available to the driver to see the pedestrian before impact is much greater, the general asymptotic shapes of the curves for different speeds of the pedestrian are similar.

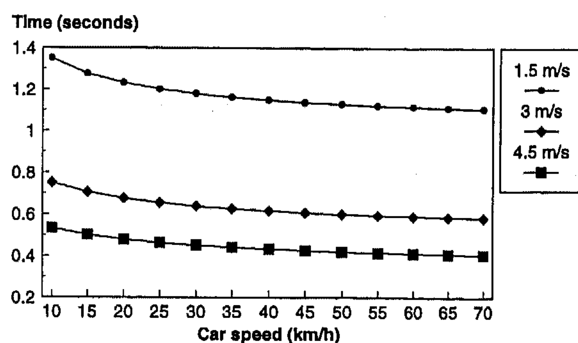

Fig. 6: The effect on time available to the driver of different pedestrian and car speeds, using the variables in the basic example

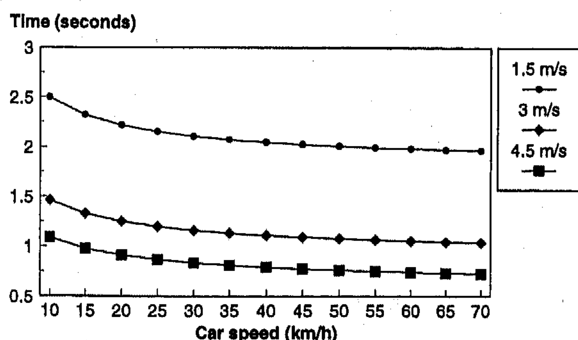

Fig. 7: As for Fig. 6, except that the car and the pedestrian have a greater clearance from the stationary vehicle (see text).

In most real world situations where car speeds are not extremely low, the speed of the pedestrian has a far greater influence than the car speed on the time available to the driver to see and possibly avoid the pedestrian: except at very low car speeds, the speed of the pedestrian essentially determines the time available to the driver (all other variables constant).

As illustrated by comparison of Figures 6 and 7, the clearance of the pedestrian from the visual obstacle is an important variable: increasing the clearance increases the time available to the driver.

Pedestrians do not always cross a road at right angles. For a given set of circumstances, there is an angle at which the time is at a minimum, and where any other angle results in a longer time for the driver. As Figure 8 illustrates, the angle can be an important factor in the time available to the driver: a pedestrian walking slightly away from the oncoming car (angle between the paths being less than 90 degrees) provides the least time, while a pedestrian walking at an angle generally towards the oncoming car (angle between the paths being more than 90 degrees) provides the most time.

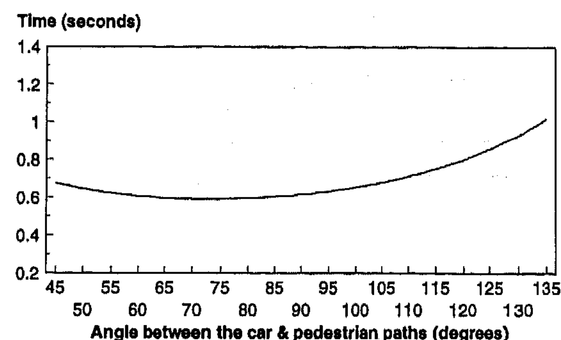

Fig. 8: The time available to the driver to see and avoid the pedestrian, with varying angles between the paths followed by the car and the pedestrian (car speed of 40 km/h, pedestrian speed of 3 m/s).

The dimensions of the impacting car and where on the front of a car the collision occurs has an effect on the time available to the driver: but how much? Figure 9 shows the time for the basic example, varying the position of impact on the front of the car from the extreme nearside front corner of the car (1.4 m laterally from the driver's eye position) to directly in front of the driver, allowing for different dimensions from the driver's eye position longitudinally to the front of the car.

The closer the driver sits to the front of the car, the more time available to the driver to see and possibly avoid the pedestrian, but, as shown in Figure 9, the effect is negligible. An impact on the car nearside corner provides more time to the driver than an impact directly in front of the driver: this

counter-intuitive result is related to the angles of sight lines around the visual obstacle. In any event, the effect on time of where on the front of the car the impact occurs is very small.

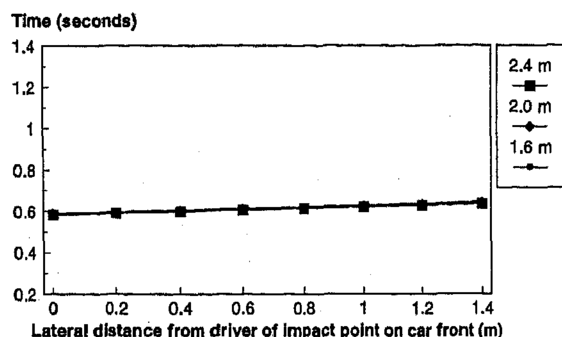

Fig. 9: The time available to the driver to see and avoid the pedestrian in a frontal collision, with different dimensions from the driver's eye position and different impact positions across the front of the car (car speed of 40 km/h, pedestrian speed of 3 m/s). All three lines are essentially superimposed on each other.

A SAFE PASSING SPEED

Courts are sometimes inclined to the view that a driver should have been travelling at a slower speed prior to the collision. And that by travelling at a slower speed, the driver could have taken successfully evasive action. In particular, courts often take the view that drivers should have been able to have braked to a stop before reaching the point of impact.

For any given situation, at what speed should a prudent driver pass a stationary vehicle such that if a pedestrian walks or runs out, the driver can react and stop the car before hitting the pedestrian?

By including in the motion of the car provision for a driver reaction time and a deceleration rate after the driver brakes, EMERGE can calculate the speed at which stopping just prior to the point of impact would have been possible. The basic principle illustrated in Figure 3 still applies, but for a given speed of the car at impact (v_{impact}, usually = 0), the speed of the car as it passes the stationary vehicle (u_{crit}) is a function of

- r the reaction time of driver, and
- a the slowing rate of the car prior to impact

The critical time when the pedestrian and driver are first in each other's field of view, t_{crit}, has the following relationship (utilising the general equation $v = u + a*t$, from Newton's Laws of Motion, where v is final velocity, u is initial velocity, a is uniform acceleration and t is time).

$$t_{crit} = r + (v_{impact} - u_{crit}) / (-a) \quad \text{.........................(3)}$$

where r and a are nominated for the calculation based on test or research data, and v_{impact} is nominated (usually = 0).

The geometry of the sight lines from the driver and the pedestrian is again as shown in Figure 5. The driver and the pedestrian are first within view of each other at t_{crit} before impact, when the angles α and β in triangles ABC and CDE are equal to each other.

At time t_{crit}, the coordinates of A are ($u_p*t_{crit}*\cos\theta$, $u_p*t_{crit}*\sin\theta$).

The Y coordinate for E is $-s_{lat}$. The X coordinate for E is the sum of the distance travelled at the critical speed during the reaction time ($u_{crit}*r$); the distance travelled during the slowing phase($[v_{impact}^2 - u_{crit}^2] / 2*[-a]$), which is found by utilising the general equation $v^2 = u^2 + 2*a*s$ (from Newton's Laws of Motion, where v is final velocity, u is initial velocity, a is uniform acceleration and s is distance over which the acceleration takes place); and the longitudinal distance from the driver to the point of impact on the car (s_{long}). Thus the coordinates of E are ($u_{crit}*r + [v_{impact}^2 - u_{crit}^2] / 2*[-a] + s_{long}$, $- s_{lat}$).

Within triangle ABC, angle BAC = α

$$= \text{atan}((x_{crit} - u_p*t_{crit}*\cos\theta) / (u_p*t_{crit}*\sin\theta - y_{crit})) \quad \text{..........(4)}$$

Within triangle CDE, angle DCE = β

$$= \text{atan}((u_{crit}*r + [v_{impact}^2 - u_{crit}^2] / 2*[-a] + s_{long} - x_{crit}) / (s_{lat} + y_{crit})) \quad \text{..........(5)}$$

The function in equation (3) is then substituted for t_{crit} in equation (4). From equations (4) and (5), the value of u_{crit} can be found which results in $\alpha = \beta$.

The example used earlier of the Toyota Camry passing the stationary vehicle with 1.2 m clearance encountering a pedestrian passing 1 m in front of the stationary vehicle at 3 m/s is used to illustrate the application. Figure 10 shows the effect on the safe passing speed of the relationship between reaction time and car slowing rate. In that particular scenario, the reaction time dominated the safe passing

speed, but even with a fast reaction time, the safe passing speed would be unrealistically low: at best only about 3 km/h. Considering that a young adult's *walking* speed is about 6 km/h, it is obvious that any realistic speed of the Camry would be too high!

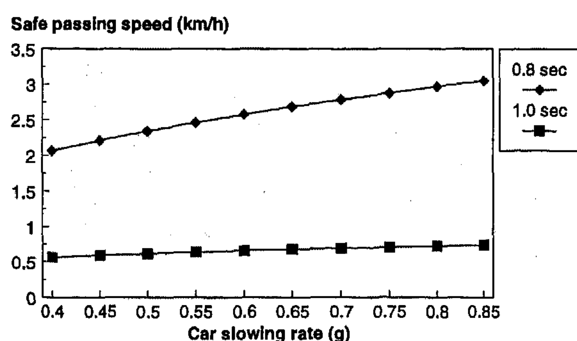

Fig. 10: The safe passing speed where the driver has a reaction time of 0.8 or 1.0 seconds (pedestrian speed of 3 m/s).

DATE FOR EMERGE

The required data for input in EMERGE can be obtained from different sources.

The point of impact on the car can be established by a variety of well documented means, often from evidence of damage on the car. The longitudinal distance from the point of impact on the car to the driver's position is sometimes available from databases (assuming the impact is on the front of the car): if not, measure it! In any event, errors in the distances from the driver to the point of impact on the car have very little influence on the calculations undertaken by the model.

The speed of the car can sometimes be established by witnesses and/or by the analysis of the post impact movement of the pedestrian and/or of the car. Unless the speeds are very low, the precise car speed is relatively unimportant and can often be addressed using speed ranges.

The speed of the pedestrian has an important effect on the outcome of the calculations. It is also usually more difficult to establish than the car speed, but it can at least usually be established as *walking, jogging* or *running* and, sometimes, (for example) *walking briskly* or *running fast.* There are published data based on population information from a variety of sources which can be used in these calculations (for example, Anon 1994; Austroads 1995; Coffin and Morral 1995; Eubanks 1994; Thompson 1991). An example from Eubanks (1994) is that of the running speeds for a sample of 42 eight year old boys: the 15th percentile speed was 4.17 fps (1.27 m/s); the 50th percentile speed was 4.99 fps (1.52 m/s); and the 85th percentile speed was 6.52 fps (1.99 m/s).

Typically a range of pedestrian speeds will be used in the analyses using EMERGE.

The point of impact in relation to the obscuring vehicle or object needs to be established, together with the paths taken by the car and the pedestrian. This information can usually be obtained from debris, objects dropped by the pedestrian and witness statements. Ranges are often used.

One of the most important parameters in considering the time available to the driver to avoid the pedestrian, and in calculation of the safe passing speed, is the driver's reaction time. A detailed study of reaction times is beyond the scope of this paper, but some discussion is warranted in considering the choice of reaction time for analysis.

REACTION TIME

The "reaction time" of a driver is the time taken to *detect* the presence of a person or an object; to *identify* that the person or object represents a potential or actual hazard; to *decide* the action to be taken in response to the hazard; and to *react* or *respond* by starting to take that action (Olson 1989). Reaction time is sometimes known as "perception-reaction" time (Triggs and Harris 1982) or "perception-response time" (Olson 1989).

Reaction time has probably been one of the most studied aspects of driver behaviour (Olson 1989). In essence, the main variables between studies have the degree of warning given to (or expectation by) the subjects of an event; the nature of the stimulus to which subjects were responding; and the complexity of background activities within which the stimulus appears.

The simplest studies involved subjects who were fully aware that they were engaged in an experiment. They were also often told to respond to a light or a sound, or similar discrete stimulus, by pressing a button or other simple action (Olson 1989, Sens et al 1989, Triggs and Harris 1982). In some instances, these experiments were testing anticipation. The net result was that reaction times achieved in such simple experiments were usually

very short, often approaching zero (Triggs and Harris 1982). While monitoring of the driving task overwhelmingly involves visual stimuli (Evans 1991), many of the studies involved responding to auditory stimuli. Whether the results from many of these simple experiments can be applied to driving situations is questionable (for example, Triggs and Harris 1982).

At the other end of the spectrum were experiments which involved monitoring of drivers in actual traffic situations: these subjects were not aware that they were being observed, nor that they were participating in experiments. These types of experiments involved observing or creating hazards on public roads where the behaviour of passing motorists was monitored. The hazards were such that there were several possible actions which motorists might take: that is, the decision making process was more complex than simply deciding whether or not to press a button (Triggs and Harris 1982). Experiments included

- responding to the yellow phase of traffic lights (mean time 1.30 seconds, standard deviation of 0.60 seconds, 85th percentile** 1.8 seconds, but with considerable variation in results from site to site - Wortman & Matthias 1983; mean time 1.14 seconds - Gazis et al 1960)

  ** the 85th percentile is a common criterion in traffic engineering and is the level at which 85 % of the population has responded

- responding to a car suddenly braking (mean time 1.45 seconds - Allen Corporation 1978; mean time 1.38 seconds, 85th percentile 1.95 seconds - Sivak et al 1979; mean time 1.25 seconds, 85th percentile 1.90 seconds - Sivak et al 1981; mean time 0.92 seconds; 85th percentile 1.26 seconds - Triggs and Harris 1982)

- a car door suddenly opening and responding by steering away (mean time 1.5 seconds - Summala 1981a, 1981b)

- amphometers (mean times 1.75 to 2.45 seconds; 85th percentile 3.40 to 3.60 seconds - Triggs and Harris 1982)

- railway crossing lights (mean times 1.16 to 1.77 seconds; 85th percentile 1.50 to 2.53 seconds - Triggs and Harris 1982)

- car under repair (mean time 1.02 seconds; 85th percentile 1.50 seconds - Triggs and Harris 1982)

- parked police vehicle (mean time 2.37 seconds; 85th percentile 2.80 seconds - Triggs and Harris 1982)

There have also been a large number of studies using techniques with conditions which were in between simple tests with alerted subjects on one hand, and the observations of actual traffic responses on the other (Olson 1989, Sens et al 1989, Triggs and Harris 1982). The "in between" studies tended to result in reaction times slower than for the simple tests, but faster than those in actual traffic (Sens et al 1989).

Studies have suggested that reaction time for older drivers is longer than for younger drivers (for example, American Automobile Association 1966). Other studies showed no major difference with age (for example, Olson et al 1984).

Alcohol is known to lengthen reaction times (Fricke 1990; Sens et al 1989). Fatigue is also known to lengthen reaction times to varying extents (for example, Muto & Wienville 1982), and there is also evidence that fatigue exacerbates the effects of alcohol (Corfitsen 1982).

Traffic engineering practice in many countries has been to design for a reaction time of 2.5 seconds, although research in several countries has resulted in proposals for much longer times to be used (Triggs and Harris 1982).

Overall, the published research has shown that reaction times in actual traffic are generally much longer than those measured in test environments which involve at least a degree of artificiality. While there will be considerable variation between individuals and circumstances, a reaction time of 1 second can be considered to be fast to very fast in most cases.

DISCUSSION

EMERGE provides a easy method for calculation of both the time from when the pedestrian came into view to the collision, and of the safe passing speed from which the driver could have braked to a stop. EMERGE can be readily used through a spreadsheet program (such as Lotus 123 or Excel). The speed and ease of use means that an envelope of ranges of variables can be very quickly and accurately compiled.

Some of the variables used in EMERGE are more important than others: in particular, the most important are pedestrian speed and where in relation to the obscuring vehicle or object the collision occurred. The angle between the paths followed by the pedestrian and the car can be important in some cases. Other variables are such that even very wide ranges of values in the input data will have little effect on the results.

The safe passing speed calculation is often a very powerful tool for demonstrating that any driver passing at a reasonable or even low speed could not have avoided the collision. The safe passing speed calculation is sensitive to driver reaction time and car deceleration rate.

The safe passing speed concept can also be applied where a car has braked and skidded before impact, and where the impact speed can be calculated through the pedestrian's post impact kinematics (for example, Aronberg and Snider 1994; Searle and Searle 1983; Searle 1991; Szydlowski and Jenkins 1991) and/or post impact skidding of the car. Consider, for example, where a car had braked and skidded 12 m before impact and continued for another 8 m from impact to rest. The slowing rate when skidding was, say, 0.7 g. From the skidding distances, the impact speed was about 38 km/h and the pre skidding speed was about 60 km/h. By inserting into the model an impact speed of 38 km/h and a deceleration of 0.7 g, the reaction time can be varied until a "safe passing speed" of 60 km/h is found. That will establish the reaction time likely to have been applicable in this instance, as well as the total time and distance to impact. One can then consider whether the reaction time was reasonable, or indicated an inattentive driver.

While EMERGE was developed for collisions involving emerging pedestrians, it has also proved useful for other types of "emerging" crashes, including both bicycle crashes and car crashes.

EMERGE can also be used where, for example, a pedestrian crossing a road "disappears" behind a large vehicle stopped in traffic before reappearing immediately prior to collision. In that case, the process involves two calculations of times before impact: the first in relation to the critical corner which determines when the pedestrian disappears; and the second in relation to the (diagonally opposite) critical corner when the pedestrian reappears. Figure 11 illustrates the application.

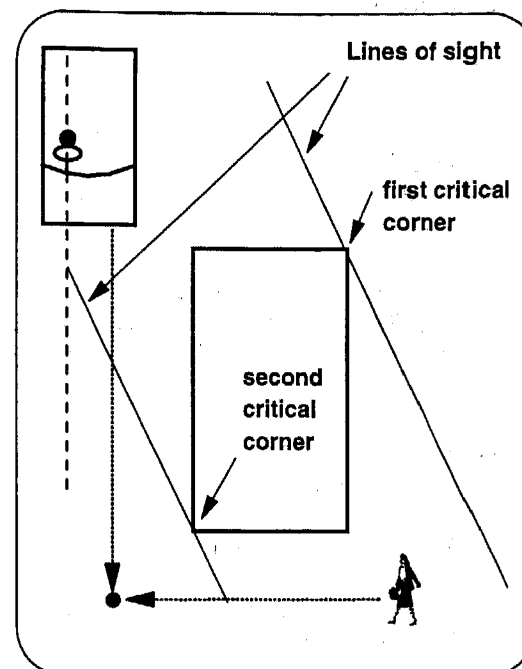

Fig. 11: The two critical corners where a pedestrian "disappears" behind a large vehicle in traffic, before reappearing just before collision.

SUMMARY

A mathematical model, "EMERGE", has been developed which can be used through a spreadsheet program. The model enables the rapid calculation of the time available to a driver from when a pedestrian emerges into his path, until colliding with the pedestrian. It is a tool for assessing whether the driver had sufficient time to take evasive action. It can also be used to calculate the safe passing speed from which the driver could have braked to a stop before colliding with the pedestrian.

EMERGE is mainly sensitive to pedestrian speed, and to the distances of the car and the pedestrian from the obscuring object (usually a stationary vehicle). It is not very sensitive to the car speed, unless the car speed is very low. The safe passing speed calculation is sensitive to the driver's reaction time and to the car slowing rate when braking. Other variables usually have relatively little influence on the outcomes.

It is also a useful tool for collisions involving emerging bicycles and cars.

Reviewer's Discussion
by David Sallmann, Rudny & Sallmann Engineering, Ltd.
Avoiding the Emerging Pedestrian: a Mathematical Model
Rodney G. Vaughan, Author

The author presents a unique mathematical model for analyzing timing in limited sight distance accidents. EMERGE can be used not only with spreadsheet software but also on calculators with equation solving routines. The discussion focuses on the emerging pedestrian case, but the model can be utilized equally well for intersection collisions between vehicles where limited sight distance exists. Driver reaction times can be computed using the model, after impact speeds and speed before braking has been determined.

The case described in this paper involves a right hand drive vehicle with the pedestrian approaching from the left. The model also applies for left hand drive vehicles and for far side impact situations. It should be noted, however, that the lateral distance from the point of impact on the car to the driver (S_{lat}) is a negative value when the point of impact is farther from the emerging vehicle/pedestrian than is the driver's position.

Motorcycle Slide to Stop Tests

Christopher J. Medwell, Joseph R. McCarthy, and Michael T. Shanahan
BTS Consulting Engineers

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper reports the results of testing conducted to determine the post-upset sliding friction factor on asphalt pavement for a sport motorcycle equipped with a full coverage fairing. A literature review revealed limited data regarding this type of motorcycle. Therefore, these tests were conducted and are reported in the interest of adding to the database available to accident investigators.

BACKGROUND

Motorcycle accident reconstruction often involves the determination of the speed of a motorcycle at the beginning of an accident sequence. In virtually all serious motorcycle accidents, the involved motorcycle will, at some point, fall to the ground and slide along the road surface for some distance. Accurate calculations of the motorcycle's speed prior to it falling over depend on evaluating the energy dissipated by the sliding motorcycle. This energy calculation, in turn, depends on the determination of an appropriate friction factor.

A brief review of the published literature reveals some data sources which address the friction factor of motorcycles sliding on their sides. For example, Day and Smith (1) reported on motorcycle friction factors in 1984. Various accident reconstruction handbooks (2,3,4) either refer to Day and Smith's paper or publish similar values from other testing. Typical friction factors for motorcycles sliding on their sides on asphalt pavement range from 0.35 to 0.75. Values for softer surfaces such as grass, gravel, or sand are higher, ranging from 0.65 to 1.1 or more. Refer to the Appendix of this paper for a review of the published data.

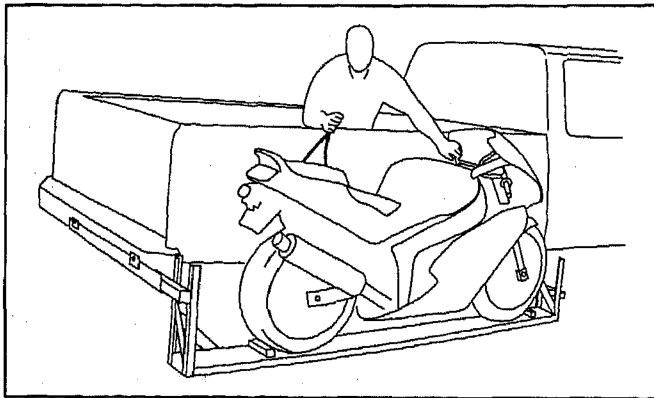
Most of the data originate from tests performed in the mid 1980's. Some dependence on speed was noticeable in some testing, with higher speeds generally resulting in lower friction values. Some dependence on motorcycle type was also observed, with lower friction values obtained from tests of motorcycles with broad or rounded surfaces such as crash bars or fairings. Friction factors for racing style sports motorcycles with full coverage fairings were unavailable, since this type of motorcycle was not generally available for street use.

A few more recently published test results for modern motorcycles (5,6,7) indicate that fairing-equipped sport motorcycles do tend to slide on their sides at lower friction values than do conventional motorcycles. Results for these tests range from 0.26 to 0.42 for high speed tests (80 to 100 km/hr). Data for current motorcycle designs, however, continue to be sparse. Therefore, a decision was made to undertake the tests reported herein.

PROCEDURE

The motorcycle utilized in the slide tests was a 750cc 1992 Kawasaki Ninja ZX-7. The motorcycle had approximately 4400 km on its odometer at the time of the testing. The Ninja was a sport-style street motorcycle equipped with triple disc brakes, in-line 4-cylinder engine, aerodynamic full fairing covering both sides of the motorcycle, cast aluminum wheels with relatively wide tires and low mounted handlebars. The fairing presented a large, smooth surface to the roadway, much like a toboggan. The handlebars and foot pegs, made of aluminum, protruded less from the side of the motorcycle than corresponding steel components on other classes of street motorcycles. These factors were expected to produce a lower friction factor than that of a conventional motorcycle. The motorcycle was also equipped with a factory 4-into-1 exhaust with a single large muffler canister on the right side.

This motorcycle had been involved in a single vehicle accident prior to our tests. The accident involved a long slide to a stop on the motorcycle's right side. The motorcycle's left side was undamaged. In order to prepare the right side of the motorcycle for our tests, we undertook a number of repairs prior to the test. These repairs included:



- Rotation of the muffler on the exhaust pipe so an undamaged surface of the muffler was exposed to the road surface during our test.
- Replacement of the right side lower fairing assembly.
- Replacement of the right side driver's foot peg bracket.

- Replacement of the upper fairing support bracket.

- Installation of the handlebar, turn signals, and side reflector from the left side of the motorcycle onto the right side.

With the exception of the right outboard edge of the upper fairing, the right side of the motorcycle was undamaged immediately prior to our testing. The fairing had sustained slight cracking and scuffing during the original accident which we did not deem necessary to repair prior to our tests.

The tests were designed to approximate, as closely as possible, the motion of a motorcycle falling over from an upright position. The motorcycle was positioned upright on a fabricated platform mounted on the right side of a pickup truck. (See Figure 1.) The height of the platform was adjusted so that its underside was as close as possible to the roadway surface. This test setup resulted in the motorcycle tire contact surface being approximately 90mm above the roadway. The motorcycle was held upright by an assistant riding in the bed of the pickup truck. The truck was accelerated to the test speed, then the motorcycle was released and allowed to fall over sideways onto the road surface.

Figure 1. Test Vehicle Platform

The tests took place on a straight, level roadway located on the property of a local airport. The road surface consisted of asphalt pavement approximately 6.5 m in width. The surface was weathered and had not been open to vehicular traffic for some time. The roadway aggregate projected beyond the level of the black binder, giving a light colour and some coarseness to the surface as opposed to a smooth pavement surface. The road surface was bordered on both sides by grass-covered shoulders. The grass was quite long and well-established. The surface underlying the grass was relatively smooth.

Tests were conducted at a speed of 80 km/hr. The test speed was monitored to within 1 km/hr by radar aimed at the pickup truck. The radar device was a Muniquip MDR2 and was calibrated with a 50 km/hr and a 95 km/hr tuning fork just prior to the tests.

The motorcycle was photographed before and after each test and the damage documented. The tests were video taped by cameras located both in the pickup truck and on the side of the roadway.

After the motorcycle slid to a stop, the sliding distance was measured. Measurements were taken from the location of the first evidence of the motorcycle's touchdown on the road surface to the centre of the position of the motorcycle at rest. A total of four tests were conducted, three on the right side of the motorcycle and one on the left.

OBSERVATIONS

RESULTS OF TEST NO. 1 - During test no. 1, the pickup truck was driven parallel to the roadway, and the motorcycle was released at a location near the centre line. Gouge marks created by the right foot peg and front axle, along with green paint transfers from the fairing, were the first evidence of touchdown. Also at touchdown, the front tire and wheel rim of the motorcycle left a deep scrape and a black tire scuff in the asphalt. A radial deformation of the cast aluminum rim of the front wheel was obvious after the test. The motorcycle, with the exception of its front wheel, slid smoothly on the asphalt surface. The front wheel, after the initial touchdown, immediately bounced up and then back down, leaving another black scuff mark at a second location. The tire then came down again and bounced lightly several more times, leaving black scuff marks to the road surface during the contact time. The intermittent black tire scuff marks were visible for the majority of the length of the slide on the paved surface.

The motorcycle slid in a direction about 4 or 5 degrees to the right of the travel path of the pickup truck and test platform. The motorcycle slid for 41 m on the asphalt surface before it left the right edge of the roadway and went onto the grass. During the "on-pavement" portion of the slide, the motorcycle was relatively stable with the front wheel leading. Evidence from the slide along the road surface consisted of intermittent black tire scuff marks from the front tire, as previously described. There were also scrape marks and scuff marks from the various aluminum components of the motorcycle contacting the road surface. Beyond the paint transfers at initial touchdown, there was no other evidence on the asphalt of the fairing contact. After the 41 m on the asphalt, the motorcycle continued on the grass shoulder to a point 56 m from its original touchdown point before coming to rest. While on the grass, it tore up a substantial quantity of turf which became lodged in the fairing. The motorcycle rotated counterclockwise approximately ½ of a revolution about the front wheel during the final 15 to 20 m of the slide. It came to rest with its front wheel pointing in the direction from which it had come.

In addition to the deformation of the front wheel rim, the motorcycle sustained abrasions to the lower right side fairing assembly, the lower edge of the right

fork tube, the right handlebar, the brake lever, the brake lever pivot area, the right side of the upper fairing, the driver's foot peg, the passenger's foot peg, and the outboard casing of the muffler. The right mirror broke from its mount, and the right front turn signal came out of its mounting area. With the exception of the damage to the front wheel, all of these damages were consistent with the expected damage for this kind of slide.

RESULTS OF TEST NO. 2 - Test no. 2 was also conducted at 80 km/hr. The motorcycle's initial sliding trajectory was similar to test no. 1. It came into contact with the grass 43.2 m from the touchdown point. During the slide on the asphalt, the motorcycle rotated slightly in a clockwise direction. As a result, the front tire of the motorcycle came into contact with the grass first. This occurred after the motorcycle rotated approximately 90 degrees to an orientation approximately perpendicular to the roadway, with the tires of the motorcycle leading the slide. As the front tire entered the grassy surface, turf was dug up and the motorcycle began to rotate rapidly clockwise. As it entered the grass, the motorcycle rotated rapidly while traveling approximately parallel to the edge of the road (i.e., having changed direction slightly from its original path towards the right). The motorcycle rotated approximately 540 degrees before coming to rest with its front wheel pointed towards the direction of the start of the slide. The total slide distance was 63 m, 43 m on asphalt and 20 m along the asphalt/grass shoulder interface. At rest, the handlebars and front wheel were located over the asphalt surface with the remainder of the motorcycle on the grass.

The evidence on the road surface from test no. 2 was similar to that from test no. 1 except the initial front wheel contact with the asphalt was less severe. A black scuff from the front tire was visible for the majority of the slide distance on the asphalt. Various scrapes and short duration scratches to the asphalt were noted along the entire distance of the slide. There was sufficient evidence to note the beginning of the slide, the direction of the slide, the location of the interface between the asphalt and the grass, and the distance the motorcycle slid on the edge of the grass.

Additional damage to the same surfaces of the right side of the motorcycle was noted. There was new evidence of additional scuffing to the front tire and wheel rim from this test; however, there was no deformation of the wheel rim.

RESULTS OF TEST NO. 3 - For test no. 3, the pickup truck was driven on a 4 or 5 degree angle to the left at the time of the release so that the motorcycle would travel parallel to the road during its slide. This method produced a slide straight down the roadway a distance of 69.5 m. The motorcycle was initially stable with the front wheel leading, but rotated 180 degrees counterclockwise toward the end of the slide and came to rest with the front wheel pointing back toward the start of the slide. Similar evidence on the road surface was produced during this test. The initial front wheel contact with the asphalt was minimal. The black tire scuff from the front tire was present throughout the length of the slide. Additional damage to the same surfaces of the right side of the motorcycle was noted.

RESULTS OF TEST NO. 4 - The last test was conducted by releasing the motorcycle onto its left side. Since the platform was mounted to the right side of the pickup box, this involved releasing the motorcycle with its rear wheel leading. The absence of a muffler on the left side of the motorcycle exposed more of the plastic fairing to the road surface and allowed the end of the rear axle to contact the asphalt.

During the initial portion of the slide, the motorcycle rotated clockwise 180 degrees to a position with the front tire leading. It was stable in this attitude until near the end of the slide, when it began to rotate counterclockwise slightly, just before it came to rest.

The pickup truck was again driven on an angle so that the total slide distance was on the paved surface as in test no. 3. The test speed was 80 km/hr, and the sliding distance was 86.3 m.

Short gouges were created on the road surface at touchdown by the handlebar end and the rear axle. The remainder of the slide distance exhibited short scratches and scuff marks similar to those observed in the other tests.

The motorcycle exhibited abrasions to a larger area of the lower fairing assembly than had been the case on the right side tests. At the rear, the absence of a muffler canister had allowed abrasions to the rear fairing area just below the seat and to the protruding end of the rear axle.

ANALYSIS

TEST NO. 1 - Based on an 80 km/hr release speed, and the 56 m slide length, the average friction factor for the slide was 0.45. Because of the grass torn and dug up during the portion of the slide on grass, it was obvious that the motorcycle had decelerated more rapidly on the grass than on the asphalt. Also, the digging in of the front wheel rim and tire at the beginning of the slide probably created a temporary additional drag. Drag from the front tire of the motorcycle eventually resulted in the motorcycle's rotation as the sliding velocity decreased.

TEST NO. 2 - Based on the 80 km/hr test speed and the 63 m slide distance, the average friction factor for the total slide was 0.4, a factor slightly lower than in test no. 1. Two reasons were immediately apparent for the difference:

1. The digging in of the front tire at touchdown was much less than during test no. 1.

2.The interaction with the grass at the edge of the road was less, with less material being torn up and the motorcycle never being fully onto the grass.

Other possible factors such as the grinding down of projecting surfaces are less likely, in our opinion, to have had a significant effect.

TEST NO. 3 - The motorcycle slid a distance of 69.5 m on asphalt pavement during test no. 3. Based on the 80 km/hr release speed, the friction factor for this test was 0.36.

TEST NO. 4 - The motorcycle slid a distance of 86.3 m on asphalt pavement during test no. 4. Based on the 80 km/hr release speed, the friction factor for this test was 0.29. We suspect that the lower friction factor was at least partially due to the absence of a left side muffler, which increased the portion of the weight of the motorcycle which was resting on plastic fairing components during this test.

Test Number	Distance (m)		Drag Factor
	Asphalt	Grass	Average
1 (right side)	41	15	0.45
2 (right side)	43	20	0.4
3 (right side)	69.5	-	0.36
4 (left side)	86.3	-	0.29

The tests were designed to obtain values for the friction factor on asphalt. However, due to the 4 or 5 degree angle at which the motorcycle departed from the test platform, the last 15 m of sliding in test no. 1 and the last 20 m of sliding in test no. 2 took place on the grass. The 4 or 5 degree angle stayed constant throughout the four tests, suggesting that it was due to the lateral velocity attained during the fall to the roadway. The angle could affect the test speed by about 0.3 km/hr. The asphalt portions of all tests appeared to be virtually identical in terms of motorcycle dynamics, except for the unusually severe front wheel interaction at the start of test no. 1. Therefore, tests nos. 1 and 2 should have produced results similar to those of tests nos. 3 and 4 if not for the fact that the motorcycle left the asphalt surface.

Based on the similar distances the motorcycle slid on the asphalt in tests nos. 1 and 2, the motorcycle should have been traveling at about the same speed in both tests as it entered the grass. Because the grass portion of test no. 1 involved much more interaction with the turf than was the case in test no. 2, the motorcycle slid a significantly shorter distance on the grass in test no. 1.

To test the hypothesis that the asphalt friction factor was similar for all four tests, we calculated the resultant grass friction factors. Our calculations, assuming an asphalt friction factor equal to the average of the results from tests nos. 3 and 4, suggest that the motorcycle was traveling at about 53 to 55 km/hr when it entered the grass in test nos. 1 and 2. Thereafter, the friction factor on the grass was approximately 0.78 in test no. 1 and 0.55 in test no. 2. The magnitude of these values appeared to be consistent with the observations made of the motorcycle during these two tests.

In analyzing the data from tests nos. 3 and 4, an error factor of plus or minus 1.5 km/hr for the initial speed was included. This error factor accounts for the possible error within the radar unit and for the angle at which the motorcycle slid with respect to the path of the pickup truck. Therefore, the range for the asphalt friction factor for this motorcycle in these tests was between 0.28 and 0.38.

We note that the lower end of the range was obtained from test no. 4, when the motorcycle was sliding on its left side. During this test, more of the weight of the motorcycle was being carried by the fairing, since there was no muffler canister on the left side of the motorcycle. The reduction in friction factor expected from a fairing equipped motorcycle may depend on how much of the weight of the motorcycle is borne by the fairing components as opposed to the metal protrusions such as foot pegs, handlebars, and exhaust components.

The lower end of the range from these tests was consistent with the results reported by Raftery (6). Raftery's method used cables to suspend the motorcycle horizontally an unspecified distance above the roadway before it was released. Raftery reported a result of 0.26 after testing an unspecified make and model motorcycle retrofitted with a fairing at a speed of 85 km/hr.

A similar test method was utilized by Carter et al (7) to test a number of motorcycles, including two sports models with fairings. The motorcycles were suspended with their lowest point approximately 50mm above ground. For the 1987 Yamaha FZ700T, a sports model, tested once at 97 km/hr, the reported result was 0.42. When the same motorcycle was tested at 48 km/hr, the results ranged from 0.40 to 0.48.

Carter et al also tested an earlier sports motorcycle, the 1984 Yamaha FJ1100, and reported results ranging from 0.38 to 0.48 at 97 km/hr and from 0.42 to 0.52 at 48 km/hr. The fairing on the FJ1100 did not extend to fully cover the sides of the motorcycle as it does on most current sport model motorcycles. It may be that the fairing on this motorcycle does not bear the majority of the weight of the motorcycle during sliding tests.

FALL TIME - Analysis of the video tapes showed that the time for the motorcycle to fall from an upright position to roadway contact was about 2/3 of a second. This fall time was relatively constant throughout the testing.

SUMMARY

Based on our test results, the friction factor for fully-faired motorcycles on asphalt ranges from 0.28 to 0.38 when considering a typical accident scenario with a fall; some distinct, short gouges at touchdown; and a final rest position on, or near, the pavement. Where gouge marks are deep or longer than a few inches, or where significant deformation of motorcycle components has occurred due to digging in, higher friction values may be warranted. Where the plastic fairing components bear all or nearly all of the weight of the motorcycle during the slide, the lower values would probably apply.

The values we obtained fall within the lower portion of the range of values previously published. As always, we recommend that accident investigators apply this and any other test data with caution. Motor vehicle accidents are complex events, and the test data reported here does not necessarily apply in every case.

ACKNOWLEDGMENTS

The authors wish to thank the members of the Traffic Unit of the Windsor Police Service for their valuable assistance in the staging of these slide tests.

SAE #970963
Reviewer's Discussion
by Terry D. Day, Engineering Dynamics Corporation
Motorcycle "Slide to a Stop" Test
Christopher J. Medwell, Joseph R. McCarthy, Michael T. Shanahan, Authors

This paper extends the current knowledge of drag factors for motorcycles sliding after an upset (either caused by impact or simple loss of control). The tests are well-documented, and the additional data for the new generation of fairing-equipped sport cycles is valuable. In addition to the quantified results, an important contribution of this paper is the qualitative description of the cycle's motion during each test, allowing one to conclude there is a variability in the resulting drag that is dependent on how the cycle interacts with the surface. Viewing the test videos might be as useful (perhaps educational is a better word) as the actual drag factors.

Motorcycle "Slide to a Stop" Test
Christopher J. Medwell, Joseph R. McCarthy, Michael T. Shanahan, Authors

The title "Motorcycle Slide to Stop Tests" is very appropriate. The authors were unable to locate adequate references and decided to test a motorcycle. This paper discusses a series of four tests completed by the authors and is very specific on how the tests were conducted. The material is presented in a straight forward fashion allowing the reader to understand the method of testing and how the findings can be related to collisions involving a specific type of motorcycle.

The information is limited to one series of tests. The limitation does not reflect on the value of the material presented. The authors willingness in sharing their test information becomes a valuable resource and adds to work completed by other investigators.

An added benefit of the paper is the compilation of information provided by the Appendix. The authors took the time to research other papers and articles concerning deceleration factors for sliding motorcycles. This appendix has been organized into a very useful resource for the reconstructionist or investigator.

On-Demand Four Wheel-Drive Transfer Case Modeling

J. Asgari and D. Hrovat
Ford Motor Co.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper describes the development of a Matrixx Model of an electronically controlled on-demand 4 Wheel-Drive (4WD) Transfer Case. The model was partially validated with respect to available vehicle test data and subsequently used for control system design and evaluation.

1. INTRODUCTION

As an aid in conceptual development of sophisticated control strategies in ground vehicles, efficient and validated physically based system models are necessary. The model should capture the basic features of the system, and represent the most essential system behavior. It should be readable and should preserve the physical meaning of system variables and parameters. The models must be sufficiently complete to include the important dynamics, but not so complex that insight is obscured.

The purpose of this project was to develop a Matrixx-based computer model of on-demand 4 Wheel-Drive (4WD). This model is complete enough to predict a correct trend of behavior in vehicle simulation and simple enough to study the influence of the main design factors on the dynamic behavior of the vehicle.

The transfer case is an independent unit in the 4WD system, mounted at almost the mid-section of the vehicle. Its primary function is to split power automatically between the rear and front axle, when predetermined slip of the rear wheels is exceeded.

Bond graph techniques [1] were used for model development. Bond graphs are a pictorial representation of different energy domain systems, and allow a priori determination of the computability of a proposed model through assignment of causality. It further permits the modeling of vehicle subsystems which are later assembled into overall system models. These subsystem models can even be tested independently and as long as their causality remains invariant, the subsystem model can straight-forwardly be integrated into system models. This paper describes the application of such an approach, described in general terms in [1], where additional bond graph applications are given.

2. SYSTEM CONCEPT

Figure 1 shows a simplified concept cross section of the transfer case. When the on-demand 4WD is engaged, torque from the transmission goes to the rear prop-shaft, and also through the clutch assembly to the front prop-shaft. A more complete drawing of the transfer case is illustrated in Fig. 2.

The transfer case transfers torque using four main components: control module, solenoid, ramp and roller assembly, and clutch assembly.

The control module measures the rotational speed of front and rear prop-shafts, and when this difference is large, it increases the duty cycle of PWM input signal to the solenoid. The solenoid average current follows the PWM command and generates an electromagnetic force which attracts the solenoid plate and collar (see Fig. 1). A change in PWM will translate in a change in the pressure and (primary) torque between the solenoid plate and collar. The solenoid plate is connected to the front prop-shaft by a spline coupling, and has the same angular speed. It is free to move axially.

The apply plate is connected to the rear prop-shaft by a spline coupling, which can move axially while rotating at the speed of rear prop-shaft. The collar is connected to the apply plate by a ramp and roller assembly (Fig. 3). When the 4WD is disabled, the collar rotates with the speed of the rear prop-shaft (Fig. 3a) and no torque is transferred to the front prop-shaft.

When the 4WD is actuated, the collar speed reduces due to the (primary) friction torque between the collar and solenoid plate (see Fig. 1). As the result of the difference between the speeds of the collar and the apply plate, the rollers roll up the ramp (Fig. 3) causing axial motion of the apply plate. This axial movement of the apply plate causes the engagement of the front and rear clutch plates which transfer the torque from the rear prop-shaft to the front prop-shaft (secondary torque).

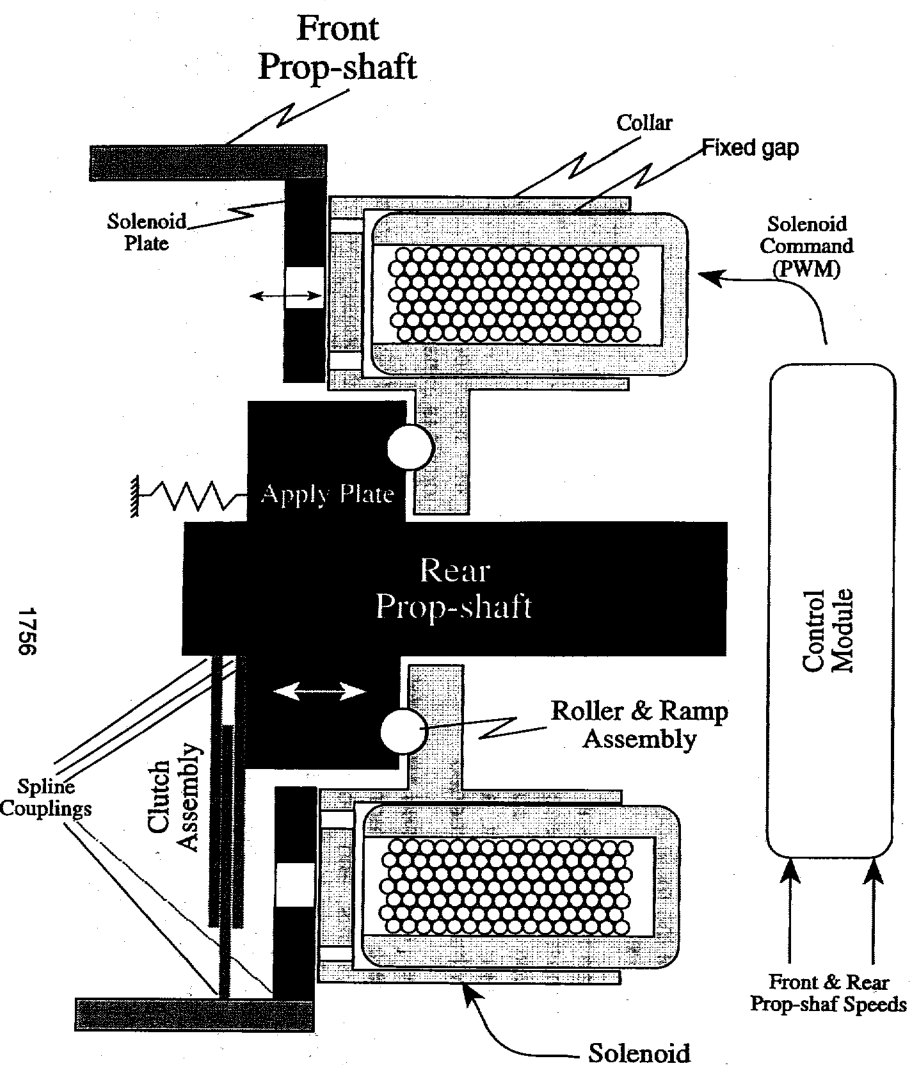

Fig. 1. Simplified Concept Cross Section of Transfer Case

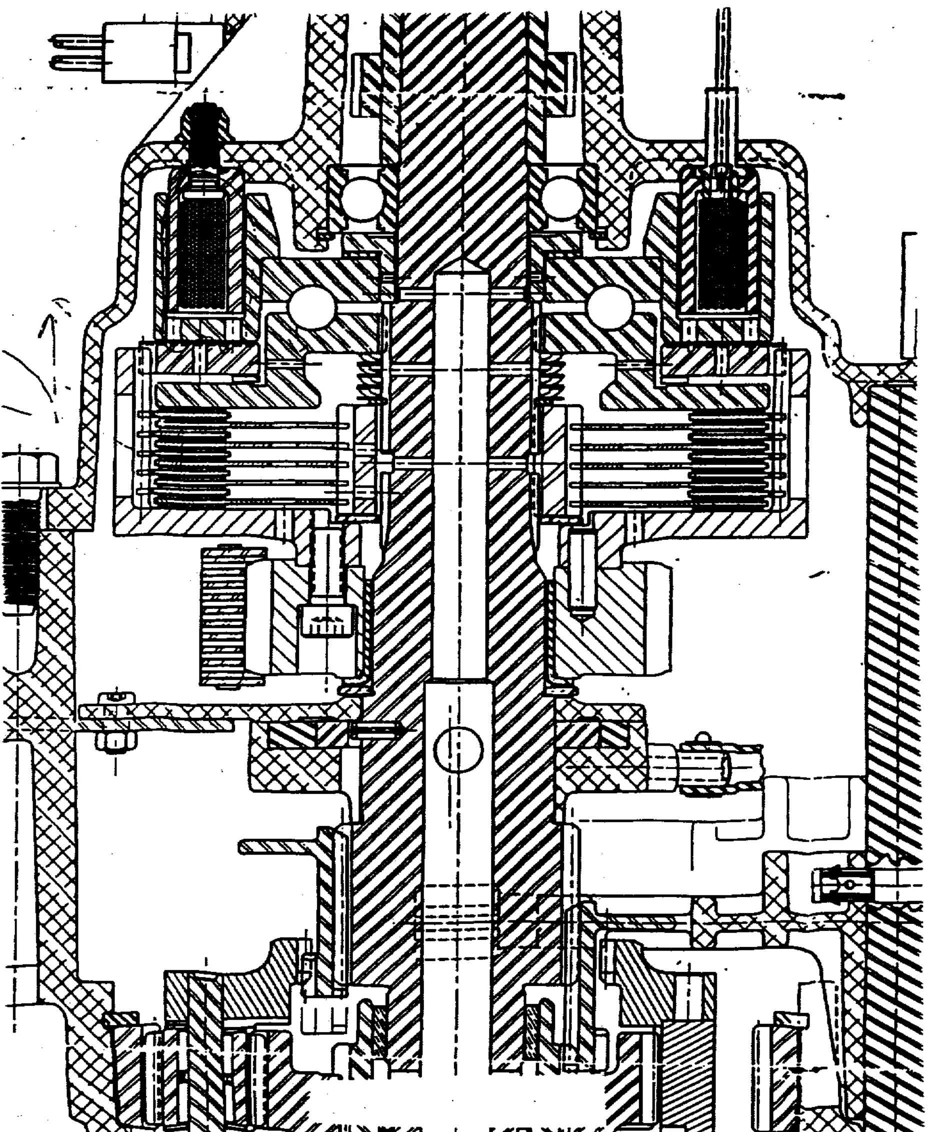

Fig. 2. Transfer Case Drawing

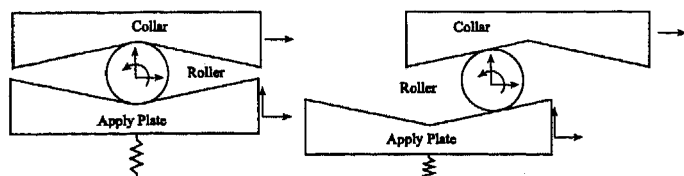

Figure 3. Ramp and Roller Assembly.

3. MODEL DEVELOPMENT

As indicated earlier, the bond graph modeling technique has been used for the model development. Figure 4 shows the word bond graph representation of the system. The word bond graph represents the major subsystems to be considered. The main submodels consist of:

1) transfer case
2) drive train
3) differential and axles
4) tires
5) vehicle model

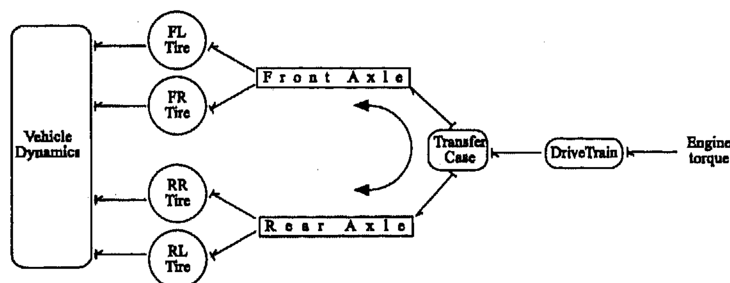

Figure 4. Word Bond Graph Representation of the Model

These submodels are discussed below.

3.1) TRANSFER CASE

As was previously discussed, the transfer case consists of four main sub components: solenoid, ramp and roller, clutch assembly, and control module. Figure 5 shows the way these parts are connected together. These subcomponents will be discussed in detail below.

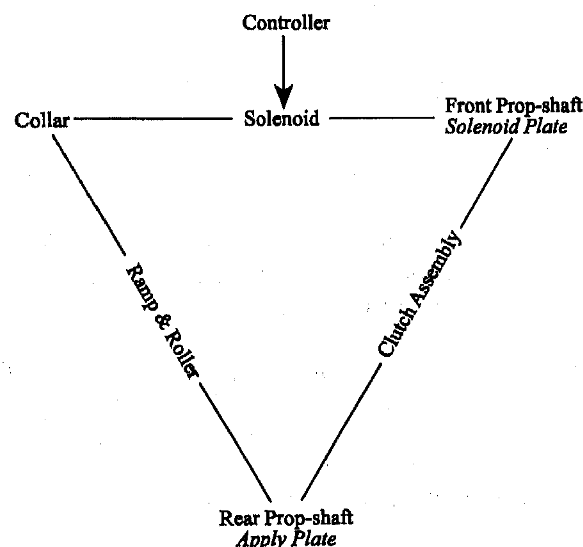

Figure 5. Transfer Case Connectivity

3.1a) Solenoid

The solenoid is capable of transforming an electrical signal into mechanical movement. The response time of the solenoid is of primary importance. The system (Fig. 1) consists of a coil of wire, a fixed piece of soft iron, and a moveable core (solenoid plate). When the current increases in the coil, the solenoid plate gets closer to the stationary core.

The corresponding model is divided into three areas: (I) electrical model (II) the electromagnetic model which describes the interaction of the iron magnetic flux path with the solenoid coil winding; and (III) the magnetic to mechanical interaction model which describes the force due to magnetic flux.

I) Electrical model

The electrical model follows the rise of current in the coil. The effective voltage in this system is reduced by the resistance in the coil as shown by equation 1.

$$e = V_{in} - R_E i \qquad (1)$$

II)Electromagnetic model

The electromagnetic model follows the rise of magnetic flux in the iron path, gaps, moving and stationary parts. By using the Faraday's law applied to the coil, we have

$$e = \dot{\lambda} = N\dot{\phi} \qquad (2)$$

where λ is flux linkage, N is the number of turns of coil, and ϕ is the flux. The driving force which sets up the flux in the core is the magnetomotive force, M.

$$\sum M = M_g + M_c + M_{g_a} = Ni \qquad (3)$$

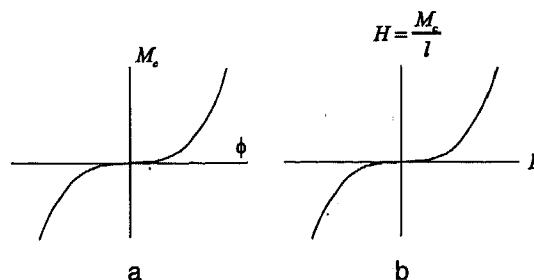

Figure 6. Solenoid Housing Charactristics

In the iron the magnetomotive force, M_c, and flux are related by a nonlinear relation (Fig 6a) which is function of material and geometry. To characterize a core material [1], it is convenient to use a curve independent of core configuration. For this purpose usually the B-H curve is used (Fig. 6b) where

B ≡ Magnetic flux density (weber/ square meter)
H ≡ Field strength (Amper-Turn/meter)

$$M_c = f(\phi) \qquad (4)$$

In the gap, the relation between the magnetomotive force and flux is defined by

$$M_g = \frac{\phi_g}{C_g} \quad (5)$$

$$C_g = \frac{\mu_o A_g}{4x_g} \quad (6)$$

where x is the gap length, A is the gap area and μ_o is permeability of free space $\equiv 4\pi * 10^{-7}\ Tm/A$. (assumed air (free space), space may contain some transmission fluid).

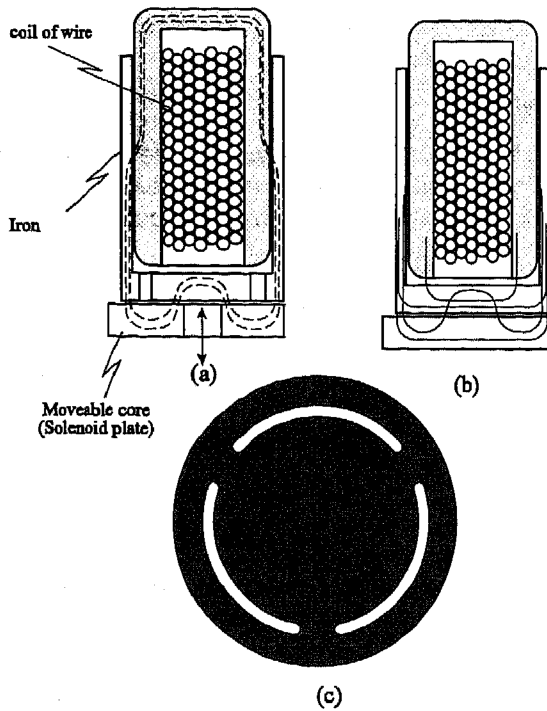

Figure 7. Flux Path.

For a fixed gap,

$$M_{g_a} = \frac{\phi_g}{C_{g_a}} \quad (7)$$

$$C_{g_a} = \frac{\mu_o A_{g_a}}{2L_{g_a}} \quad (8)$$

Ideally it is desired to have flux follow the path shown in Fig. 7a, but since some paths through the solenoid plate (Fig. 7c) and the stationary part are solid, and since there is some leakage in the system, the flux follows a combination of the paths shown in Fig 7b. This results in a significant flux leakage in the system.

III) The magnetic to mechanical interaction model

In [1] it has been shown that the force due to flux is equal to:

$$F = \frac{\phi_g^2}{2\mu_o A}. \quad (9)$$

Figure 8 shows the complete bond graph representation of the solenoid. Using Fig. 8 the overall equations of the solenoid can be written as follows:

$$i = (M_g + M_{g_a} + M_c)/N \quad (10)$$

$$\dot{\phi} = \frac{V_{in} - R_E i}{N} \quad (11)$$

$$F = \frac{\phi_g^2}{2\mu_0 A_g} \quad (12)$$

$$\ddot{x}_g = \frac{-F - Kx_g - Rv_g}{m} \quad (13)$$

Where *K* and *R* are the effective stiffness and damping applied at the solenoid plate.

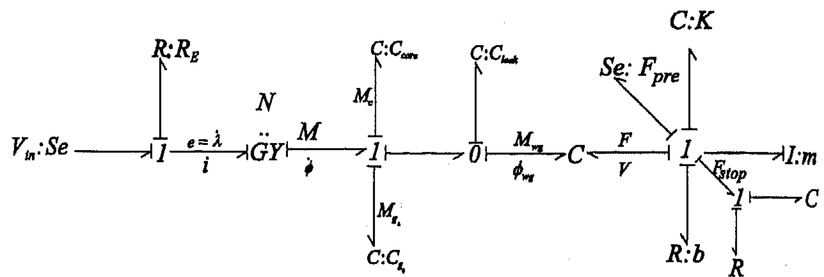

Figure 8. Bond Graph Representation of Solenoid

3.1b) Ramp & roller

Figure 3 shows a free body diagram of the ramp and roller. Figure 9 shows the bond graph representation of the system which includes the dynamics of the roller (3 DOF) and the apply plate. The inertias on bonds 1, 2, and 3 (in the right hand side of Fig. 9) represent the dynamics of the roller in x-direction, y-direction, and rotation of the roller (see Fig. 3). The compliances on the bonds 4 and 5 represent the stiffness of the roller with respect to the apply plate and the collar, respectively. The resistance on the bonds 6 and 7 represent the friction force between the collar and roller. Since there are two ramp surfaces in the apply plate and collar, there is another set of compliance- and resistance-like bonds with α replaced with -α in the appropriate transformers. The inertia on bond 8 represents the dynamics of the apply plate in the axial direction. The compliances on bonds 9 and 10 represent the stiffness of the return spring and clutch assembly respectively. The force in the bond 10 is used to generate the secondary torque. Bond 11 will be connected by a transformer to a 1-junction representing the collar rotational rate, and bond 12 will be connected to a 1 junction representing the rear prop-shaft rotational rate. This model can be substantially simplified by (approximately) replacing the above dynamics with a simple spring and damper.

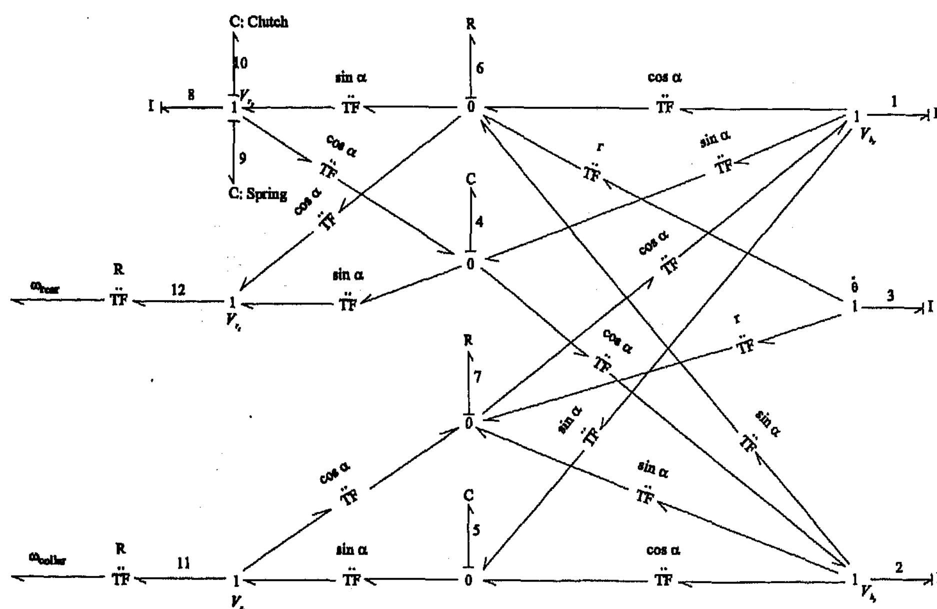

Figure 9. Bond Graph Representation of Ramp and Roller

3.1c) Clutch Assembly

The friction torque in the clutch was calculated by [2]:

$$if\ \Delta\omega < \Delta\omega_{sat}\ then$$

$$\tau = NRF_{n_c}\mu(1 + 0.2e^{-0.2\Delta\omega_{sat}})\frac{\Delta\omega}{\Delta\omega_{sat}}$$

$$else$$

$$\tau = NRF_{n_c}\mu(1 + 0.2e^{-0.2\Delta\omega})$$

where

$N \equiv$ the number of clutch plates,

$R \equiv$ effective radius,

$F_{nc} \equiv$ Normal load (calculated in the ramp and roller),

$\mu \equiv$ friction coefficient,

$\Delta\omega \equiv$ the difference between rotational rate of front and rear prop-shaft,

$\tau \equiv$ the friction torque in the clutch (secondary torque),

$\Delta\omega_{sat} \equiv$ the saturation point.

This equation approximates the stick/slip characteristic of the clutch.

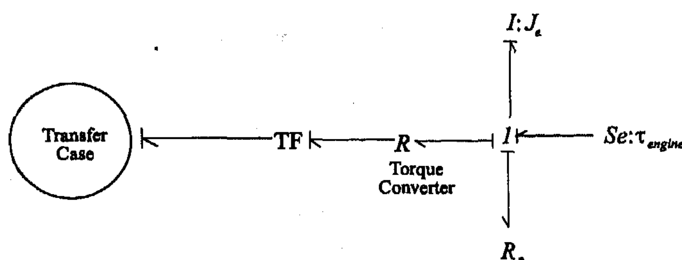

Figure 10. Bond Graph Representation of Drive Train.

3.2) Drive Train

The bond graph representation of the drive train model is shown in Fig. 10. The model includes the engine torque source, engine rotational inertia, engine loss, torque converter, and the transmission gear ratio. The downstream rotational inertia has been combined with the rear prop-shaft inertia.

3.3) Differential and Axle

The function of the differential is to provide driving torque to both left and right tires, while allowing for unequal left and right angular speeds. The axle and differential are modeled [3, 4] by two transformers followed by a three-port 0-junction (Fig. 11). The first transformer represents the final drive speed ratio, and the second transformer accounts for the torque split to the two wheels. The half shaft compliance and damping are also included. The drive shaft compliance could be ignored or alternatively included in half shaft compliance.

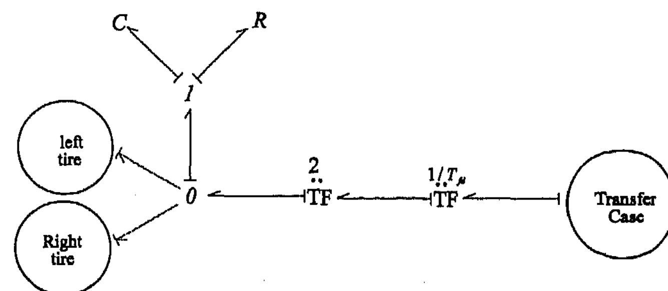

Figure 11. Bond Graph Representation of Axle and Differential

3.4) Tire

Except for aerodynamic forces and gravity, all the forces which affect vehicle handling are determined by tires. Tire forces provide the primary external influence, and because of their highly nonlinear behavior, cause the biggest variation in vehicle handling properties throughout the longitudinal and lateral acceleration maneuvering range. As a result, it is important to use a realistic nonlinear tire model, especially when investigating large control inputs that result in response near the limits of the maneuvering capability of the car. In such situations, the lateral and longitudinal motions of the vehicle are strongly coupled through the tire forces and large values of longitudinal slip and slip angle occur simultaneously.

The many existing tire models are predominantly "semi-empirical" in nature. The model structure is determined through analytical considerations, but the key parameters still depend on tire data measurements. They range from extremely simple (where lateral forces

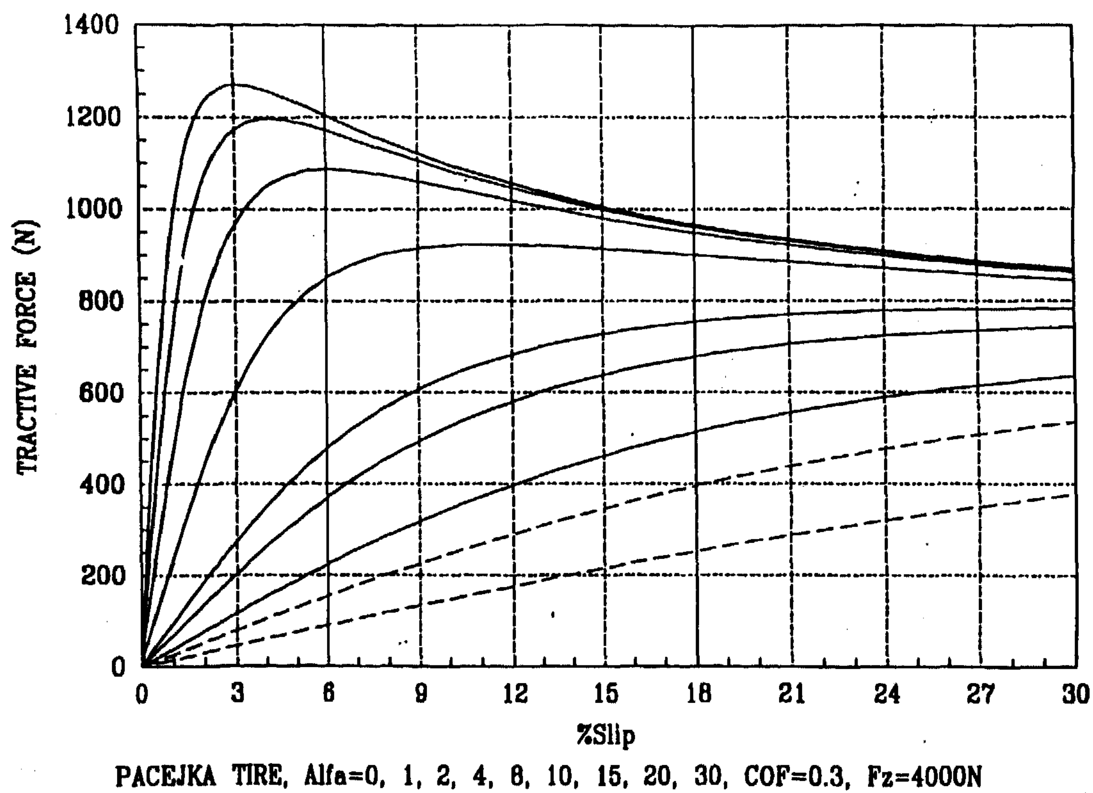

Fig. 12a. Tractive Force as a Function of % Slip during Braking and Cornering.

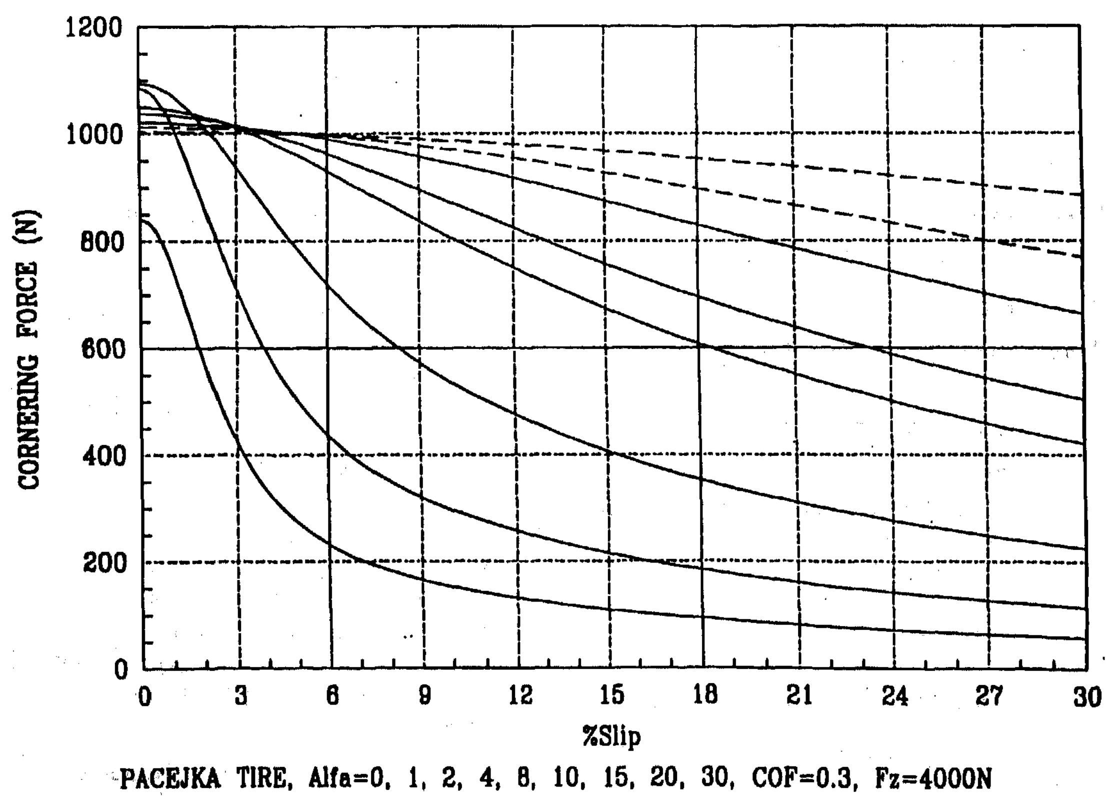

Fig. 12a. Cornering Force as a Function of % Slip during Braking and Cornering.

are computed as a function of slip angle, given only a measured slope at α=0 and a measured value of the maximum lateral force) to relatively complex expressions, which use tire data measured at several loads and slip angles.

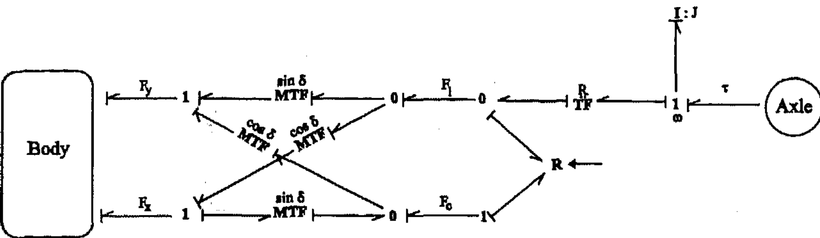

Figure 13. Bond Graph Representation of Tire.

The model for tire tractive and cornering forces used here (Pacejka's tire model [5]) is a complex semi-empirical model of a tire that takes into consideration the interaction between the tractive force and the cornering force in combined braking and steering. The longitudinal and cornering forces are assumed to depend on the normal force, slip angle, and longitudinal slip. Sample plots of modeled longitudinal and lateral forces versus longitudinal slip and slip angle are shown in Figs. 12a and 12b. In this model, the dynamic effect of tires while negotiating sudden changes of operating conditions [6] has been ignored, but could be included in the future if needed.

Figure 13 shows the bond graph representation of a tire. It includes: the tire inertia, steering effect, and nonlinear tire cornering and longitudinal force production mechanism modeled as (nonlinear) R-field.

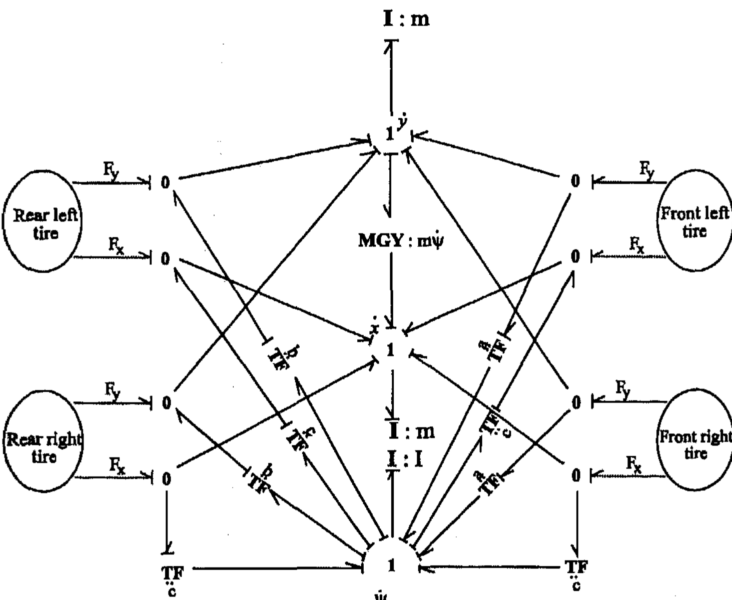

Figure 14. Bond Graph Representation of Body

3.5) Body

This model is intended for simultaneous studies of vehicle fore-aft and handling dynamics [7]. It has 3 degrees of freedom: lateral and longitudinal velocities, $\dot{y}$ and $\dot{x}$, and yaw rate, $\dot{\psi}$. The body moves as a result of forces transmitted from the road through the tires. A bond graph schematic of the model is shown in Fig. 14. Here, m represents the body mass and I represents the body moment of inertia about a vertical axis through the center of gravity.

3.6) Overall Model and Assumptions

Figure 15 shows the overall system model. The main inputs to the model are: engine torque (Fig. 15a), road coefficient of friction (Fig 15b), and steering input (Fig 15b). In this model the transient effect of the tire during sudden changes, the slip/stick characteristic of clutch, engine dynamics, and vehicle heave and pitch dynamics were not included. These submodels are available and can be included in the overall model as necessary. The tire characteristics used are generic and may not necessarily exactly represent the Explorer tire curves.

4. PARTIAL MODEL VALIDATION

To study the accuracy of the model, comparison tests were done between experimental and simulation results for different surface, speed, and load conditions. The experimental data available included: front and rear prop-shaft speeds, front and rear axle torques, and solenoid current.

An example of an experimental test done on packed snow is shown next. The controller strategy requested a medium-to-high level of torque. Figures 16 and 17 show the comparison between the experimental and simulation results. Figure 16a shows the experimental prop-shaft speeds, while Fig. 16b shows the corresponding model results. Figure 17 compares the corresponding solenoid currents. The high frequency oscillation in Fig. 17 is due to PWM duty cycle. Overall, there is a good agreement between the experimental and simulation results especially taking into account the fact that the road (snow) properties are not exactly known.

5. OPERATION OF A LOCKED SYSTEM

It is well-known that the 4WD vehicles should be driven in 4WD-lock position only at low speeds, and preferably on straight sections of slippery/muddy roads. If however, one attempts such a drive on dry roads and higher speeds, then, one could occasionally feel a chatter-like behavior both for cars and trucks. An attempt was done to qualitatively reproduce this result through simulations. Due to the lack of complete data, an exact comparison was not possible. To recreate the observed phenomena, the rear tire radius was increased by about 7% to simulate different front to rear load distribution and tire conditions. Figures 18 to 20 show the corresponding simulation results.

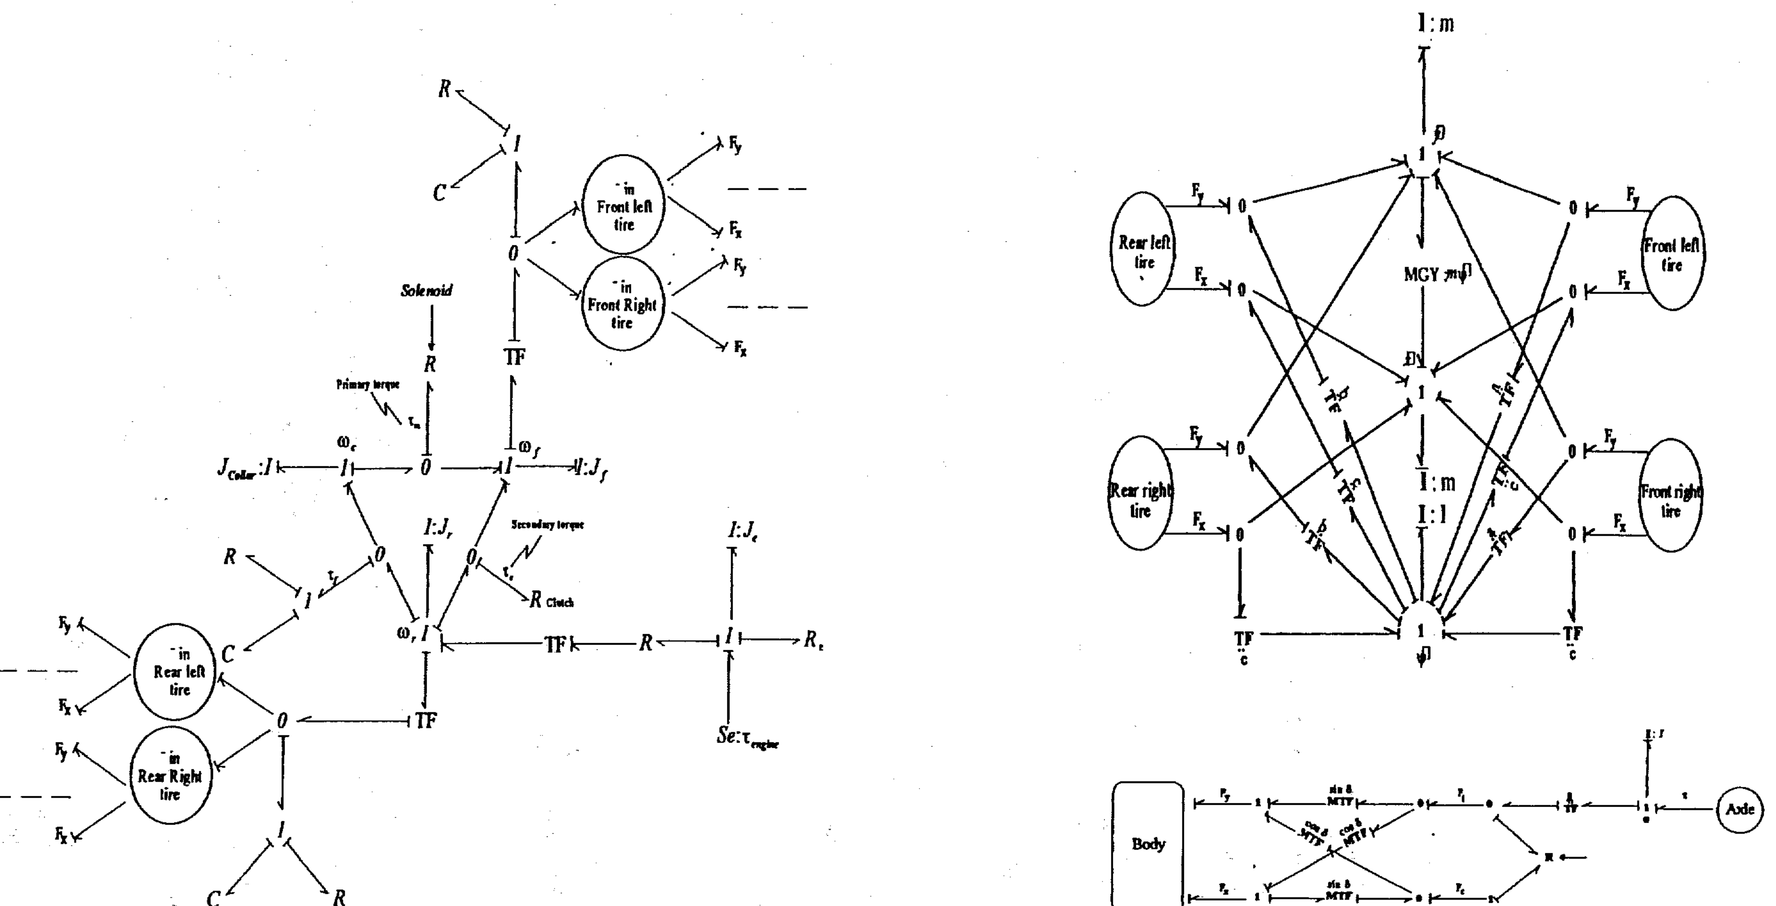

Fig. 15a. Overall Vehicle Model with Simplefied TOD Model

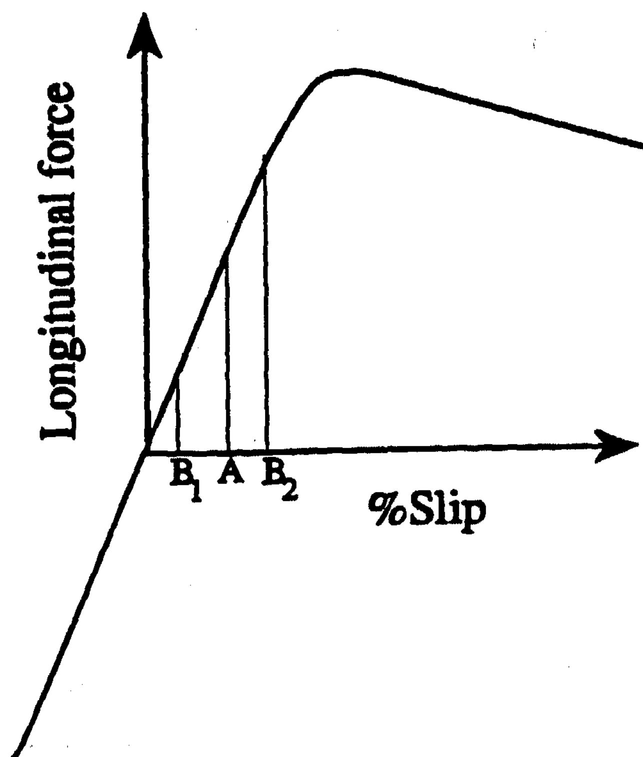

Fig. 21. Typical Longitudinal Force as Function of % Slip.

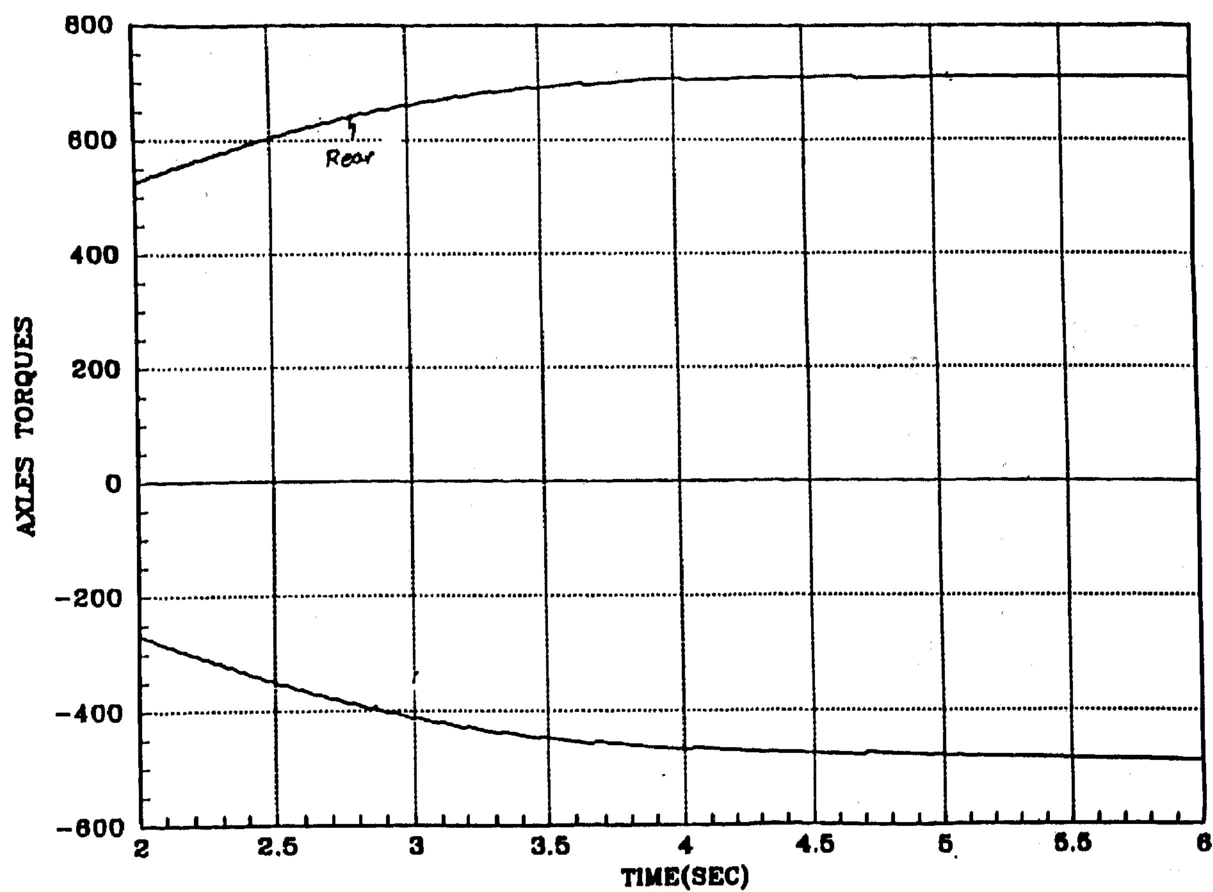

Fig. 22. As fig. 19 but with Smaller Difference in Tire Radius.

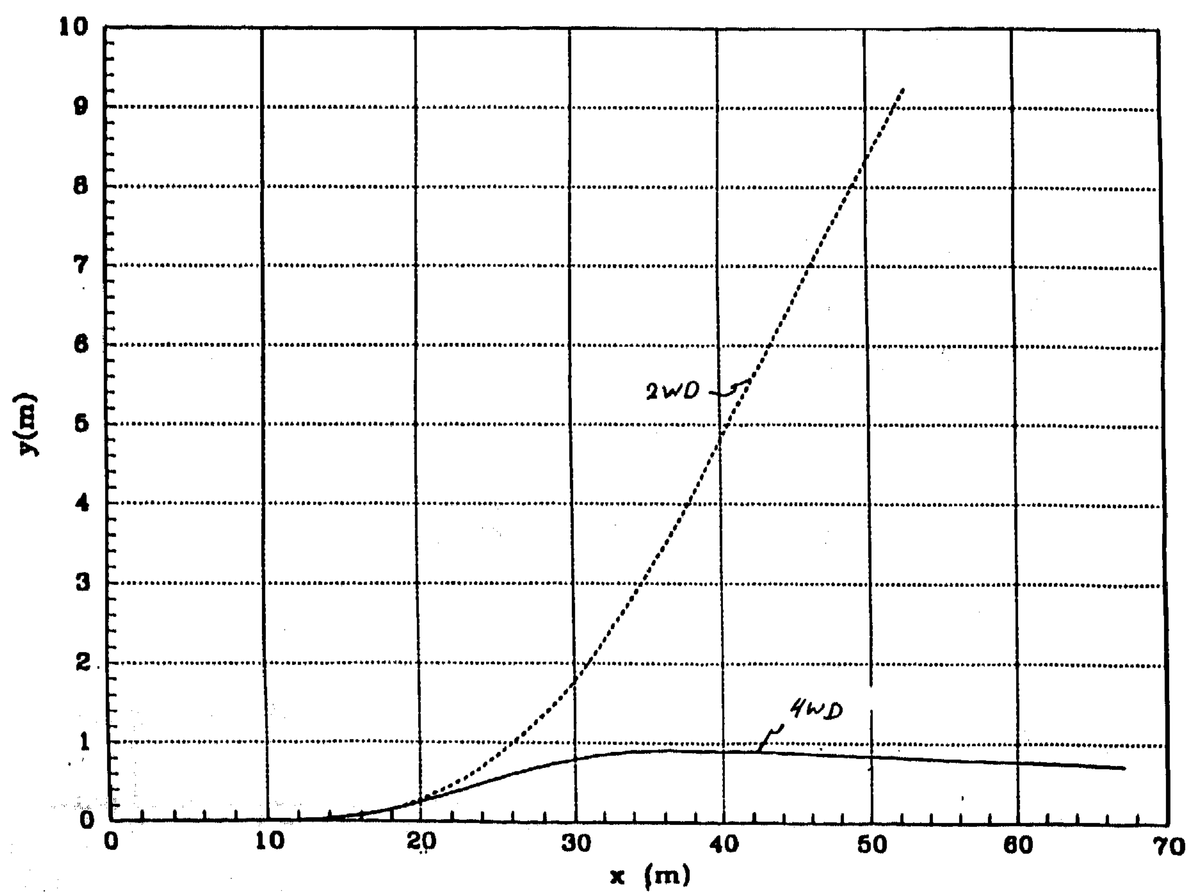

Fig. 23. Simulation Results for 2WD and Control Trac Handling Maneuver on Snow.

Although the above simulation results are very preliminary and warrant further investigations, one possible rationalization for the above phenomenon is given below. If one assumes equal loads and radii of front and rear tires -since the transfer case clutch is locked- both front and rear tires would operate at point A in Fig. 21. Increasing the rear tire radius (still we have the hub velocities $\omega_f = \omega_r$) will result in rear tires having larger percent slip than the front tires resulting in operation at point B_2 in Fig. 21. The corresponding front slip is at B_1 in Fig 21. This can also be seen from the corresponding simulated slip traces shown in Fig. 20. If the difference in tire radius is big enough it can cause the front tire to operate on the negative side of tire longitudinal force characteristics. An oscillation or chattering occurs when the rear tire forces pass over the maximum of the traction force diagram. This is illustrated by the slip traces of Fig. 20 for the above case of 7% effective tire radius difference. For the smaller difference, of 3.5%, these oscillations are not present (see Fig. 22).

6. MODEL USAGE

To study the effect of the transfer case on handling, a comparison test was done between RWD and a 4WD-equiped vehicle. The simulation was done on snow with a harsh steering input that is typical of, for example, emergency lane change maneuvers. Figure 23 shows the trajectory of the two simulations. As can be seen the 2WD vehicle was unstable while vehicle equipped with on-demand 4WD transfer case had very good handling characteristics under these circumstances.

7. CONCLUDING REMARKS AND FUTURE WORKS

A Matrixx model of an on-demand 4WD transfer case was developed and partially validated against available vehicle test data. Bond graphs were used to represent the components of the vehicle models, and causality was used to coordinate the assemblage of these components into an overall computer model. This model was used to gain an insight into the vehicle system dynamics. It was also used to to guide the overall system design and verification process. The model can be used to study the effects of parameter changes such as number of clutch plates, the number of coil turns, etc. and recommend possible improvements. Finally the model is also well suited for development and evaluation of different control strategies.

An Improved Real-Time Model of a Planetary Gear Train

B. Klages, R. J. Woermann, and H. J. Theuerkauf
University of Kassel

ABSTRACT

Advanced automatic transmissions are controlled by electronic control units (ECUs) which perform the gear change and furthermore a lot of complex control and diagnostic functions. Hardware-in-the-loop simulation (HIL) is a powerful tool to develop and test the control algorithms implemented in the ECUs. The simulation is based upon mathematical models of the different power train components, adapted to the real-time requirements. In this paper an improved real-time model of an automatic transmission with a Ravigneaux planetary gear train is presented. This transmission contains among other components numerous clutches and brakes. The time-variant states of these nonlinear elements (sliding and static friction) lead to numerical problems with respect to real-time simulation. In the suggested model the transferred torques of the different clutches and brakes are calculated using the methods of multi-variable control.

INTRODUCTION

Today automotive ECUs are not only adapted to existing mechanical or hydraulic systems, like the combustion engine or the automatic transmission, but they are designed and developed as integral parts of these systems. This parallel development process is characteristic for the principles of simultaneous engineering and means a completely new working method for the engineers.

In the beginning the mechanical system may exist only as a concept, no hardware tests or measurement results are available. In a first step the general concept of control can be developed and tested using an off-line simulation. But the parallel development of the ECU and the mechanical components require tests and verifications in each stage of development with an increasing test amount. When the ECU or significant parts of the mechanical system work sufficiently, new developed control algorithms, as well as components, should be already tested under real-time conditions in the laboratory. This has significant advantages with respect to the quality of the software in the ECUs. Additional transfer errors, when programming the ECUs with detailed (off-line) simulation results, can be avoided. To combine real components of the system with simulated ones, means to simulate parts of the system in real-time.

The demand for a time and cost efficient development process leads to the following restrictions on the simulation system:

- availability of a hierarchical modeling structure, which allows a transition from a global simulation in the phase of specification up to a function specific simulation of special system components,
- availability of design methods for mathematical models, appropriate as well to off-line simulation methods as to real time computing,
- modular structured software with an interface for the implementation of user defined models,
- modular structured hardware, consisting of a basic system, which is adaptable by standard modules and scaleable computing power to different types of ECUs and simulation models.

The real-time simulation system measures the output signals of the ECUs and simulates the sensor signals of the corresponding power train components. This is the application field of the real-time simulator CARTS®, developed by the University of Kassel upon the basis of a cooperation with Volkswagen Research, Wolfsburg, Germany.

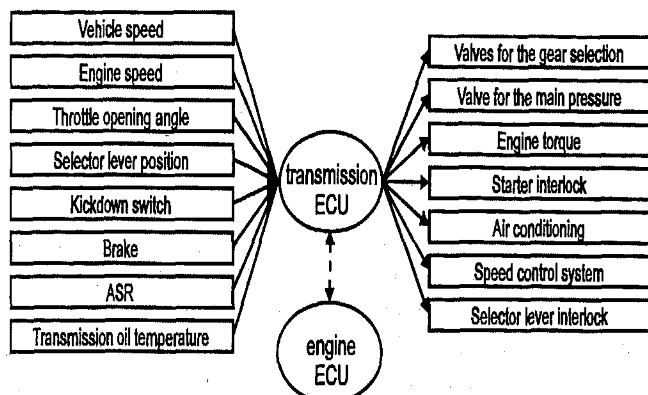

Figure 1 *Information flow between the real-time simulator and the ECU*

AUTOMATIC TRANSMISSION WITH ELECTRONIC CONTROL - Nowadays automatic passenger-car transmissions have 4 ore 5 gears. The main mechanical components are:

- a hydrodynamic (Foettinger) torque converter provided with a lockup clutch,
- a Ravigneaux planetary gear train,
- multi-disc clutches and brakes assigned to the different wheels and axles to allow gear shifting under traction,
- an oil pump for the power supply of the hydraulic shifting components and the torque converter.

The transmission control is realized by an ECU which chooses the gears and controls the oil pressure according to the torque to be transmitted. **Figure 1** shows the signal flow between the automatic transmission, the sensors, and actuators and the ECU. Electronic control allows the realization of driver dependent shift programs, the adaptation to environmental conditions, or different vehicles. The main sensors and actuators necessary for electronic transmission control are:

- load-sensors, e.g. throttle potentiometer or the according information by the engine ECU and kickdown-switch,
- speed sensors for vehicle speed and engine speed or the according information by the engine ECU,
- position sensor of the selector lever,
- oil-temperature sensors,

- solenoid valves to switch the clutches and brakes,
- modulation valve to control the oil pressure.

The transmission ECU processes the sensor information and controls shift point, shift quality, lockup clutch, and special safety features. In addition it communicates, e.g. via CAN, with the engine ECU in a mesh connected network.

Assuming a powerful simulation system and a suitable mathematical model, the interaction between the (real) transmission ECU and the (simulated) transmission can be tested and verified in the electronic laboratory, also with respect to data exchange with a (real) engine ECU.

MECHANICAL STRUCTURE OF A RAVIGNEAUX PLANETARY GEAR TRAIN

A Ravigneaux planetary gear train (*ref. [5]*) consists of a ring gear (R), a small and a large sun wheel (S1 and S2) and a short and a long planetary wheel (P1 and P2) which are attached to the planetary carrier (PC).

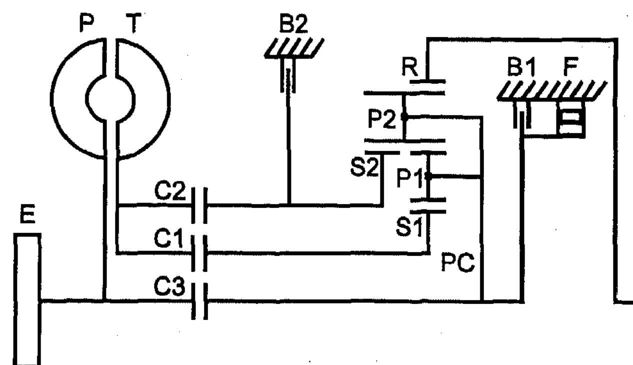

Figure 2 *Scheme of the Ravigneaux planetary gear train with engine (E) and torque converter (pump (P) and turbine (T))*

Figure 2 shows the arrangement of the gear wheels in the transmission. With the aid of the clutches C1, C2, and C3, the brakes B1 and B2, and free-wheel F it is possible to realize four forward gears and one reverse gear.

gear	B1	B2	C1	C2	C3	F
R	x			x		
1H			x			x
2H		x	x			
3H			x	x		
3M			x	x	x	
4M		x			x	

Table 1 *Combination of clutches and brakes* (*ref. [3]*)

CARTS (Computer Aided Real-Time Test System) is a registered trademark of the Institute of Power Engineering - Drive Engineering, Prof. Dr.-Ing. H. J. Theuerkauf, University of Kassel, Germany

Table 1 shows the combination of the activated clutches and brakes in the different gears. There exist further combinations (*ref. [3]*) between the third and the fourth gear which are not described in the table. They are used as transient states to improve the gear change.

NEWTON'S LAW OF MOTION FOR THE RAVIGNEAUX PLANETARY GEAR TRAIN

The differential equations of a planetary gear train can be derived using Kane's equations (Jourdains's principle). Jourdain's principle states, that the internal virtual power produced by the resulting constraint forces F^Z and torques M^Z in a system of n rigid bodies is equal to zero. The mathematical formulation yields:

$$\sum_{i=0}^{n}\left[\delta\,\vec{v}_{i,0}\cdot\vec{F}^{z}_{i,0}+\delta\,\vec{\omega}_{i,0}\cdot\vec{M}^{z}_{i,0}\right]=0 \qquad (1)$$

While the first index i characterizes the body, the second one indicates the reference vector base. The described Ravigneaux planetary gear train consists of six wheels performing only rotations and equation (1) can be reduced to

$$\sum_{i=0}^{n}\left[\delta\,\vec{\omega}_{i,0}\cdot\vec{M}^{z}_{i,0}\right]=0 \qquad (2)$$

Since the directions of all the axes of rotation and the external and internal torque coincide, the vectors $\vec{\omega}_{i,0}$ and $\vec{M}_{i,0}$ are replaced by the corresponding scalars $\omega_{i,0}$ and $M_{i,0}$.

The constraint torque $M^{z}_{i,0}$ can be obtained from Newton's equation

$$J_{i,0}\frac{d\,\omega_{i,0}}{dt}=J_{i,0}\dot{\omega}_{i,0}=M^{z}_{i,0}+M^{e}_{i,0} \qquad (3)$$

where $M^{e}_{i,0}$ represents the sum of external torques, acting on wheel i which has the moment of inertia $J_{i,0}$. Eq. (2) can now be written in the form:

$$\sum_{i=0}^{n}\left[\delta\,\omega_{i,0}\cdot\left(J_{i,0}\dot{\omega}_{i,0}-M^{e}_{i,0}\right)\right]=0 \qquad (5)$$

Writing the sum in detail for the planetary gear train yields:

$$\begin{aligned}&J_{S1}\dot{\omega}_{S1}\delta\omega_{S1}+J_{S2}\dot{\omega}_{S2}\delta\omega_{S2}+J_{PC}\dot{\omega}_{PC}\delta\omega_{PC}+\\&J_{P1}\dot{\omega}_{P1}\delta\omega_{P1}+J_{P2}\dot{\omega}_{P2}\delta\omega_{P2}+J_{R}\dot{\omega}_{R}\delta\omega_{R}\\&=M_{C3}\delta\omega_{PC}+M_{C1}\delta\omega_{S1}+M_{C2}\delta\omega_{S2}-M_{B1}\delta\omega_{PC}\\&-M_{B2}\delta\omega_{S2}-M_{R}\delta\omega_{R}\end{aligned} \qquad (6)$$

After deriving the kinematic relations between the angular velocities of the different gear wheels, the number of variables can be diminished to two, according to the number of degrees of freedom. Keeping ω_{PC} and ω_R as variables, ω_{S1}, ω_{S2}, ω_{P1} and ω_{P2} are replaced by the right terms of the following kinematic equations :

$$\omega_{S1}=\left(1-\frac{z_R}{z_{S1}}\right)\omega_{PC}+\frac{z_R}{z_{S1}}\omega_R \qquad (7)$$

$$\omega_{S2}=\left(1+\frac{z_R}{z_{S2}}\right)\omega_{PC}-\frac{z_R}{z_{S2}}\omega_R \qquad (8)$$

$$\omega_{P1}=\left(\omega_{PC}-\omega_R\right)\frac{z_R}{z_{P1}} \qquad (9)$$

$$\omega_{P2}=\left(\omega_{R}-\omega_{PC}\right)\frac{z_R}{z_{P2}} \qquad (10)$$

(z = number of teeth)

After introducing the abbreviations

$$P_1=1-\frac{z_R}{z_{S1}} \qquad H_1=\frac{z_R}{z_{S1}} \qquad (11)$$

$$P_2=1+\frac{z_R}{z_{S2}} \qquad H_2=-\frac{z_R}{z_{S2}} \qquad (12)$$

$$P_3=\frac{z_R}{z_{P1}} \qquad H_3=-\frac{z_R}{z_{P1}} \qquad (13)$$

$$P_4=-\frac{z_R}{z_{P2}} \qquad H_4=\frac{z_R}{z_{P2}} \qquad (14)$$

the substitution of Eq. (7) to (14) into Eq. (6) yields:

$$\begin{aligned}&\big(J_{S1}P_1^2\dot{\omega}_{PC}+J_{S1}P_1H_1\dot{\omega}_R+J_{S2}P_2^2\dot{\omega}_{PC}+J_{S2}P_2H_2\dot{\omega}_R\\&+J_{PC}\dot{\omega}_{PC}+J_{P1}P_3^2\dot{\omega}_{PC}+J_{P1}P_3H_3\dot{\omega}_R+J_{P2}P_4^2\dot{\omega}_{PC}\\&+J_{P2}P_4H_4\dot{\omega}_R\big)\cdot\delta\,\omega_{PC}\\&+\big(J_{S1}P_1H_1\dot{\omega}_{PC}+J_{S1}H_1^2\dot{\omega}_R+J_{S2}P_2H_2\dot{\omega}_{PC}+J_{S2}H_2^2\dot{\omega}_R\\&+J_R\dot{\omega}_R+J_{P1}P_3H_3\dot{\omega}_{PC}+J_{P1}H_3^2\dot{\omega}_R+J_{P2}P_4H_4\dot{\omega}_{PC}\\&+J_{P2}H_4^2\dot{\omega}_R\big)\cdot\delta\,\omega_R\\&=\left(M_{C3}+M_{C1}P_1+M_{C2}P_2-M_{B1}-M_{B2}P_2\right)\cdot\delta\,\omega_{PC}\\&+\left(M_{C1}H_1+M_{C2}H_2-M_{B2}H_2-M_R\right)\cdot\delta\,\omega_R\end{aligned} \qquad (15)$$

With further abbreviations

$$a_{11} = J_{S1}P_1^2 + J_{S2}P_2^2 + J_{PC} + J_{P1}P_3^2 + J_{P2}P_4^2$$
$$a_{12} = J_{S1}P_1H_1 + J_{S2}P_2H_2 + J_{P1}P_3H_3 + J_{P2}P_4H_4$$
$$a_{21} = J_{S1}P_1H_1 + J_{S2}P_2H_2 + J_{P1}P_3H_3 + J_{P2}P_4H_4$$
$$a_{22} = J_{S1}H_1^2 + J_{S2}H_2^2 + J_R + J_{P1}H_3^2 + J_{P2}H_4^2$$
$$M_1 = M_{C3} + M_{C1}P_1 + M_{C2}P_2 - M_{B1} - M_{B2}P_2$$
$$M_2 = M_{C1}H_1 + M_{C2}H_2 - M_{B2}H_2 - M_R$$

the equations of motion for the planetary gear train result:

$$\begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \begin{bmatrix} \dot{\omega}_{PC} \\ \dot{\omega}_R \end{bmatrix} = \begin{bmatrix} M_1 \\ M_2 \end{bmatrix} \tag{16}$$

CALCULATION OF INTERNAL TORQUE UNDER REAL-TIME CONDITIONS

The considered Ravigneaux planetary gear train contains three clutches and two brakes, allowing the gear shift under traction. In order to solve Newton's equation of motion for the planetary gear train (Eq. (16)), it is necessary to determine the transferred torque of clutches and brakes (M_{C1}, M_{C2}, M_{C3}, M_{B1}, M_{B2}) with respect to their actual state.

A HIL simulation requires mathematical models with appropriate size and structure in order to fulfill the real-time conditions. Real-time simulation means, that the computing of the mathematical equations must be finished in a given interval of time (e.g. in several milliseconds if integrating an ECU as real part).

Apart from the computing power of the simulation system, which has to be fitted to the model extent, the model structure itself must guarantee a determinate computing time. For this reason time-variant model structures and numerical methods, which require iterative calculations have to be avoided, because they are characterized by variable and unpredictable execution times, which could exceed the limited real-time interval.

A friction clutch is an example for a system with a time variant structure. If the friction discs slip the device is characterized by two degrees of freedom because the discs rotate independently. During adhesion the clutch represents a one mass system.

If the clutch slips the internal torque M_C is limited to the "torque capacity" $M_{C,cap}$ and is assumed as nearly independent on the rotational speed difference (**Figure 3**). $M_{C,cap}$ is a function of the clutch's surface coating, as well as a function of the pressure force acting on the discs. The torque capacity will become zero if the clutch is released. If the clutch adheres, the transferred torque is a function of the external torque acting on the discs.

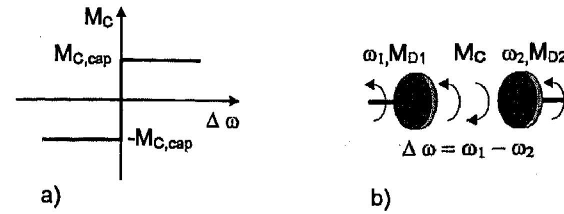

Figure 3 *a) Characteristic curve for static ($\Delta\omega = 0$) and sliding friction ($\Delta\omega \neq 0$) b) Speed and torque variables*

If the states and the external torques are known, the internal torque can be derived exactly from the equations of motion of the planetary gear train. A problem occurs if there are state transitions during gear change. In this case the states and torques have to be determined in two or more steps until all states remain stable. This iterative procedure should be avoided for real-time simulation. Therefore other approaches were developed in the past to realize simplified real-time models of the clutch. These models are also suited as brake models with the difference that one disc is fixed.

REAL-TIME MODELS OF A CLUTCH

Most real-time models of the clutch calculate the torque as a function of the rotational speed difference between the clutch discs, regarding the discs as separate masses even during static friction.

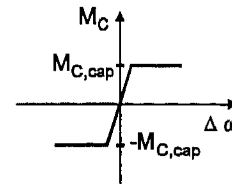

Figure 4 *Simplified characteristic curve*

Figure 4 shows a simple approach (*ref. [2], [4]*) represented by a limiter which models static friction by a proportional part for little speed differences ($M_C = c\cdot\Delta\omega$). While the clutch slips the torque is limited to the torque capacity "$M_{C,cap}$" ($|M_C| = M_{C,cap}$).

A block diagram, representing this model, is shown in **Figure 5**. The speed difference between the clutch discs is calculated by an integrator as a function of the internal clutch torque M_C and the external torque M_D acting on the clutch discs.

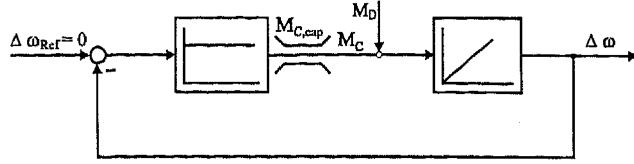

Figure 5 *P-algorithm with limiter (ref. [2],[4])*

The P-algorithm with saturation in **Figure 5** can be assumed as a "P-controller" with limiter because the torque M_C acts as "manipulated variable", which decreases the "system deviation", represented by the rotational speed difference $\Delta\omega$. The amplification of the controller, which is ideally infinite, must be limited to values not leading to numerical instability. This kind of torque determination has the disadvantage that the slip is not zero during static friction, even in steady-state, though the clutch discs physically adhere.

An obvious model improvement to decrease the "control error", i.e. the speed difference $\Delta\omega$, is the replacement of the P- by a PI-algorithm. This leads to a neglectable steady state speed difference during static friction. Nevertheless, if the external torque M_D, that is acting on the clutch, changes dynamically, there will be a transient speed error, until the PI-algorithm has adapted the clutch torque to its new steady-state value.

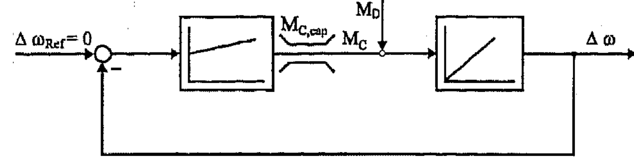

Figure 6 *PI-algorithm with limiter*

IMPLEMENTATION IN A MODEL OF A RAVIGNEAUX PLANETARY GEAR TRAIN

The implementation of the PI-algorithm in the planetary gear train model leads to five "PI-control-loops" calculating the torques of the clutches C1, C2 and C3 and the brakes B1 and B2. A remaining problem of this gear train model is the fact that the five "control loops" interact during simulation and form a complex dynamic system (**Figure 7**). Each torque does not only act as "manipulated variable" in its own "control loop" but also as a "disturbance" in the other ones.

Due to the internal coupling it is difficult to optimize each control loop with regard to stability, exactness, damping and speed. Moreover, in order to guarantee the stability of the numerical integration, the step size has to be adapted to the eigenvalues of the total system which are also determined by the PI-parameters.

Several methods exist to adapt controllers in a multi-variable control system. If the control loops can be completely decoupled, the problem is reduced to the adaptation of a single variable control loop. After decoupling the control loops a compensation of measurable or known disturbances would additionally improve the control.

Regarding the simulation system of a planetary gear train as a multi-variable control structure leads to the block diagram in **Figure 7.** It can be optimized, using the methods of decoupling and feedforward.

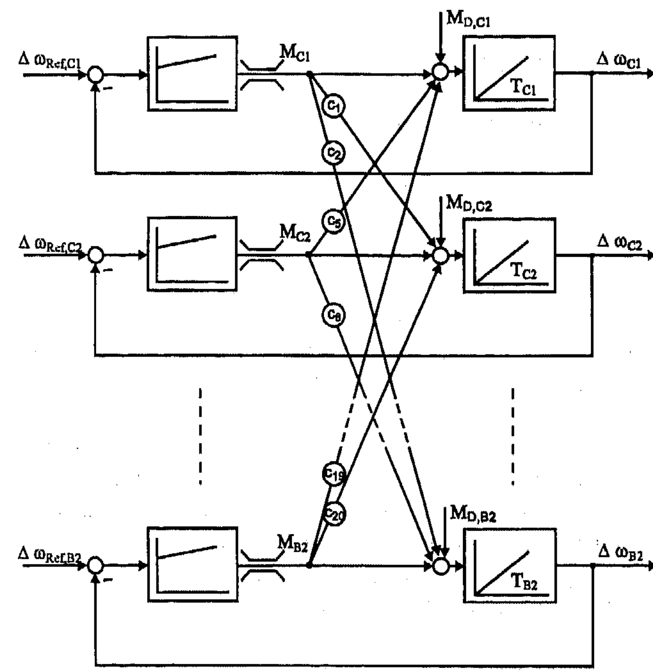

Figure 7 *Interaction of clutches and brakes*

DECOUPLING AND FEEDFORWARD CONTROL

Figure 8 shows an example of a control system with two inputs and outputs. Each input acts on both outputs via the transfer functions p_{11} and p_{12} respectively p_{12} and p_{22}. With the aid of the additional transfer elements k_{12} and k_{21} both control loops can be dynamically decoupled with the aim that a diagonal transfer matrix $\underline{Q}$ results. The Laplace transform results in the following matrix equation (*ref.[6]*):

$$\underbrace{\begin{bmatrix} p_{11}(s) & p_{12}(s) \\ p_{21}(s) & p_{22}(s) \end{bmatrix}}_{\underline{P}(s)} \underbrace{\begin{bmatrix} 1 & k_{12}(s) \\ k_{21}(s) & 1 \end{bmatrix}}_{\underline{K}(s)} = \underbrace{\begin{bmatrix} q_{11}(s) & 0 \\ 0 & q_{22}(s) \end{bmatrix}}_{\underline{Q}(s)}$$

The coefficients of matrix $\underline{K}(s)$ result from:

$$\underline{K}(s) = \underline{P}(s)^{-1}\underline{Q}(s) \quad \Rightarrow k_{ij}(s) = (-1)^{i+j}\frac{\det \underline{P}_{ji}(s)}{\det \underline{P}_{jj}(s)}$$

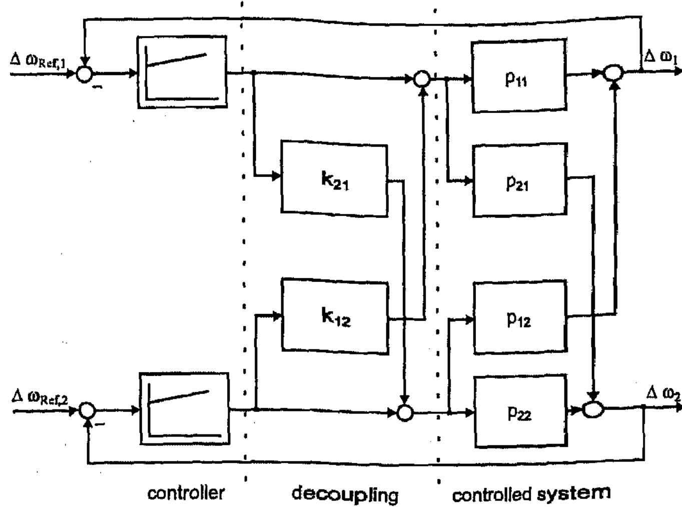

Figure 8 *Decoupling of interacting control loops*

After decoupling the control loops, measurable disturbances with a determinable disturbance point can be compensated, using feedforward control (**Figure 9**). In the example of **Figure 9** an ideal feedforward control must fulfill the equation

$$f_j(s) = -q_{ii}^{-1}(s)\, d_j(s)$$

in order to compensate the disturbance M_{Dj} completely. After the addition of decoupling and feedforward elements the dynamic of the resulting system is only determined by the poles of the transfer functions $q_{ii}(s)$. Therefore the algorithm can be adapted to a given integration step size or to a requested closed-loop behavior.

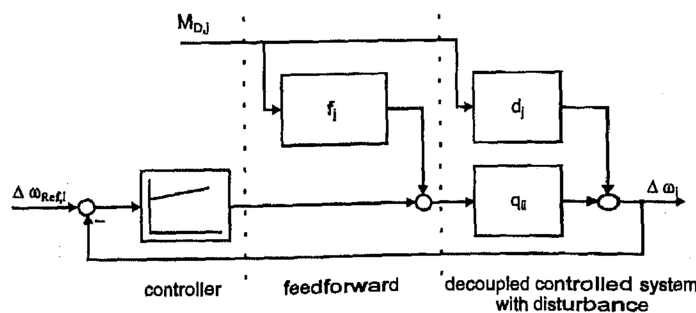

Figure 9 *Feedforward control of disturbances*

APPLICATION TO THE PLANETARY GEAR TRAIN

The decoupling matrix depends on the actual states (static or sliding friction) of clutches and brakes. If a clutch/brake slips the torque will be limited to the torque capacity $M_{C,cap}$ and will be represented by a real two mass system, which forms an open loop in the simulation model. Only adhering clutches and brakes lead to closed and consequently active "control loops" which can be decoupled. On the other hand the torque of an open loop can be regarded as a disturbance for the remaining active loops and can be compensated using feedforward control. The case of releasing the clutch is equivalent to the case of sliding friction setting the torque capacity to zero.

The torques of clutches and brakes are further determined by the external torques from engine, turbine, and drive shaft, acting on the planetary gear train. These external torques appear as further disturbances in the "control loops". Their effect on the control error can also be eliminated by feedforward control.

As an example the decoupling and feedforward control is shown in the second gear (**Figure 10**). The clutch C1 and brake B2 adhere, while C2, C3 and B1 are released. The control algorithms to calculate M_{C1} and M_{B2} are dynamically decoupled by the coefficients k_{21} and k_{12}. The feedforward coefficients f_{T1}, f_{T2}, f_{R1} and f_{R2} compensate the effects of the external torques from turbine (M_T) and gearbox output (M_R), which would otherwise cause faulty speed differences $\Delta\omega_{C1}$ and $\Delta\omega_{B2}$ in the simulation. The engine torque has no influence on the speed differences of clutch C_1 and brake B_2.

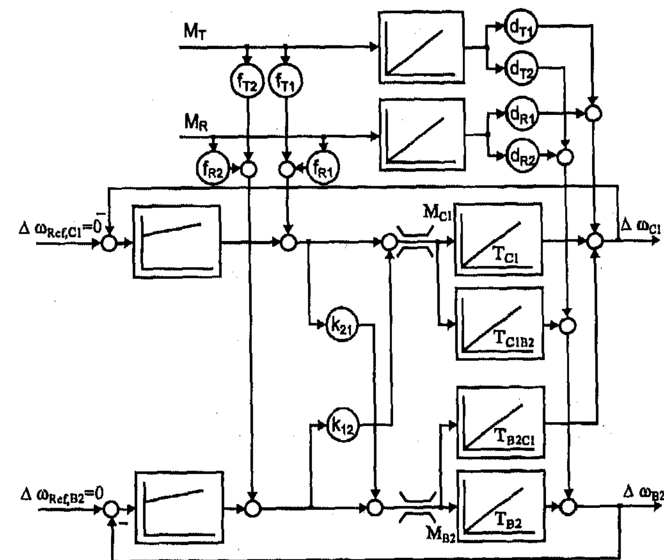

Figure 10 *Decoupling and feedforward control in the second gear*

In order to minimize the computing time, the matrices for the decoupling and feedforward control are calculated in an initialization routine before the real-time simulation.

HIL-SIMULATION OF A DRIVE TRAIN WITH AN AUTOMATIC TRANSMISSION

The transmission models are implemented in a drive train model, consisting of an engine, a Foettinger torque converter and a drive shaft with load (*ref. [8]*). The models of the engine and the torque converter are steady-state models based upon measured maps. The drive shaft is modeled as a damped spring, while the load model simulates the vehicle's aerodynamic drag, the rolling resistance, and the gradient of the road. The drive train model is implemented in MATLAB/ SIMULINK® as well as in the real-time simulator CARTS.

The HIL-simulator CARTS (**Figure 11**) is generally described in *ref. [7]*. Therefore this chapter concentrates on the specific simulator equipment for transmission-ECUs.

Figure 11 *Real-time simulator CARTS*

The transmission simulator consists of a VMEbus system with a separated I/O-subsystem and a PC. The VMEbus system based on OS-9® is the real-time unit of the simulator which is controlled by a Windows-PC. The VMEbus computer contains a master CPU (MC68060) executing the simulation program and four I/O-CPUs (MC68030, MC68340) for the parallel processing of the I/O-data. In dependence on the model extend sample rates of 2 ms can be reached.

The simulator is adapted to the required I/O-signals of the transmission ECU, using Mezzanine-modules (M-modules) for signal generating and measurement. Level adaptation is done in the I/O-subsystem which is placed in a separate box. It also contains an adjustable power supply, modulation valves as real parts and power resistors for load imitation.

SIMULATION RESULTS

A result of a HIL drive train simulation using CARTS is presented in **Figure 12**. It shows four variables during the gear change from second to third. After the clutch C2 adhered and brake B2 was released, the speed of the turbine, of the large sun wheel, and of the planetary carrier coincide. The torque at the gear box output shows several peaks which are caused by the elasticities of the drive shaft. Equivalent simulation results were validated by test-bench measurements.

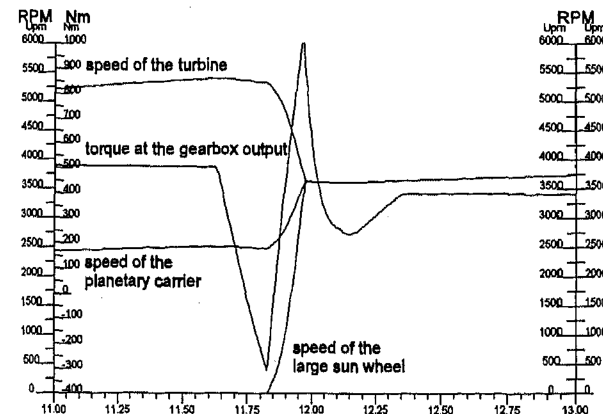

Figure 12 *Result of a real-time simulation*

Figure 13 points out the effects of the interacting control algorithms on the simulation results. The parameters of the appropriate PI-algorithms were experimentally optimized with respect to damping and stability. The plot shows as an example transient characteristics during the gear change from first to second. Though the clutch C1 actually adheres there exists a speed difference between the turbine and the small sun wheel in the simulation.

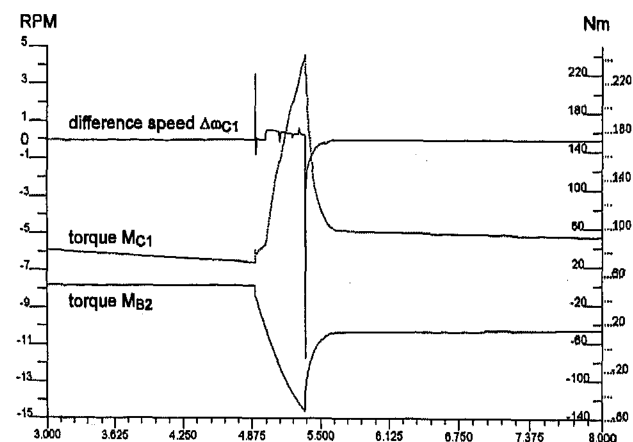

Figure 13 *Gear change without decoupling*

After applying decoupling and feedforward algorithms the parameters were individually determined for each clutch and brake in a theoretical analysis in advance. This routine also respects certain restrictions of the step size either by numerical stability of the mathematical model or the requirements of real-time processing. Using this method damping and stability of the PI-loops are guaranteed. As a result the faulty speed difference in the simulation between the adherent discs was significantly decreased (**Figure 14**).

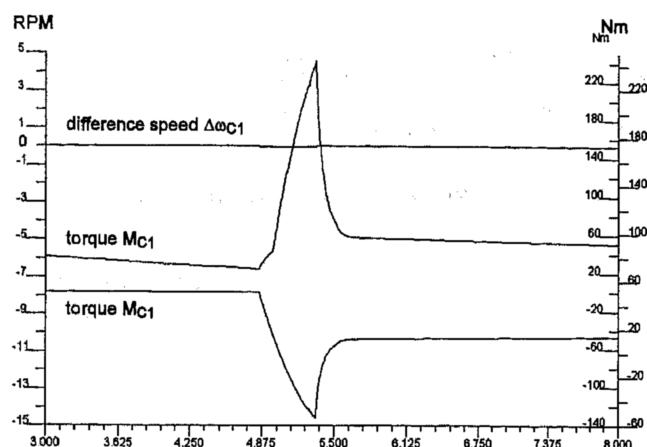

Figure 14 *Gear change with decoupling and feedforward*

SUMMARY

In this paper a real-time model of a Ravigneaux planetary gear train is presented which uses methods of the multi-variable control theory to calculate the internal torques of clutches and brakes. First the mechanical structure of the automatic transmission is described and the equations of motion are derived. Simplified models of a clutch/brake are explained which are suitable for real-time applications. The numerical problems of their implementation in a planetary gear train model are discussed and as a consequence an improved model is suggested. Simulation results of different model implementations are finally shown and compared.

ABBREVIATIONS

Variables

a, P, H	general abbreviation
c	coefficient
F	force
f, d, k	transfer functions
J	moment of inertia
M	torque
n	number
p	plant transfer functions
s	Laplace variable
t	time
T	time constant
v	velocity
ω	angular velocity
$\Delta\omega$	rotational speed difference between the clutch discs
z	number of teeth

Indices

0	reference vector base
B	brake
C	clutch
D	deviation
e	external force and torque
cap	capacity
i,m	general indices
z	constraint force and torque
P1	short planetary wheel
P2	long planetary wheel
PC	planetary carrier
R	ring wheel
S1	small sun wheel
S2	large sun wheel
T	turbine

ABSTRACT

Contour hardening of small gears, such as automotive transmission gears, is beneficial due to the higher strength characteristics and lower distortion. In the past, conventional induction hardening was not used due to its inability to produce a contour case pattern. However, carburizing also has inherent problems such as abnormal carburized layer, distortion due to high temperatures and long heating time, and retained austenite.

The Micropulse system, using both high and low frequencies, has been developed to alleviate some of the problems with traditional induction hardening. This Micropulse process makes it possible to produce a contour hardened pattern on a variety of gearing. This process is very rapid, as final heat time normally does not exceed 0.250 seconds.

The advantages to the Micropulse process include: high hardness, fine microstructure, high residual compressive stress, and low distortion. In addition to these benefits the process is environmentally friendly, energy efficient and easily adaptable to in-line processing.

INTRODUCTION

Induction hardening is a surface hardening method of directly heating a component using a high frequency induced current. The Micropulse process has been found to improve wear resistance, fatigue strength and toughness of a steel component. In addition to these mechanical property advantages, the process is also very clean and environmentally friendly.

The unique characteristics that differentiate this process from traditional induction heating are the very rapid heating (<0.250s) and contour surface hardening. With traditional induction hardening, small module gears which are used in automotive transmission gearing are hardened through the entire tooth section. Because of the through hardened gear, it is understandable why higher strengths and lower distortion are not achievable for some applications. These disadvantages have led to the continued used of carburizing in small module gears. By carburizing the small module gears, a contoured surface hardening results, lending itself to higher strength gears. The diffusive carburizing process also has problems which are detrimental to gear life such as: abnormal carburizing layer, distortion due to high temperatures and long heat times, and retained austenite.

To alleviate some of the downfalls of traditional induction hardening, the Micropulse system has been developed which uses both high and low frequencies high power generators. This process makes it possible to achieve contour hardening of small module gears. This contour is achieved by a suitable pre-heating time and a very quick final heating time of approximately 0.10 - 0.25 seconds.

The resulting process produces higher fatigue strength due to higher hardness and lower distortion. Other advantages to the process are the energy savings and the ease of in-line processing.

Due to the rapid heat times of the Micropulse process, the prior microstructure plays a very important role in obtaining a uniform martensitic case pattern. The Micropulse process requirements will be discussed in the following report.

Contour Hardening Technical Development - According to patent applications, the contour hardening process was developed by "heating" using dual frequencies or "using two steps for heating" in Japan thirty years ago as shown in Figure 1.

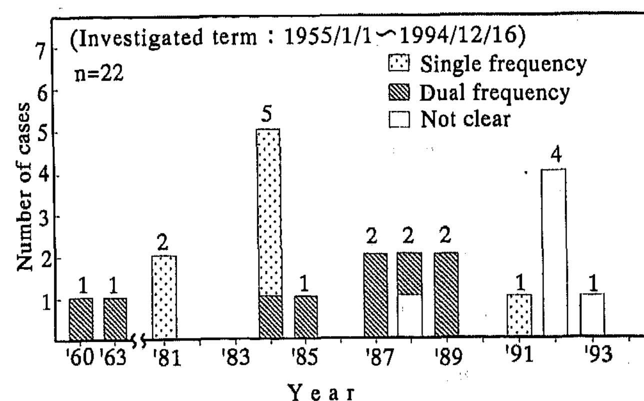

Figure 1 - Patents in Japan relating to the induction hardening process

The process did not advance during this period due to carburized gearing having higher overall strength. The technology was not available to adequately support the dual frequency method as it is today. Because the process lacked the technological support, the components produced using this method showed excessive distortion and lower strength than

carburized components. Due to this fact, this method was shadowed by carburizing for years. Within the past ten years, the contour hardening technology has advanced enough that induction is the preferred method to carburizing in some applications. One of the important breakthrough in technology other than better power supplies was the Micropulse system developed by Contour Hardening, Inc. USA. This process allows very accurate timing of high output generators with the patented A.P.C. (Absolute Pulse Controller). It is with these types of technological advances that induction can outperform carburized gearing. Induction hardening is in the infant stage of development and more research is needed to further improve this promising process.

Specifications of Contour Hardened Gear - Basic testing of the contour hardening process were conducted as shown in Table 1. The standard gear used for this test had O.D. of 126 mm., thickness of 20mm, and a module of 3. The evaluations of such tests were performed at Neturen's facility and the fatigue tests were performed in collaboration with Ryukoku University.

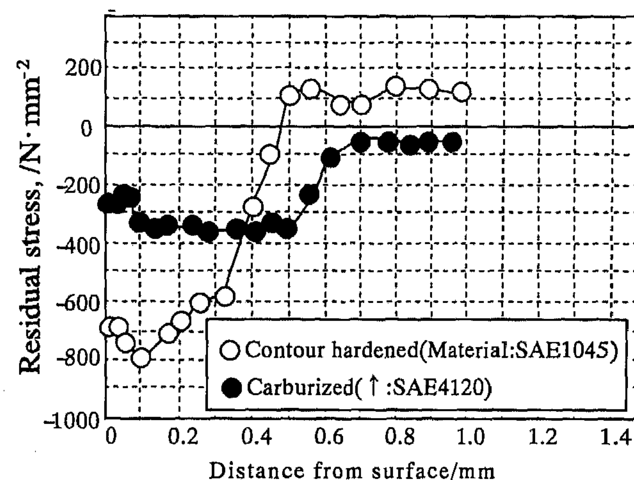
Helix angle	0

COMPARISON OF CONTOUR HARDENING VERSUS OTHER GEAR HEAT TREATING

Four types of gear hardening methods were compared: Micropulse contour hardening, soft nitriding, conventional induction hardening and carburizing. The results from each of these processes are shown in Figure 2. The root case depth was 0.5mm for the contour hardened and carburized gearing. The conventional induction hardening root case depth was 1.0mm. The soft-nitrided gear had a root case depth of 0.022mm.

The resulting microstructures, with the exception of the nitrided gear, all exhibited a uniform martensitic microstructure. The soft-nitrided gear microstructure was $Fe_3N + \gamma$ compound layer. The contour hardened gear showed the highest residual compressive stress and the least amount of distortion after heat treatment. The conventional induction hardened sample was through hardened from the tip down as shown in Figure 2.

The residual compressive stress in the root fillet was measured for all four samples by x-ray diffraction stress apparatus. The results of this test showed the Micropulse contour induction hardened sample to exhibit the highest residual compressive stress followed by carburizing, conventional induction hardening and finally soft-nitriding. The contour induction hardened sample was three hundred percent higher in residual compressive stress than the carburized gear. Figure 3 shows the compressive stress vs. depth of hardened zone for the contour induction hardened and carburized gears.



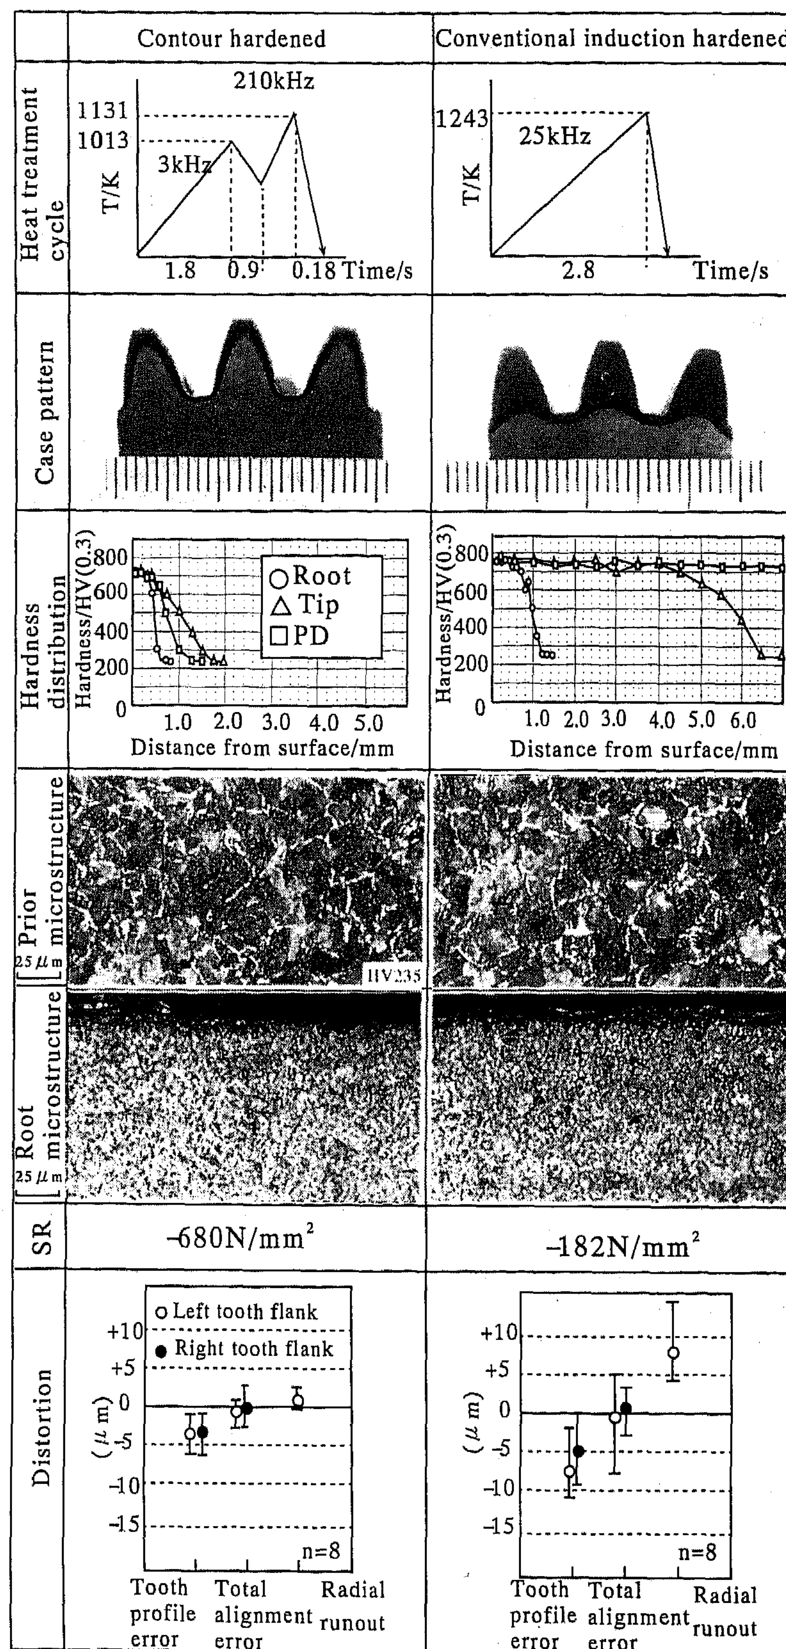


Figure 3 - Root Radius Residual Stress Comparison between Contour Hardening and Carburizing

Figure 2 also shows the amount of gear movement in tooth profile error, total alignment error, and radial run out. The soft-nitrided process was used when distortion had to be kept to a minimum while maintaining a hard wear resistance surface. The contour hardened sample showed distortion movement very similar to that of soft-nitriding. The contour hardened sample not only has low distortion, but strength unlike the soft-nitrided sample.

Tooth bending fatigue results for each of the gears tested are shown in Figure 4. The contour hardened gear was superior in strength to the soft nitrided sample and the conventional induction hardened gear and slightly stronger than the carburized gear. The high fatigue strength of the contour hardened gear is due to its very high residual compressive stress in the root fillet area. The apparatus used to test for bending fatigue can be seen in Figure 5.

Figure 2 (cont). - Comparison of Four Different Heat Treat Processes

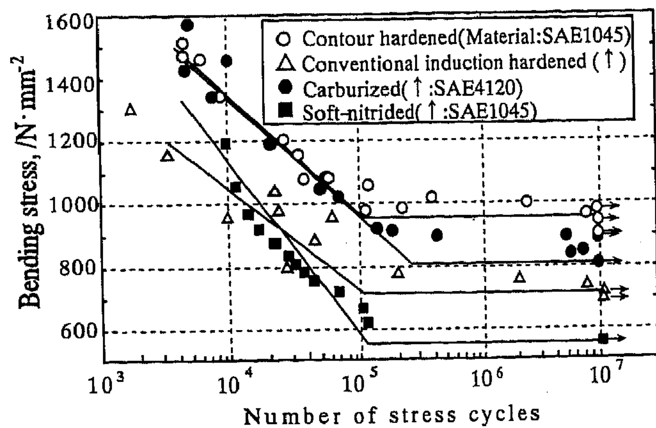

Figure 4 - Bending Fatigue test results of Heat Treated Gears

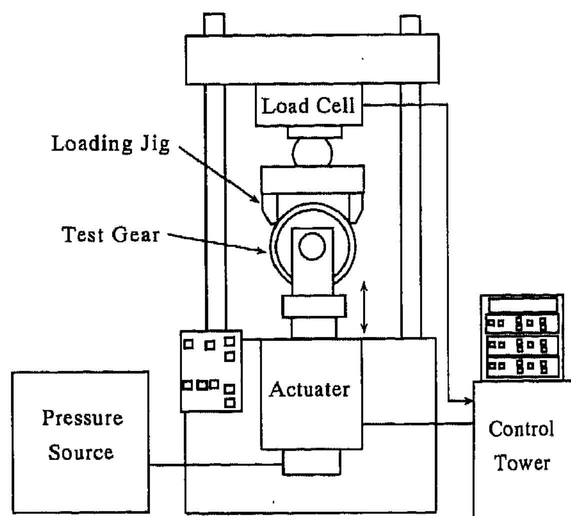

Figure 5 - Bending Fatigue Test Apparatus

The single overload bending test showed different results than the bending fatigue test. The strongest gear in the single overload bending test was the carburized gear followed by the Micropulse contour hardened, conventional induction hardened and soft nitriding. The test results are shown in Figure 6.

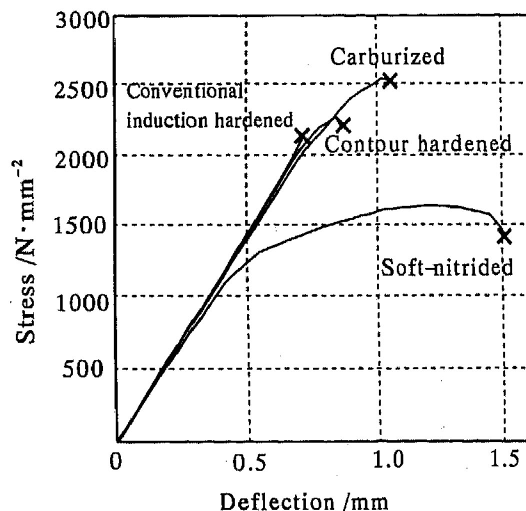

Figure 6 - Single Cycle Overloading Bending Test

The reason the carburized gear strength is greater in the overload test compared to the contour hardened gear is the core strength of each sample. The core hardness for the carburized gear was HV 350 where the contour induction hardened sample was HV 235. The core of the carburized sample was able to withstand higher subsurface stress due to the higher core hardness. To achieve the same level of performance, the core hardness of the contour induction hardened sample would have to be raised to a higher hardness. It is predicted that the performance would be much greater than the carburized gear if the core hardness was as high as the carburized sample. With this knowledge the Micropulse contour induction hardened gear has both higher strength and lower distortion.

Relationship of heat treatment condition and heat treatment quality - The Micropulse contour hardening is obtained by the use of the A.P.C. which accurately controls the time ($5X10^{-6}$sec.), and a high power generator using dual frequencies. The two frequencies are not administered simultaneously, but at two different times with a short dwell between them. To establish this new heat treating technique, the influence of each heat treating condition was compared to the resulting quality of the component. In Figures 7 and 8, a relationship between the heat treating processes and hardened depth, residual stress and distortion can be seen. These results show that when a contoured pattern is achieved or hardening depth is shallower, the component distorts less and has a higher residual compressive stress.

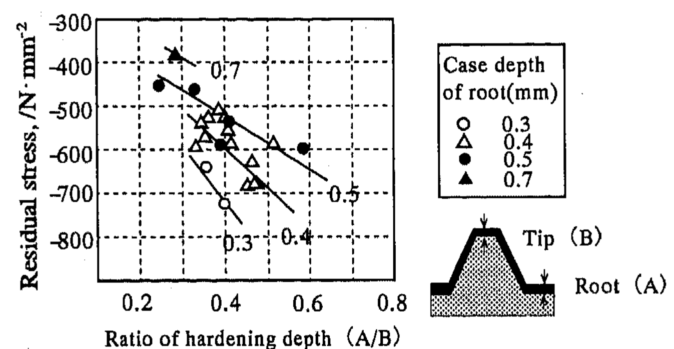

Figure 7 Case Depth versus Residual Stress

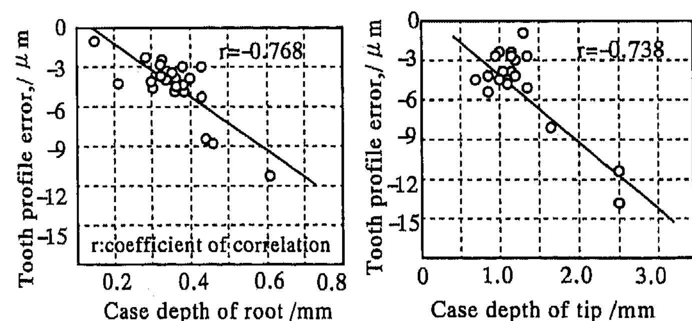

Figure 8 Case Depth versus Distortion

INFLUENCES OF PRIOR MICROSTRUCTURE ON CONVENTIONAL INDUCTION HARDENING

The final mechanical properties of an induction hardened component is influenced by prior microstructure. The Micropulse process is even more susceptible to prior microstructure due to the short heating times involved. In a typical Micropulse process, the time of heating is less than 0.5 seconds.

The material used for these tests was S45C or SAE1045.

The prior microstructure of this steel was controlled to several prior microstructural conditions. These conditions can be seen in Table 2.

Table 2 - Nomenclature of Microstructures

Symbol	Microstructure
F+P(F20)	20% Ferrite in Pearlitic Matrix
F+P(F32)	32% Ferrite in Pearlitic Matrix
F+P(F45)	45% Ferrite in Pearlitic Matrix
Q&T	Tempered Martensite
F+Spheroidal	Ferrite with spheroidal cementite

Figures 9 through 11 show the influence of prior microstructure on conventional induction hardening. Figure 9 shows the relationship between prior microstructures heating temperature and resulting hardness. The F32 and F+Spheroidal samples have low hardness at low temperatures and the hardness across the range is not consistent. The Q&T microstructure seen in the graph maintains a high level of hardness across the range of temperatures listed.

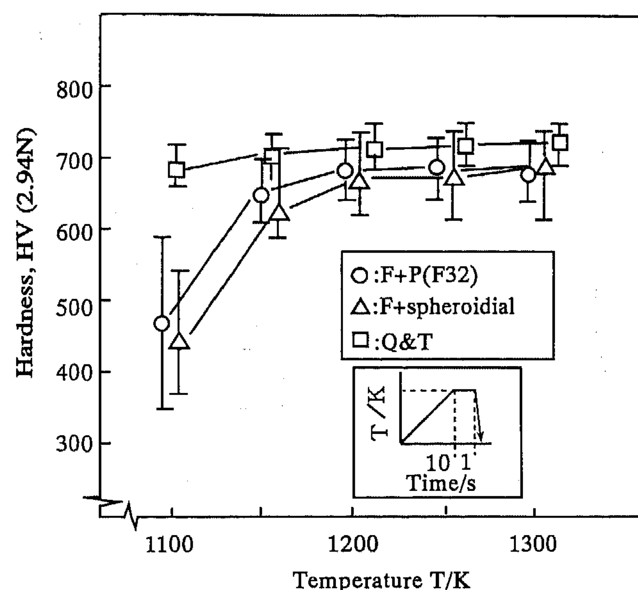

Figure 9 - Heating Temperature versus Hardness of Conventional Induction Hardened Specimens

The relationship between microstructure and lower limit of the TTA diagram can be found in Figure 10. The Q&T sample can be austenitized at a lower temperature and shorter time than microstructures that contain large amounts of ferrite or spheroidal cementite. The larger the amount of ferrite, the higher temperatures and longer heating time must be achieved before the sample can be austenitized. The same is true for spheroidal cementite as seen in Figure 10.

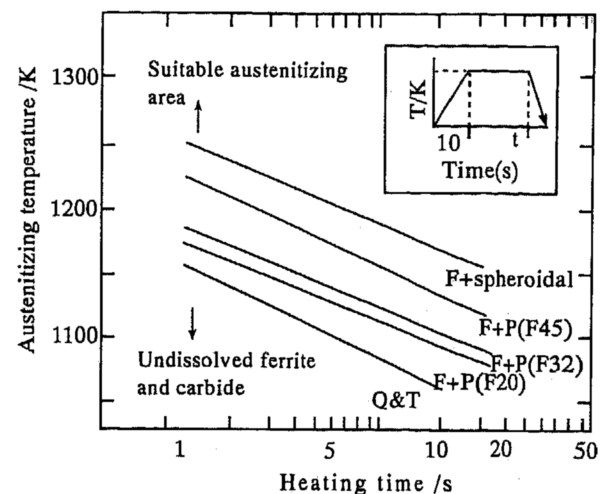

Figure 10 - Conventional Induction Hardening TTA (Time-Temperature-Austenitization) Diagram versus Microstructure

Figure 11 shows a microhardness traverse of all four microstructures given the same heating conditions. The Q&T microstructure showed the highest level of hardness and was deeper to an HV513. As the amount of ferrite increased, the hardness was lower and case depth shallower. The residual compressive stress followed trends similar to the case hardness analysis. As depicted by the data, induction hardening is highly dependant on prior microstructure. It is difficult to austenitize the material when there is a large amount of ferrite due to the long diffusion distances needed to attain a homogenous austenitic solid solution.

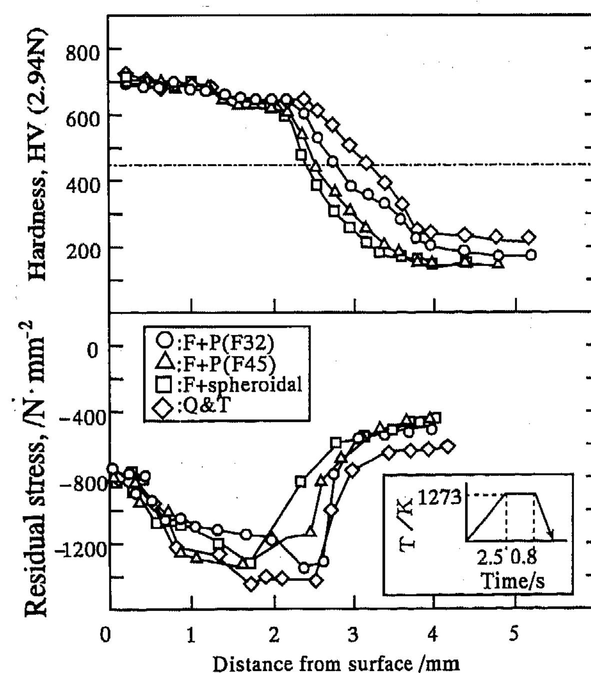

Figure 11 - Hardness and Residual Stress Profile of Induction Hardened Steel (ϕ30)

Some initial research has been done to support the theory that the larger the cementite sphere the longer time and higher temperature needed to dissolve the microstructure. In Figure 12, the radius of cementite that will dissolve under given conditions was simulated. From this data, we can conclude that the TTA curve is higher for large spheroidal cementite compared to smaller

cementite.

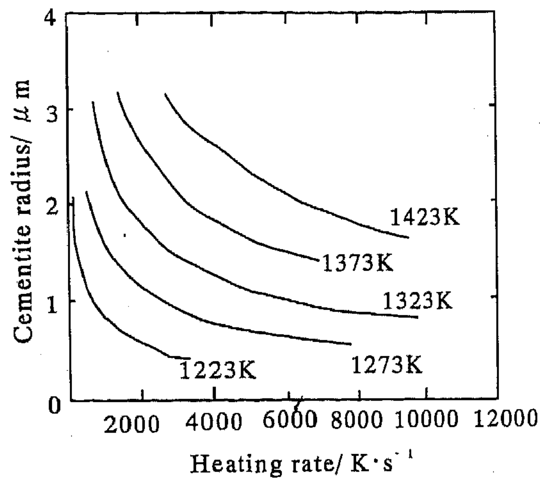

Figure 12 - Critical Cementite Radius which will Dissolve during Heating as a Function of Heating Rate

INFLUENCE OF PRIOR MICROSTRUCTURE ON CONTOUR INDUCTION HARDENING

Due to the short heating time, the contour hardening process is most responsive to the Q&T prior microstructure. This tempered martensitic structure is best when the percentage of spheroidal carbon is small. Unfortunately, the Q&T microstructure is not as easy to machine as a normalized or annealed structure, and this can be seen schematically in Figure 13. To alleviate this problem, experiments were conducted for normalizing samples by varying certain microstructural elements. The influence of ferrite and spheroidal carbon in F+Cementite were tested on static mechanical properties and fatigue strength of contour hardened gears.

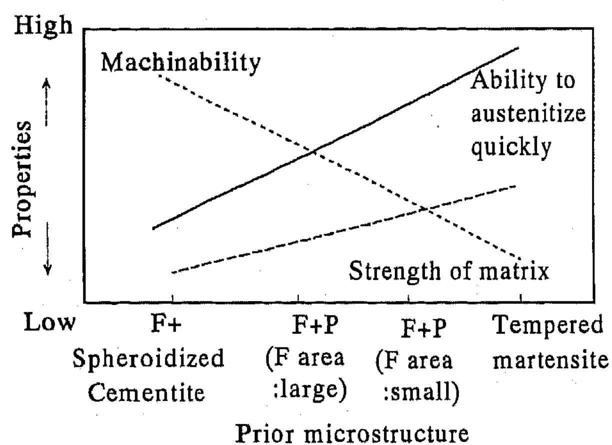

Figure 13 - Schematic Figure of Prior Microstructure versus Machinability, Ability to Austenitize, and Strength of Matrix

The material used to make the gears and conduct the various prior microstructure tests was SAE1045. The goal of varying the microstructure was to produce a uniform martensitic case after contour hardening. Figure 14 shows the various microstructures tested with concentration focused on the amount of free ferrite.

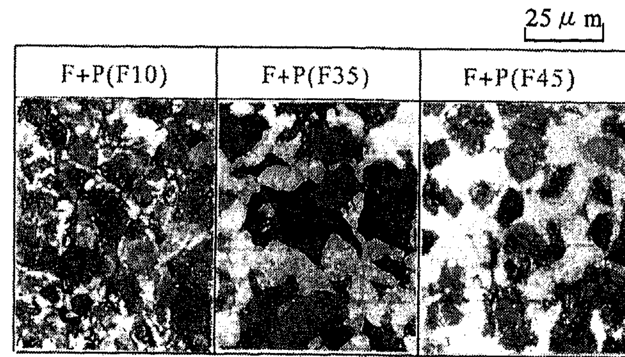

Figure 14 - Varied Microstructure of SAE1045

Results from these tests show that when the ferrite area is large, the temperature to achieve austenitization is much higher and the time is also extended. Large areas of ferrite inhibit ideal contour patterns and decrease the residual compressive stress. The distortion is also increased due to the higher temperatures and longer heat times needed to completely austenitize the sample. Figure 15 shows the lower line limit in the TTA diagram for the various prior microstructures. As the percentage of ferrite and spheroidal cementite increases, higher temperatures and longer heating times are needed to austenitize homogeneously.

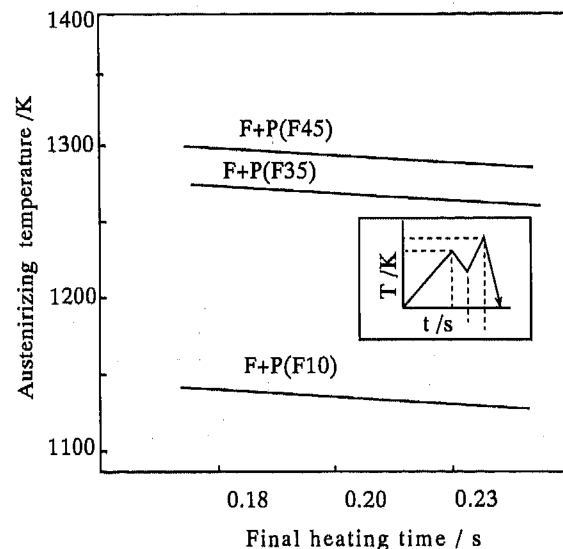

Figure 15 TTA Diagram versus Varied SAE 1045 Microstructure

Testing was performed on the various microstructures and the bending fatigue results can be seen in Figure 16.

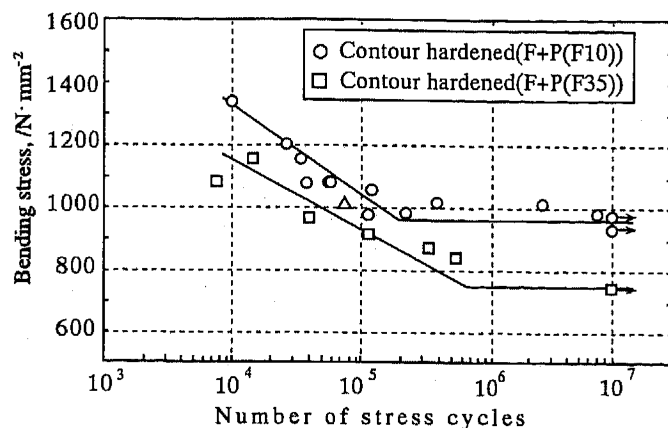

Figure 16 - Bending Fatigue of Contour Hardened Gears

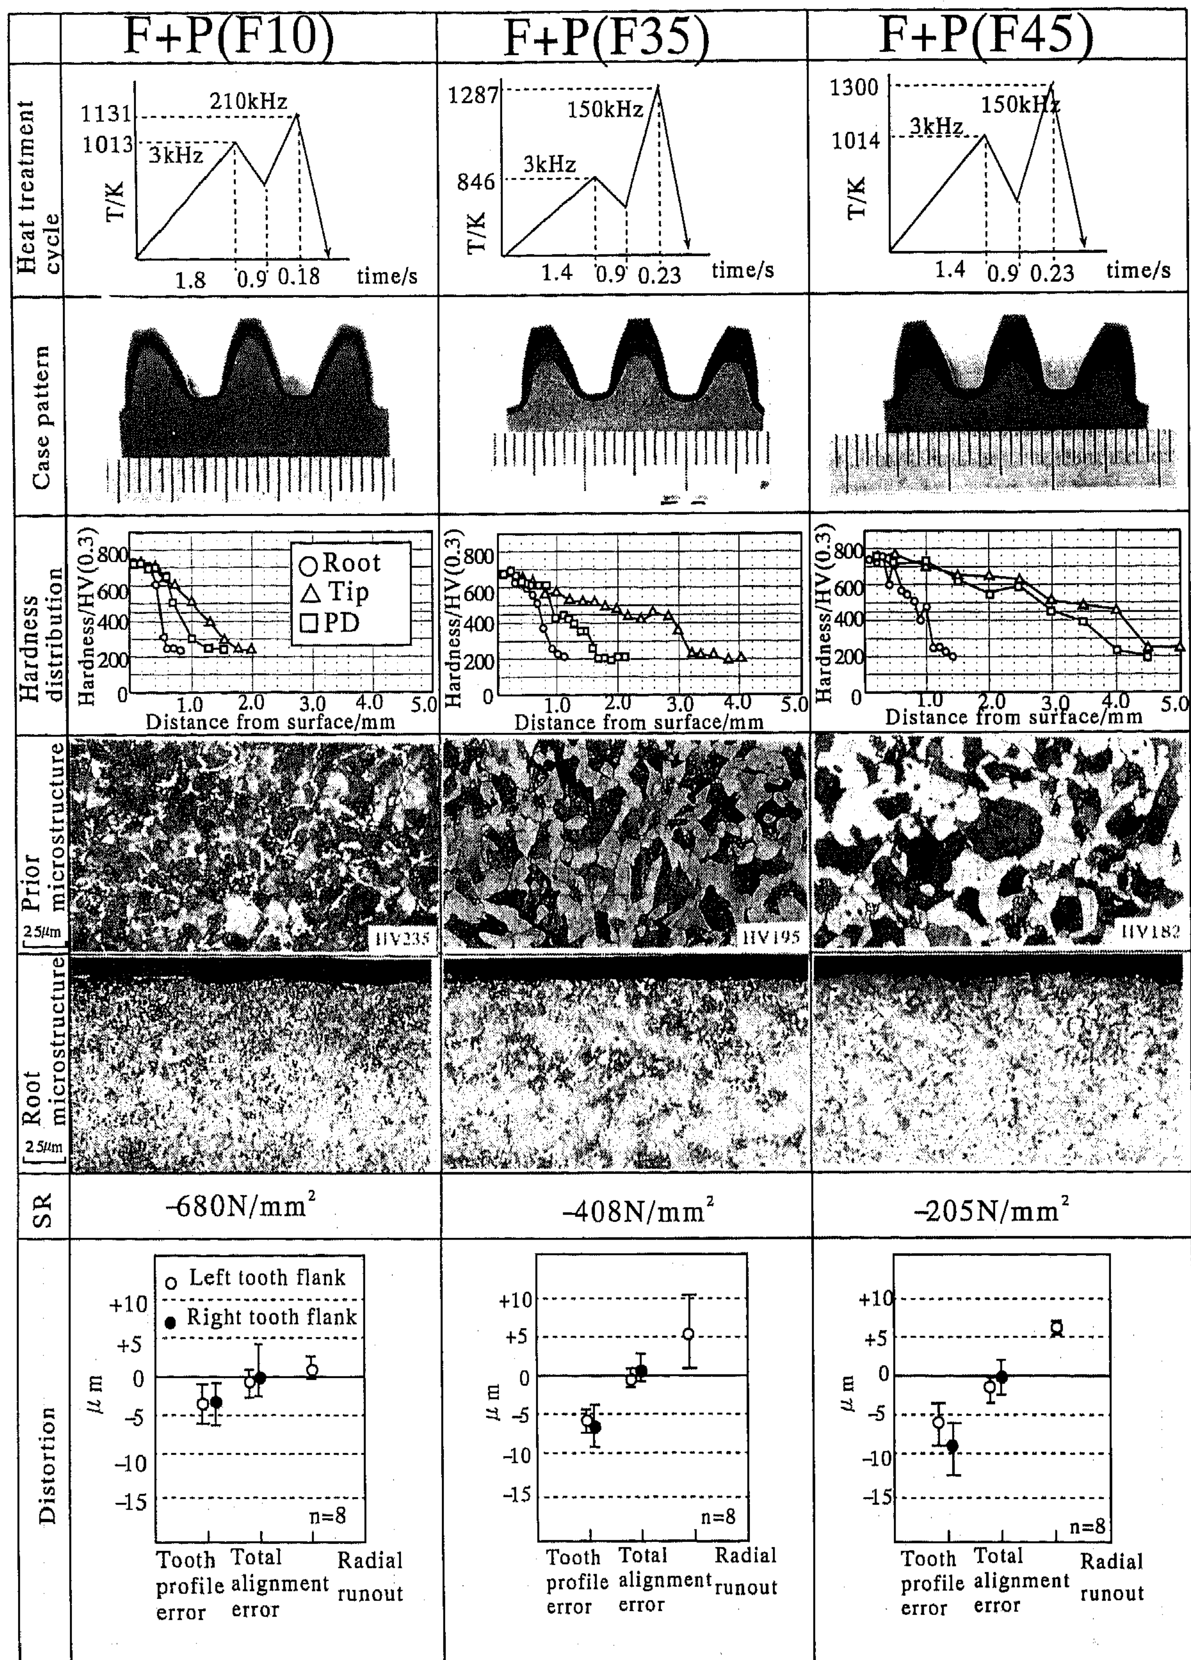
The SAE 1045 microstructures had very different results with respect to hardness, stress and distortional characteristics. The three main samples that were Micropulse contour induction hardened can be seen in Figure 17.

Steel Development for rapid induction heating and quenching - The steel that is easy to austenitize is not easy to machine, and the steel that is easy to machine does not readily transform to homogenous austenite during rapid heating. At the present, the machinability issue is sacrificed somewhat to produce the best component possible. Several steel makers are currently working on developing a steel that can meet both requirements of quick austenitization and machinability.



FUTURE RESEARCH

Demand for automotive small gearing - In the automotive industry there is a great need for gearing that is accurate, strong, low friction, lightweight, quiet and fuel efficient. These types of gears not only demand fatigue strength of tooth root, but also need good impact and contact fatigue properties. These properties are outlined in Figure 18. Carburizing has a long history and an abundance of data on the effect of material composition, hardened pattern, microstructure and compressive stress to name a few. The future goal is to establish a database for rapid induction hardening that can compare to the historical expertise of carburizing.

Technical development of process unit - One of the many goals in the future of rapid induction hardening is to improve productivity and develop a production technique that meets the users requirements. To better accommodate larger gears, a high output generator of the proper frequency must be designed.
With the higher power generators, large gears can be heated very quickly and achieve the same results as smaller gearing.

	Bending fatigue	Higher stress fatigue (impact)	Contact fatigue

CONCLUSION

Today's many technological advances in the induction power supply industry, combined with the Micropulse A.P.C. technology, now allows accurate contour induction hardening of automotive gears. This process has shifted gear hardening from carburizing and nitriding processes to a contour induction hardening process that easily can be adapted to in-line processing. Gears that are contour induction hardened with the Micropulse process have higher overall strength than gears processed by carburizing, conventional induction hardening or soft-nitriding. These results are the findings of initial testing and are not generalized of all gearing. The main focus of this study was small automotive type gearing.

To obtain the best results with contour induction hardening, a Q&T microstructure with a small percentage of spheroidal carbon is ideal. The Q&T microstructure is rather hard and is difficult to machine. In order to facilitate good machining characteristics, several microstructures were tested for quick austenitization and machinability. The main focus in this study was on the amount of ferrite in the pearlitic matrix. The best results of the normalized samples contained the least amount of ferrite in the core microstructure. The microstructure that contained ten percent free ferrite had good machinability and physical properties. Residual stress, dimensional stability, and case depth degraded as the amount of ferrite was increased in the core microstructure.

This study resulted in important discoveries about such things as: strength compared to other processes, machinability, prior microstructure, and optimizing the current process of Micropulse induction hardening. Many factors influence the outcome of contour induction hardening, but with a good database from research and development, the scope of this process is unlimited.

Effect of Normalized Microstructure in Alloy Steel on the Performance of Planetary Gear Set of Automatic Transmission

Seung Cheal Jung, Seung Gyun Ahn, Hak Jin Kim, and Young Woo Kim
Hyundai Motor Co.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The banded microstructure of pearlite and ferrite in normalized alloy steel is susceptible to thermal distortion during carburizing process due to its unidirectional orientation parallel to rolling direction. The planetary gears with material of banded microstructure have been experienced in high thermal distortion during carburizing and quenching process and result in uneven surface hardness and effective case depth at the inside of pinion gear after honing. These defects played failure initiation site roles in durability test during development of new automatic transmission. The galling between the contacting components in severe lubricating system was the main failure mechanism. Double normalizing at 920 ℃ was designed to resolve the banded microstructure of normalized alloy steel. The microstructure and grain size of the double heated steel became equiaxed and fine due to homogenizing and recrystallization through double heat treatment. The thermal distortion and subsequent surface properties at the inside of pinion gear were also improved. Finally the durability of the planetary gear set at maximum speed test is enhanced by 2.91 times.

INTRODUCTION

As the high performance engines have been developed, the driving conditions of automatic transmission have become more severe. The lubrication and cooling system are important factors to enhance the performance of automatic transmission. The temperature of ATF oil was reached to critical point under maximum speed condition. This condition causes loss of lubricating characteristics of ATF oil and results in the failure of planetary gear set of automatic transmission. Improvement of oil flow system and dynamic analysis of moving component of automatic transmission have been studied to solve these problems (1, 2). Regardless of the importance of lubrication and cooling system, failures of moving parts in automatic transmission are frequently related with some defects of materials which consist of planetary gear set. Improper surface hardness and effective case depth, abnormal microstructure, thermal distortion and roughness are among these faults (3, 4). In this research, we examined failed planetary gear set of developing automatic transmission during high speed test, revealed the failure route and mechanism. The thermal distortion of pinion gear during carburizing process increased the ovality and cylindricity of inside of pinion and resulted in uneven surface hardness, effective case depth and microstructure after honing. These defects were major sources of failure in planetary gear set.

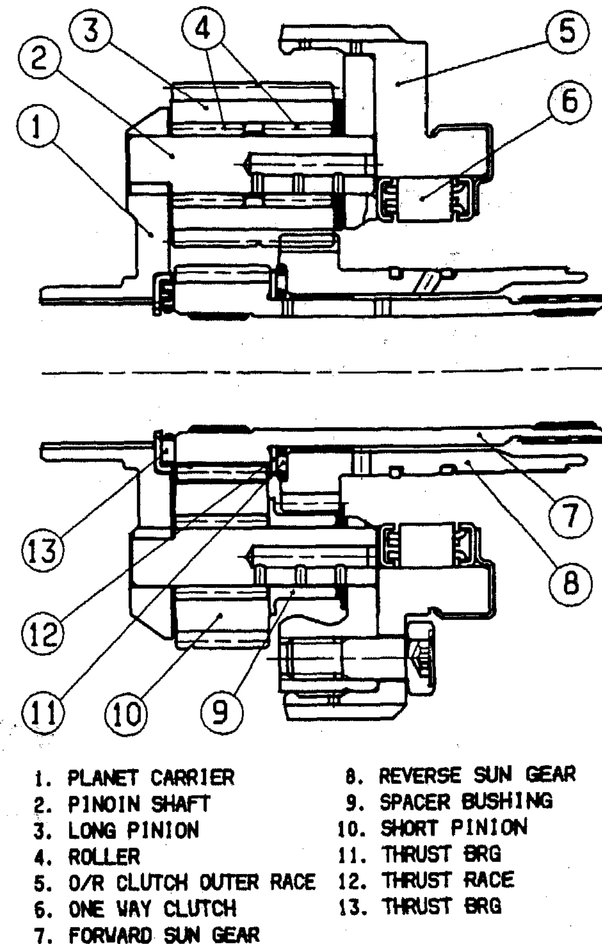
The segregation of chemical composition during steel melting, soaking, forging and rolling process could cause the banded microstructure of alloy steel (5). Because of predominant directionality, the banded microstructure showed high thermal distortion during carburizing heat treatment. To improve the banded microstructure, double normalizing at increased temperature from 880 ℃ to 920 ℃ was introduced and well equiaxed and fine microstructures were obtained. The double normalized pinion gear showed less thermal distortion after carburizing than the single normalized pinion. With improved microstructure of alloy steels which used in pinion gear, the performance of planetary gear set could be enhanced without any supplementary attachment of cooling system for gear set.

EXPERIMENTAL PROCEDURE

PLANETARY GEAR SET OF AUTOMATIC TRANSMISSION - Figure 1 shows the planetary gear system of automatic transmission which was investigated in this research. Part ②, ③, and ④ are pinion shaft, long pinion and needle roller bearing respectively, which are major components in contacting system. The material specifications for the components are shown in Table 1. The above three parts are subjected to severe driving atmosphere at maximum speed condition. When the lubrication and subsequent cooling system are not proper, the contacting parts are heated, weared and finally seized as shown in Figure 2. Improvements of lubrication routes have been made to increase oil supply as shown in Figure 3. Supplementary oil cooler was attached to decrease temperature of ATF from 125 ℃ to 110℃

MICROSTRUCTURE IMPROVEMENT OF PINION GEAR MATERIAL - The other improvement for the planetary gear set was made in microstructure modification of pinion gear by double normalizing before carburizing heat treatment. The pinion gear is directly machined from smooth turned as-rolled bar with normalizing heat treatment as shown in Figure 4. The single normalized microstructure of pinion gear showed very predominant orientation parallel to rolling direction with banded microstructure, pearlite and ferrite. Figure 5 represents the process of improved double normalizing heat treatment to obtain equiaxed microstructure of pearlite and ferrite.

BIAS MEASUREMENT OF PINION GEAR - The distortion of tooth profile can be determined by measuring profile and lead bias which mean the difference between maximum and minimum of pressure angle error and helix angle error respectively as shown in Figure 6. Two kinds of pinion gears with different microstructures, one directional banded and the other equiaxed, were



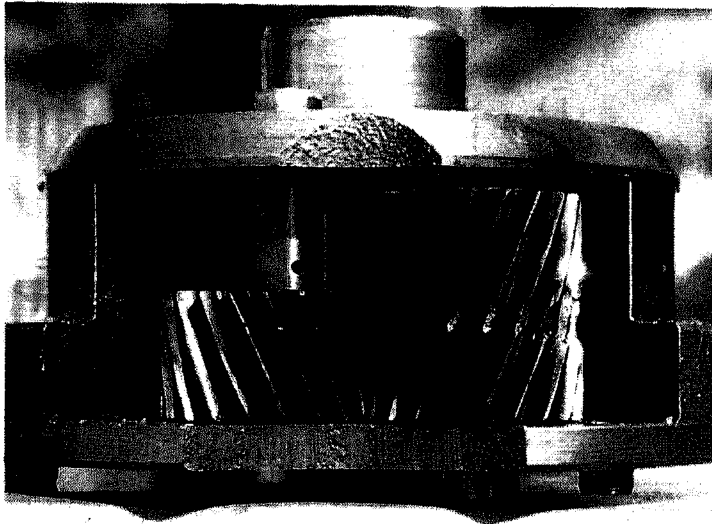


Figure 1. Planetary gear set of automatic transmission

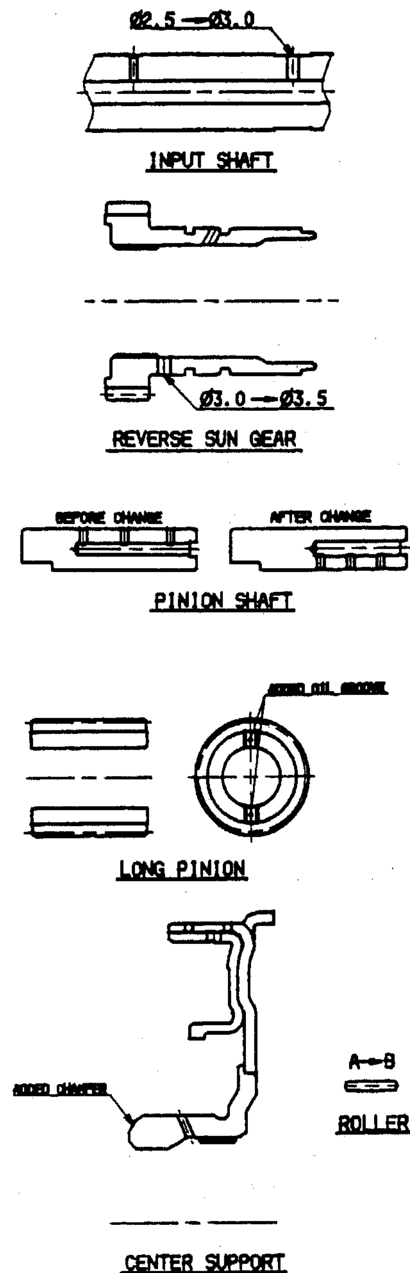

Figure 3. Improvement of lubrication root of planetary gear set of automatic transmission

prepared. After carburizing and honing the inside of pinion gear, profile and lead bias were measured to estimate the influence of microstructure on thermal distortion during the carburizing process.

THERMAL DISTORTION - To investigate the effect of microstructure on thermal distortion during carburizing process, navy-c type and cylindrical type specimens which are shown in Figure 7 and Figure 8 were machined from single and double normalized samples respectively.

The dimensional changes of c-gap, thickness, internal and external diameters after carburizing in navy-c type specimens were measured. Whereas, in cylindrical samples, the dimensional changes of internal and external radius at every 36 degree along the radial direction at hight A, B and C of Figure 8 were also measured.

METALLOGRAPHY AND HARDNESS TESTING - Metallographic samples were cut from failed gear, single normalized and double normalized new gears. The surface microstructure of failed pinion gear carefully examined to identify the failure mechanism and surface hardness distributions especially inside region were examined. The criterion of surface hardness is above 650 HV and that of effective case depth is the distance from surface to the subsurface which shows 550 HV hardness. The failed and honed surface were examined by scanning electron microscopy (SEM). The microstructure of single and double normalized samples were also examined by optical microscope. The prior austenite grain sizes were determined in accordance with ASTM E112-88, after etching in a saturated picric acid and hydrochloric acid solution in which sodium tridecylbenzene was used as a wetting agent (6).

DYNAMOMETER TEST OF PLANETARY GEAR SET - Dynamometer tests of automatic transmission gear sets were conducted to confirm the effect of improved microstructure of pinion gear on the performance of automatic transmission at maximum speed condition.

RESULTS AND DISCUSSION

FAILURE MECHANISM OF PLANETARY GEAR SET - Failed parts of planetary gear set were examined to explain the failure mechanism of automatic transmission. The failure originated from the interface between inside of long pinion gear and needle roller bearing during dynamometer test under maximum speed condition. SEM analysis for failed parts showed the failure process as following galling failure ; Severe Wear → Adhesive wear → Spalling → Seizure. General causes of galling are insufficient galling resistance of material due to low hardness, ease of welding, lack of protective layer, severe sliding in contact, severe normal load, overheating, unfavorable surface microgeometry ; roughness and inadequate boundary lubrication (7, 8). Figure 9 shows the failure process from (a) to (d) for the inside of failed pinion gear. At first stage of failure, sharp feather edge at inside of pinion

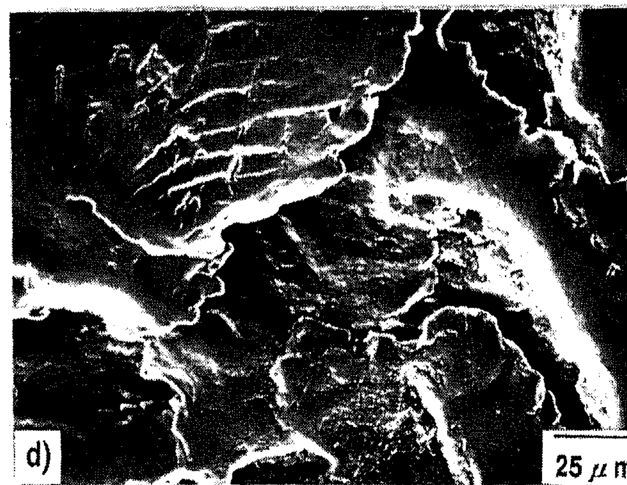

Figure 9. SEM analysis of galling failure process (a) as-honed condition (b) Severe wear (c) Adhesive wear (d) Macrospalling and Seizure.

gear after honing weared and disappeared by asperity contact with needle roller bearing as shown in Figure 9 (a) and (b). After this stage, prow type wear resulted from metal to metal adhesive wear was observed in Figure 9 (c). The prow rings were experienced additional wear and work hardened and finally resulted in spalling as Figure 9 (d). This failure process drove the planetary gear set to seizure with contacting components, needle roller bearing and pinion shaft. Surface microstructure of pinion gear inside area was observed by optical microscope as shown in Figure 10. At the early stage of failure, galling phenomena were accompanied with decarburizing as shown in Figure 10 (a) and adhesive welding wears were distributed over the entire range along the axis direction of pinion gear. Spallings were occurred after asperity contacting abrasive wear as shown in Figure 10 (b) and lubrication layer was destroyed and resulted in seizure failure.

Among the factors influencing galling failure, low surface hardness and effective case depth, coarse surface roughness, loss of oil characteristics due to excessive high oil temperature were main sources of this automatic transmission failure.

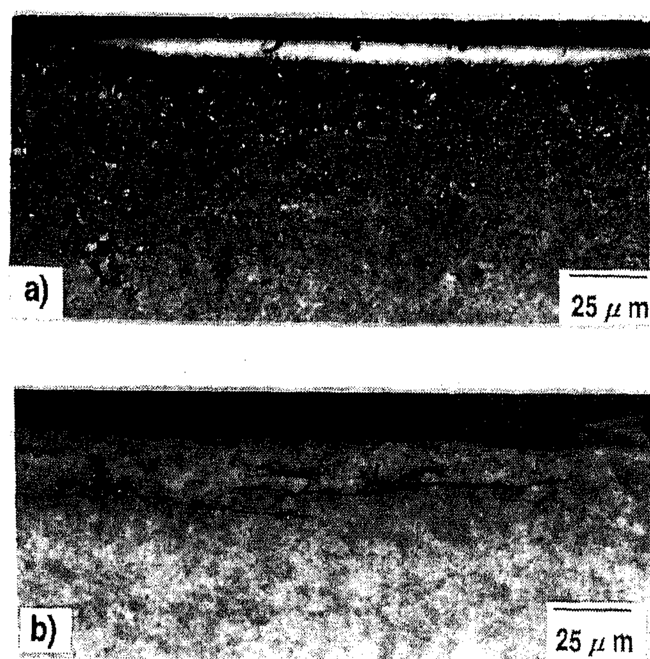

Figure 10. The microstructures of (a) surface galling and (b) spalling which are shown as white decarburized layer and subsurface microcracks respectively.

MICROSTRUCTURE IMPROVEMENT OF PINION GEAR MATERIAL - Microstructure of single normalized pinion gear material consisted of banded structure with pearlite and ferrite. This microstructure has strong directionality so that high thermal distortion during carburizing was expected. Through investigating failed pinion gear, it was confirmed that some surface area of pinion gear showed very low surface hardness and effective case depth in Figure 11 and Figure 12. The surface hardness was ranged from 550 HV to 780 HV and effective case depth was also not uniform from 0.20 mm to 0.40 mm. These inadequate mechanical properties were driven from non-uniform grinded depth for inside of pinion gear after carburizing. Because of severe ovality and cylindricity of pinion inside after carburizing, uneven grinding could be inevitable. This oval type thermal distortion is directly related with banded microstructure of smooth turned pinion gear material.

Banded microstructure comes from the segregation of chemical composition during steel melting, soaking, forging and rolling process and is basically influenced from chemical composition of alloy steel. From the results of research by Fujita, as the content of Cr, Ni, and Mn increase and those of Si and Mo decrease, the banded microstructure becomes more predominant (5). Considering the chemical composition of pinion material ; SNCM420H-ESR, it was difficult to avoid the banded structure during current steel-bar making process without modifying chemical composition. Modification of normalizing process was introduced to find alternative method for modification of alloy chemical composition. Basic concept of modified heat treatment was based on homogenization at austenite and rapid cooling through two phase, austenite and ferrite, region during normalizing. Enough thermal energy at austenite phase region was supplied to resolve chemical segregation by double normalizing with 2 hours at 920 ℃. Rapid cooling through austenite

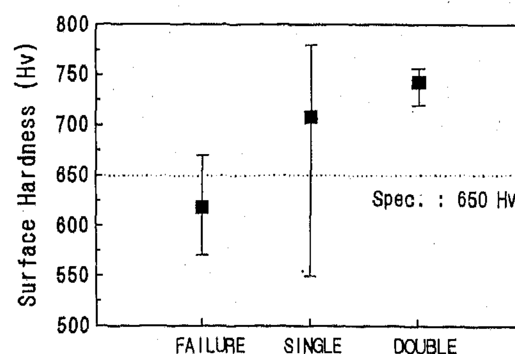

Figure 11. Distribution of surface hardness at inside of pinion gear. The marks of failure, single and double mean failed pinion during test, single normalized new pinion and double normalized new pinion respectively.

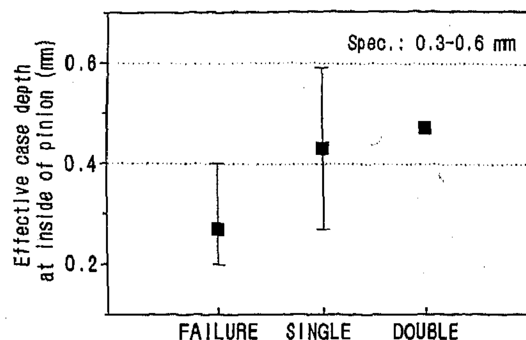

Figure 12. Distribution of effective case depth at inside of pinion gear. The marks of failure, single and double mean failed pinion during test, single normalized new pinion and double normalized new pinion respectively.

and ferrite two phase region after homogenizing was designed to avoid chemical segregation due to directional precipitation and growth of proeutectoid ferrite during cooling process through this region. Normalizing temperature was also increased from 880 ℃ to 920 ℃ to coincide with the temperature of carburizing to make stabilizing the microstructure during subsequent carburizing at 920℃.

Double normalizing was designed to transform the banded microstructure to equiaxed microstructure with pearlite and ferrite by diffusion process. By double normalizing at elevated temperature, the banded microstructure was transformed to equiaxed as shown in Figure 13. The surface hardness and effective case depth of double normalized pinion gear showed excellent uniformity with surface hardness from 720 HV to 757 HV and effective case depth from 0.45 mm to 0.48 mm respectively. The prior austenite grain size became more fine after double normalizing because of recrystallization process during second heating. The numbers of grain sizes were ASTM number 9.20 and ASTM number 11.40 for single and double normalized samples before carburizing respectively. The tendency of the difference had been maintained during carburizing. As shown in Figure 14 (a) and Figure 14 (b), the average number of grain size became ASTM number 8.68 and ASTM number 10.60 for single and double normalized samples after carburizing respectively. Figure 14 (c) shows the abnormally coarse grain of single normalized sample after carburizing. This kind of abnormal grain growth was randomly distributed and deteriorate thermal distortion and strength of pinion gear. The bending fatigue performance of carburized alloy steels can follow the Hall-Petch type relationship and carburized steels with fine austenite grain size exhibit superior bending fatigue performance. From previous research results as shown in Figure 15, the bending fatigue strength of pinion gear can be improved approximately 10 % by double heating (9, 10). The relationship between contact fatigue strength and grain size has not been studied quantitatively enough.

Tsushima reported that prior austenite grain size did not seem to influence the rolling contact fatigue life (11). But, recent studies have shown that the increase of contact strength of case hardened steel could be achieved by grain refinement with microalloying element. In dynamometer test with fine grained pinion, surface pitting failure was also improved so that even though quantitative correlation has not been proposed, the Hall-Petch type relationship between grain size and contact fatigue strength can be also estimated. This improvement of thermal distortion, bending and contact fatigue strength of double normalized pinion gear could contribute to increase the performance of planetary gear set of automatic transmission.

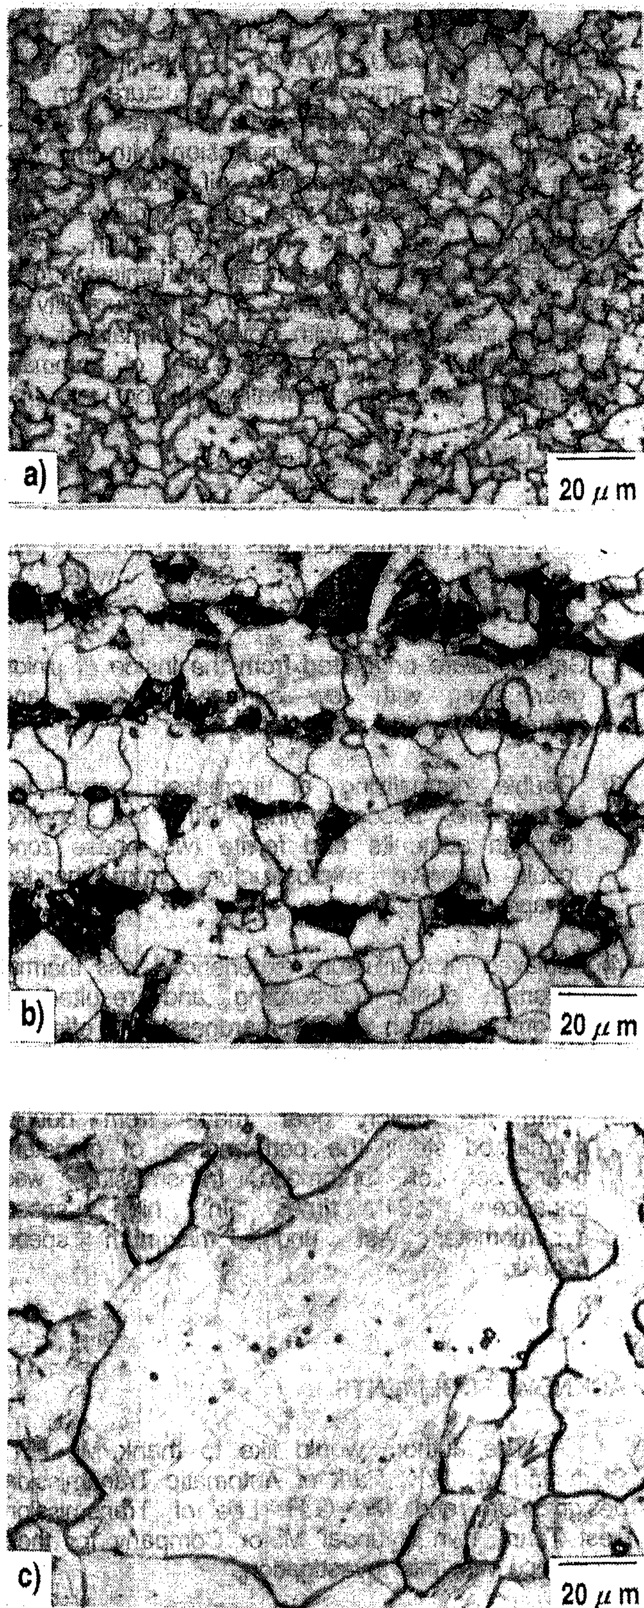

Figure 14. Prior austenite grain sizes after carburizing. (a) single normalized pinion, (b) double normalized pinion and (c) Abnormal grain growth observed at single normalized pinion after carburizing.

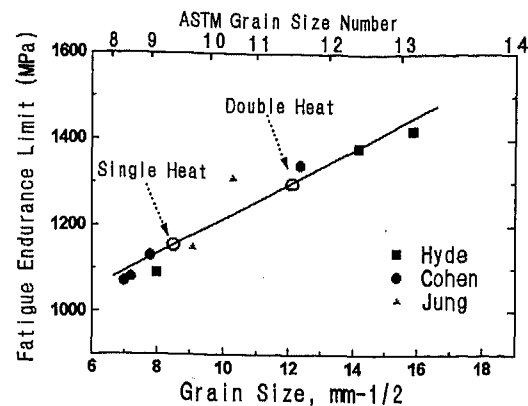

Figure 15. Bending fatigue endurance limit versus prior austenite grain size

BIAS MEASUREMENT OF PINION GEAR - The results of profile and lead bias measurement for carburized pinion gears made from single and double normalized steels were shown in Figure 16. The direction of profile bias is from root to tip of gear and perpendicular to rolling direction of material and the direction of lead bias is from bottom to top of gear and parallel to rolling direction of bar steel.

The single normalized pinion gear showed very wide deviation for profile bias and lead bias ranged from 3 μm to 30 μm and from 4 μm to 73 μm respectively as shown in Figure 16. But, double normalized pinion gears represented well stabilized bias ranged from 2.5 μm to 19.30 μm for profile direction and 8.00 μm to 29.40 μm for lead orientation. The average distribution of profile and lead bias were decreased 27 % and 33 % respectively by double heating.

The microstructure of pinion gear in parallel to rolling direction exhibited strong directionality than that of perpendicular direction in single normalized material. This means that lead bias is more susceptible to thermal distortion and the result of measurement are also coincide with this expect.

THERMAL DISTORTION - Figure 17 shows the dimensional changes of navy-c type specimen from single and double normalized samples after carburizing. The 87.8 % and 69.3% Improvements of thermal distortions were made on external and on internal diameter respectively. The improvements of thermal distortions on c-gap and thickness were also 29.3 % and 12.0 % respectively. Distortion measurement of cylindrical specimens were made on the points A, B and C of Figure 8. Cylindricity of internal and external diameter on single normalized cylinders were 8.3 μm and 23.5 μm respectively. After double normalizing, cylindricities of internal and external diameter were improved

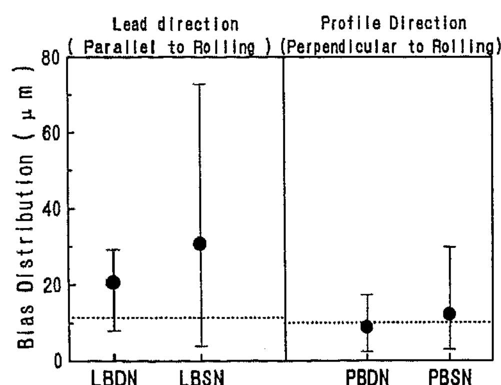

Figure 16. Comparison of bias distributions for pinion teeth which made from single and double normalized steels. LBDN and LBSN represent lead bias of double normalized and simple normalized gear respectively. PBDN and PBSN also represent profile bias of double normalized and simple normalized gear respectively

17.5 %, from 8.3 μm to 6.8 μm and 19.1 %, from 23.5 μm to 19.5 μm , respectively. Dimensional changes of internal and external diameters for single and double normalized cylinders were shown in Figure 18 and Figure 19. Single normalized samples showed higher contractive dimensional change than double normalized samples after carburizing in both internal and external diameter. The large contraction required more grinding depth after carburizing and results in localized improper low surface hardness and effective case depth at the inside of pinion gear. These localized improper surface properties of pinion inside could be the weakest points between the contacting pinion shaft and roller bearing and original sites of failure during durability test.

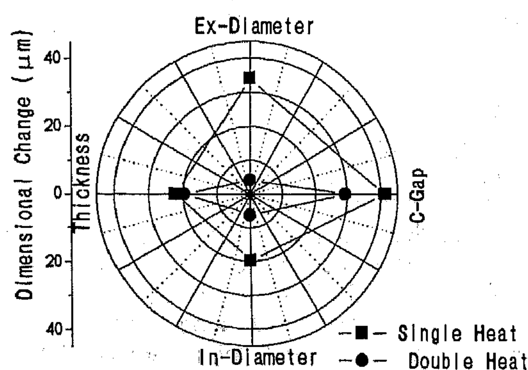

Figure 17. Dimensional change in navy-c type specimen after carburizing on single and double normalized samples

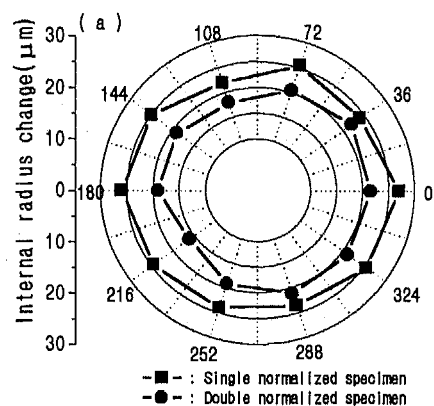
DYNAMOMETER TEST FOR PLANETARY GEAR SET OF AUTOMATIC TRANSMISSION - The effect of improved microstructure on the performance of planetary gear set was evaluated for assembled automatic transmission with improved pinion gear. The supplementary oil cooler in cooling system of transmission was not supplied in this dynamometer test. The results of high speed dynamometer tests for automatic transmission gear sets were shown in Figure 20. The durability of automatic transmission with double normalized gear was enhanced 2.91 times than that of automatic transmission with single normalized pinion.

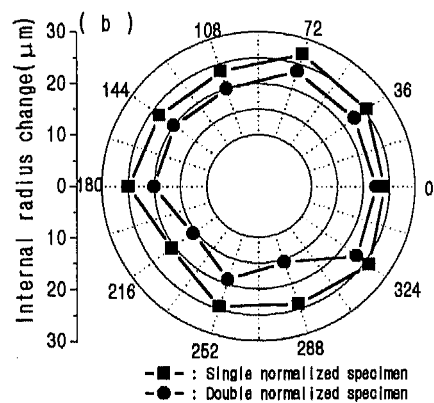
CONCLUSION

1) Failure mechanism in planetary gear set of automatic transmission was galling process with following procedure ; Severe wear → Adhesive wear → Macrospalling → Seizure.

2) Galling failure originated from the inside of pinion gear along with low surface hardness and improper effective case depth.



3) Double normalizing at increased normalizing temperature accompanying with fast cooling through austenite and ferrite two phase zone could improve microstructure from banded shape to equiaxed one.



4) Equiaxed microstructure experienced less thermal distortion during carburizing and resulted in uniform and high surface hardness and effective case depth at the inside of pinion after grinding.

5) With the pinion gear made from double normalized steel, the performance of planetary gear set of automatic transmission was enhanced 2.91 times in high speed dynamometer test under maximum speed condition.

The Influence of Fillers on Paper-Based Friction Materials Relative to Wet Clutch Slip Characteristics

Hideto Nakagawa
Aisin Chemical Co., Ltd.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Various wet friction materials, in which different fillers are compounded on the surface of fibrillated fiber base, were prepared. The friction properties of these materials were pursued at various slip speeds, loads and oil temperatures. Streibeck Diagrams of the data were obtained, and the effect of fillers on the frictional characteristics was investigated.
The following results were obtained;

(1) The slope of the Streibeck Diagram should be positive to have smooth frictional characteristics.
(2) Abrasive powders effectively improved the slip characteristics of friction materials.
(3) The effect of the abrasive fillers was further improved by using less compliant paper.

1. INTRODUCTION

In recent years, positive slipping of paper-based friction material (friction material, hereafter) has become popular for the improvement of toque transmission efficiency and shift control of automatic transmissions. Along with this trend, vibration due to the friction properties of friction material is becoming a significant problem.

Since the friction of friction material involves boundary lubrication, theoretical prediction of friction characteristics is difficult and therefore properties are often analyzed by experiments.

Both mechanical and chemical actions generate the friction force of friction material. The effect of porosity, actual contact area (1)~(3) and ATF (4)~(7) have been studied extensively.

However, research has not advanced much on the chemical action of fillers in friction material. The study of effect of filler to friction material is very important not only for the practical purposes, but also for understanding the mechanism of the friction force generated in wet clutch systems.

In this research, several friction materials with different fillers compounded only on the friction surface were prepared, and the effect of fillers on slip characteristics was examined.

2. EXPERIMENT

2.1 OUTLINE OF TEST APPARATUS

Figure 1 shows the outline of the test apparatus used in this experiment. It is composed of a motor, a test head, a pipe heater, a torsion bar and a torque meter. The slip speed can be changed by a motor from 1 to 100 rpm. The oil temperature also can be controlled by a pipe heater from 40 to 120℃. An output torque is measured by a torque meter. Actual wet clutches and separators are assembled in the test head. A method to supply ATF can be selected from shaft center method, dipping method or combination of both methods. Friction vibration during sliding can be measured using a torsion bar.

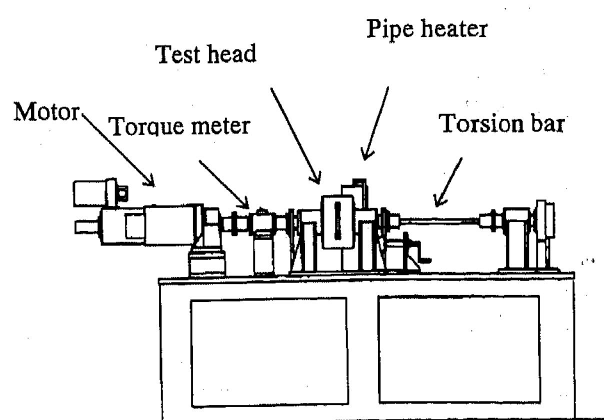

Fig.1 Test apparatus

Figure 2 shows the internal structure of the test head. Wet clutches are engaged with operating piston by increasing air pressure. The snap ring is installed in order to simulate distribution of surface pressure on the friction materials in actual vehicles. Load can be varied from 400 to 8000N.

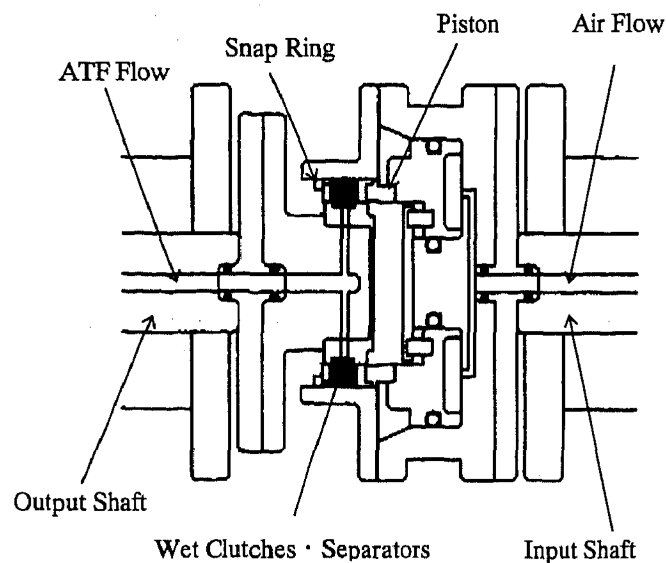

Fig.2 Internal structure of test head

2.2 PROTOTYPE SAMPLES AND FILLERS

Table 1 shows the compositions and properties of the test friction materials. Samples B to G and B' to G' are prepared by compounding various fillers only on the surface of sample A and A'. The amount of fillers are about 2% by weight. The friction properties can be affected by porosity, oil absorption speed and strain (8) ~ (10). Therefore, porosity and oil adsorption speeds of these samples were made equal to each other and a magnitude of strain was the only difference among A~G and A'~G'. The strain is measured using Rockwell Hardness Tester. The value indicates the amount of deformation in μ m after applying the 18.7MPa load for 15 seconds.

These are typical fillers used for friction materials. Hardness and abrasion of fillers are represented as relative compared with separator. The hardness of separator is Hv250. The hardness and abrasion are measured as follows. Fillers are distributed onto a separator with mirror-like polished surface. Fillers and separator are loaded to 18.7MPa.
Abrasive powder, Carbon group powder and Carbon group fibers made the surface of separator rough. Abrasive powder has the strongest abrasion as shown in Figure 3.

Table 2 shows characteristics of fillers. Figure 4 are the SEM (Scanning Electron Microscope) photos of the surface of friction materials.

Table 1 Compositions and Properties of Friction materials

Symbol	Composition	Fillers Quantity (%)	Strain (μ m)	Porosity (%)	Oil absorption speed (sec)
A	Pulp of low fibrillation degree	0.0	120	42	28
B	A + Abrasive powder	1.8	120	40	28
C	A + Carbon group powder	2.0	113	42	25
D	A + Phenol group powder	1.7	113	39	27
E	A + Solid lubricant	2.1	115	39	30

Fig.4 SEM observation of Friction Materials

Coefficient of friction is calculated by the equation below.

$$\mu = \frac{T}{n * F * \frac{2}{3} * \frac{(Ro^3-Ri^3)}{(Ro^2-Ri^2)}}$$

where T :Torque(Kgm)
n :Number of surface
F :Load(N)
Ro :Radius of outer lining
Ri :Radius of inner lining

Figure 5 shows examples of torque traces. Left side of the torque traces is an example when no vibration is observed. Right side of the torque traces is an example when vibration is observed. The average torque is used for the calculation of μ at vibration.

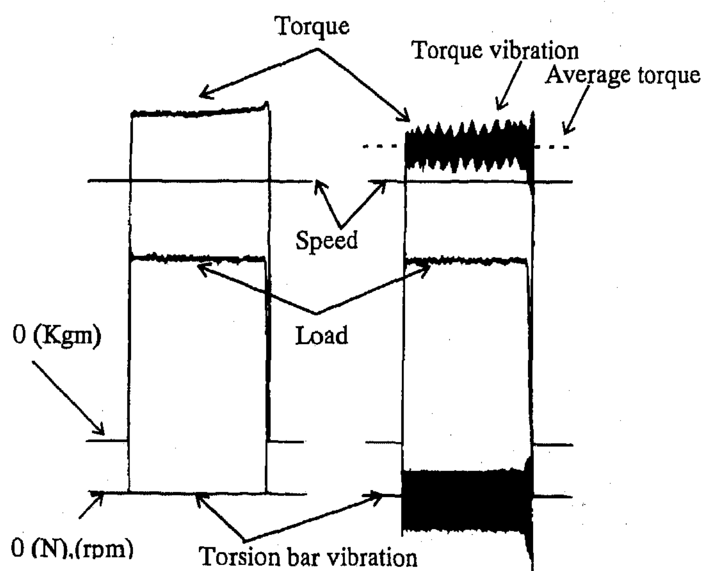

Fig.5 Torque Trace

3. EXPERIMENTAL RESULT

Friction of filler itself must be generated with as little change in porosity and actual contact area as possible, as mentioned in 2.2 and 2.3, for the understanding of filler effect itself on friction characteristics, which is the purpose of this research. Therefore, porosity, oil adsorption speed, strain, pore-size, bearing curve that indicates flatness of friction surface, and observation of adhesion of ATF additives onto friction surface were examined before and after testing. And, as a result, the following have been clear to the extent that the friction characteristics obtained from this experiment have been judged to indicate the characteristics of filler itself.

Examinations of porosity, oil adsorption speed, and pore-size —— Table 5 shows the pre-and post-test changes in the properties of friction materials. Only very small changes were observed. Figure 6 shows Sample A's pore-size distribution as a representative example.
This indicates the pore-size did not change during the experiment.

Table 5 Pre-and Post-test Change in Friction Materials

Symbol	Composition	Porosity (%)	Oil absorption speed (sec)	Strain (μ m)
A	Pulp of low fibrillation degree	0	3	5
B	A + Abrasive powder	1	5	6
C	A + Carbon group powder	2	7	6
D	A + Phenol group powder	1	7	3

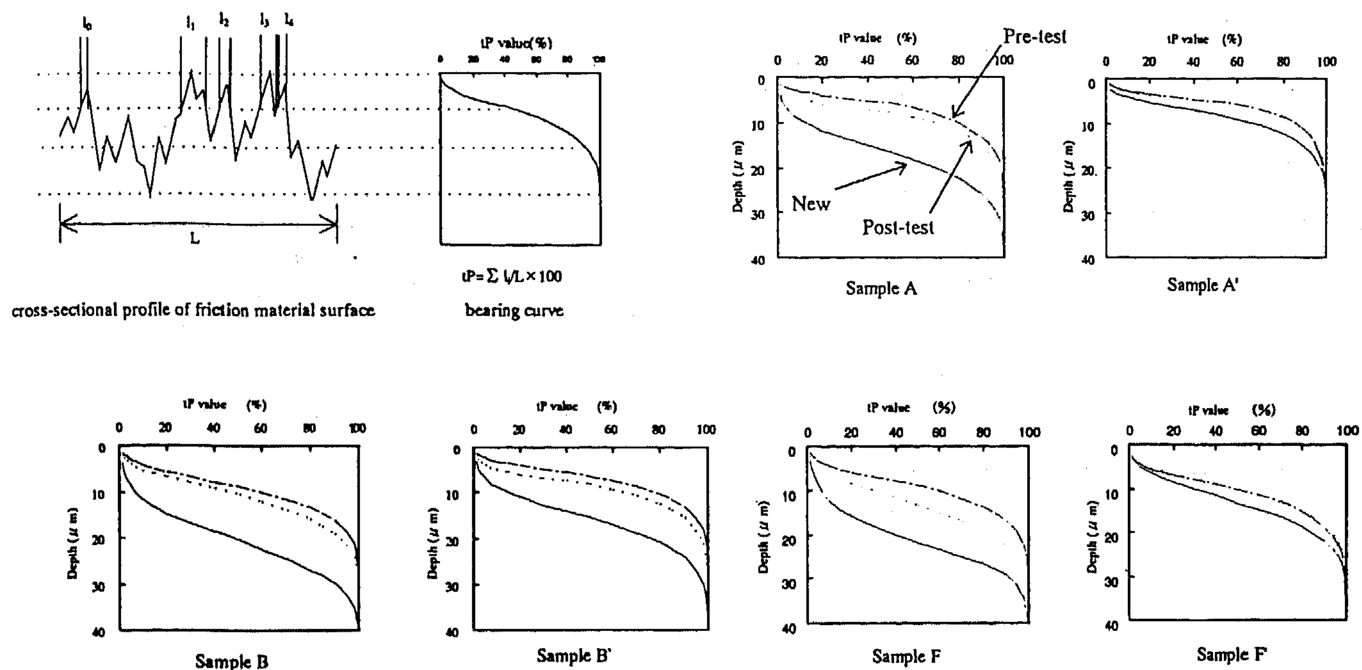

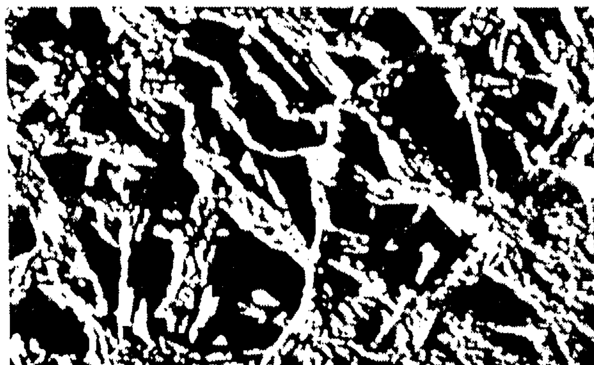

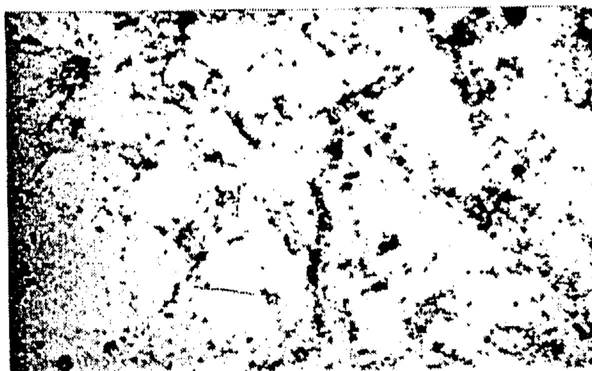

Fig. 7 Changes as time elapse in Bearing Curve

SEM observation

EPMA observation

Fig.8 Adhesion of Ca on Sample A

Examination of flatness of friction surface —— Figure 7 shows the bearing curves of surface conditions for new friction materials, pre-test material and post-test materials. Very small changes were observed between pre- and post test, (pre-test: break in material).

Examination of actual sliding material on friction surface —— Ca, which is one component of ATF additive, is adhered to pulp in friction material by friction in ATF. This phenomena is utilized to examine materials in actual friction.

Adhesion of Ca on post-test friction surface was examined by an EPMA(Electron Probe Micro Analyzer). Elements researched by this analysis are Ca, S, P and B. Only Ca is observed on the surface by this analysis. It proves that Ca will adhere to fibers. Adhesion of Ca is noticeable on friction surface of friction material(sample A) which compounded with only fibrillated fibers. The result is shown in Fig. 8. Little Ca adhesion was observed on fibrillated fibers of the friction surface of the sample compounded with filler on friction surface. This indicates no friction of pulp in friction material of which pulp surface is compounded with filler. In other words, the friction properties of friction material compounded with filler are the properties of filler material itself.

3.1 SPEED DEPENDENCY

Figure 9 shows the change(Δ μ V) in friction coefficient due to speed increase in comparison with the friction coefficient at low slip speed:1rpm(V=6.1 mm/s). This set of date is the average including variations due to oil temperatures and surface pressures.

Speed dependency of fillers is more pronounced for smaller strain of friction material. This is considered to be because less tangential force on fillers is absorbed by elasticity of base fibers when strain is small and shear force added to fillers is larger as compared to that on base fibers of larger distortion.

In regard to the speed dependency of fillers, friction coefficient decreases with increasing slip speed for filler E', with lubrication action under shear force, and filler D' that tends to become film-like, and on the contrary, friction coefficient of filler B', with abrasive action ,increases with increasing slip speed. This is considered to be due to the difference in shape stability of fillers against shear force.

3.2 TEMPERATURE DEPENDENCY

Figure 10 shows the change(Δ μ T) in friction coefficient due to oil temperature increase in comparison with the friction coefficient at 40 ℃ oil temperature. This set of data is the average including variations due to slip speeds and surface pressures.

Similar to the speed dependency, the temperature dependency of fillers is also prominent when strain of friction material is small, and this, too, is considered to be due to the difference of shear force added to fillers which is caused by the different strain of base fibers. Temperature dependency of fillers is related to the thermal stability of filler material and the temperature dependencies of filler B',C', and F' of high thermal stability are low.

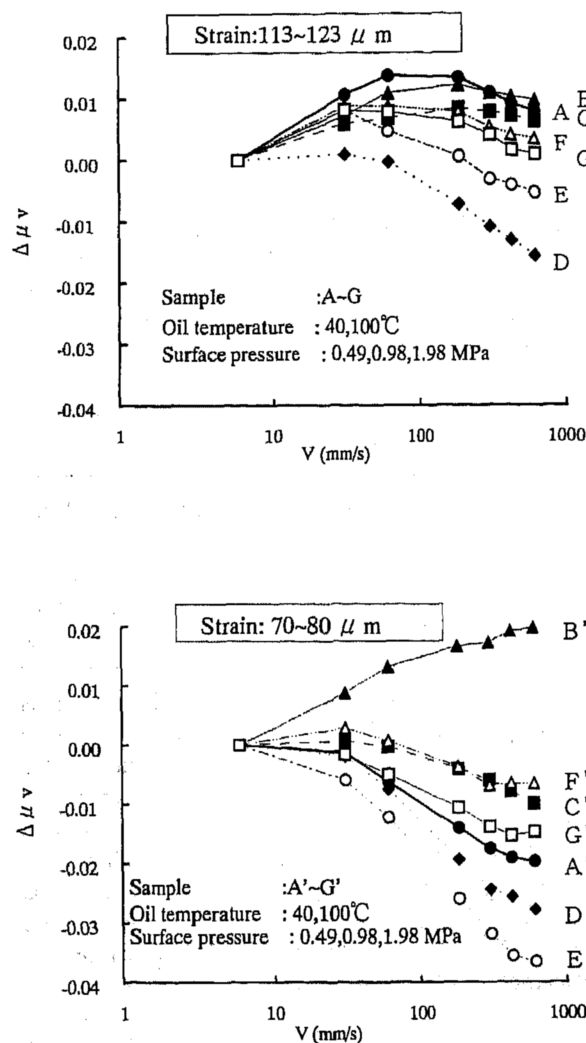

Fig.9 ⊿ μ v-V Characteristics

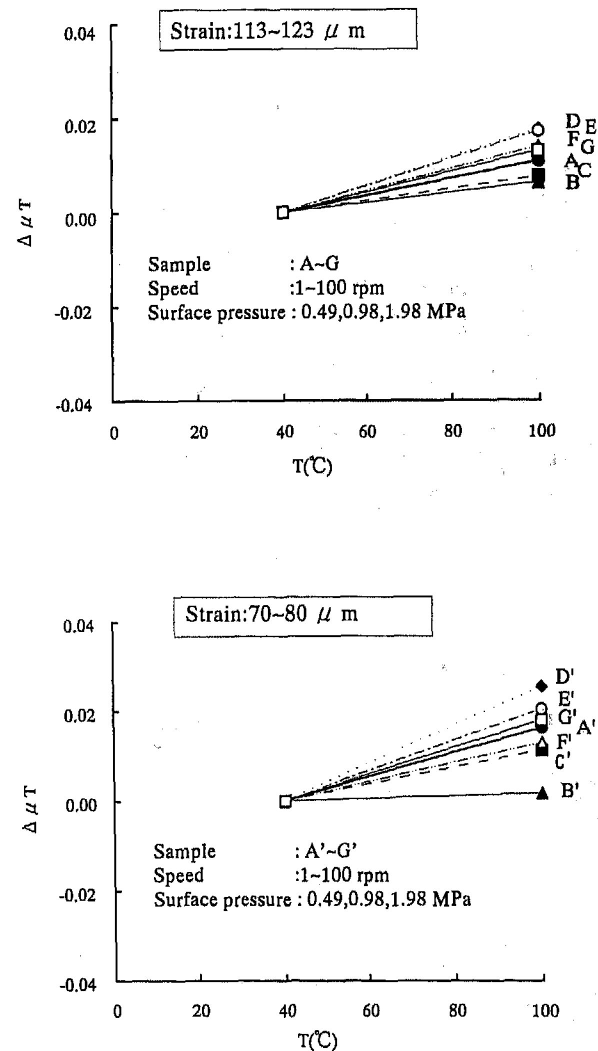

Fig.10 ⊿ μ t-T Characteristics

3.3 SURFACE PRESSURE DEPENDENCY

Change($\Delta\mu$ P) in friction coefficient due to increase in surface pressure is shown in Fig. 11, in comparison with the coefficient at 0.49 MPa surface pressure. This set of data is the average including variations due to oil temperatures and slip speeds.

Surface pressure dependency of fillers is also affected by the strain of friction material, and this character of fillers appears on the side of lower surface pressure when strain is smaller. This is considered to be because of a broader difference, under lower surface pressure, of shear force added to fillers which is caused by different strain of base fibers. Surface pressure dependency of fillers is lower for higher hardness of fillers, and filler B' shows little dependency. This is considered to be due to the difference in shape stability of fillers against load.

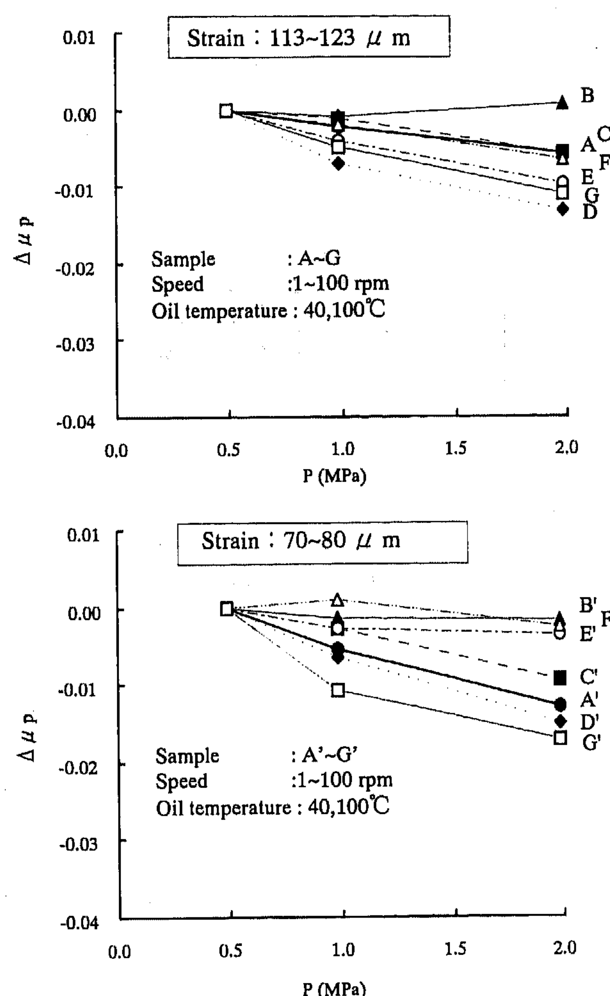

Fig.11 $\Delta\mu$ p-P Characteristics

4. EXAMINATION USING THE STREIBECK DIAGRAM

Friction properties of samples compounded with fillers is dependent on slip speed, oil temperature and surface pressure. These tests results are plotted into a Streibeck Diagram. Figure 12 shows the Streibeck Diagrams of the test samples. The value S is defined by the following equation.

$S = \eta V/P(m)$

where η : ATF viscosity(Pa*S)

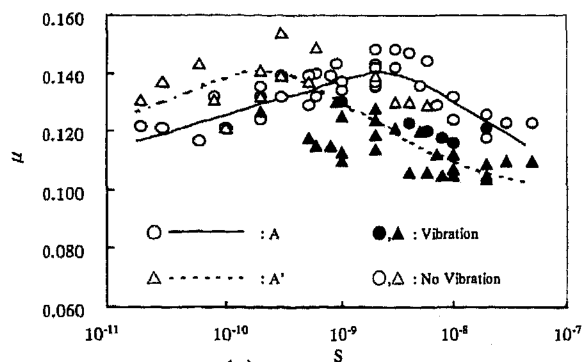
P : Surface pressure(Pa)

V : Slip speed(m/S)

Black plots in the diagram indicate the data points which generate friction vibration. μ-S curves are shown are obtained by regression.

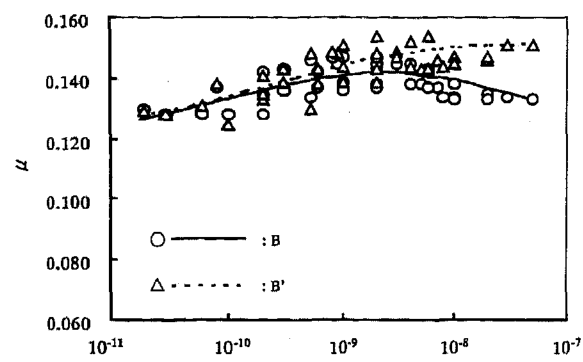
4.1 INFLUENCE OF FILLERS ON LUBRICATION CHARACTERISTICS

Figure 12(a) shows the Streibeck Diagram of A-A'. The difference of lubrication characteristics between A and A' is thought to be caused by the difference of thickness of boundary lubrication oil film, because the strain of sample affects the thickness of oil film. At low to medium S value, μ increases along with the increase of shear force of oil film. At medium to high S value, the data indicates the characteristics of fibrillated fibers. Lubrication characteristics of test samples compounded with fillers are compared with the ones of samples A and A'.



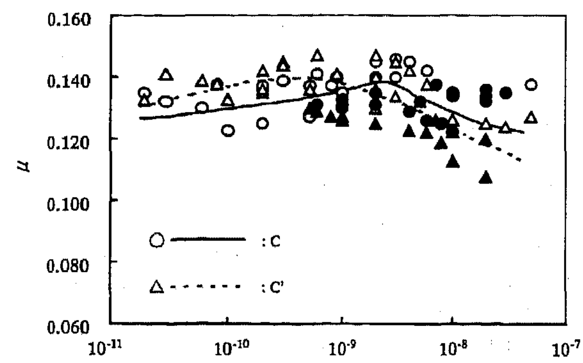
1)Fiber-like fillers (F-F' and G-G')---Figure 12 (f) and (g) show the Streibeck Diagrams of F-F' and G-G'. The differences of characteristics between Carbon group fibers and phenol group fibers are the hardness and temperature resistance. However, Carbon group fibers and Phenol group fibers have similar lubrication characteristics. These fillers do not affect the characteristics of A-A'. This result proves that fiber-like fillers do not affect the lubrication characteristics of the original paper base A-A'.

2)Powder fillers (B-B', C-C', D-D' and E-E')---Figure 12(b), (c), (d) and (e) show the Streibeck Diagrams of B-B', C-C', D-D' and E-E'. The lubrication characteristics of powder fillers depend on the characteristics of fillers.



-Abrasive powder (B-B') improves the lubrication characteristics of the original paper base A-A' to positive slope.

-Carbon powder (C-C'), which has high hardness and low abrasion, does not affect the lubrication characteristics of the original paper base A-A'.



-Materials E, E', D and D', which have low resistance to shear force, show more negative slope on the lubrication characteristics of the original paper base A-A'.

(f) Fiction materials No.F,F'

(g) Friction materials No.G,G'

Fig.12 The Streibeck Diagrams

3)Comparison of strains---Figure 13 shows the Streibeck Diagrams classified according to the strain. The less compliant paper obviously represents the characteristics of fillers. As mentioned earlier, the difference of strain affects the forming of boundary lubrication oil film. The friction force of fillers has more effect on less compliant paper because thinner oil film forms on the surface.

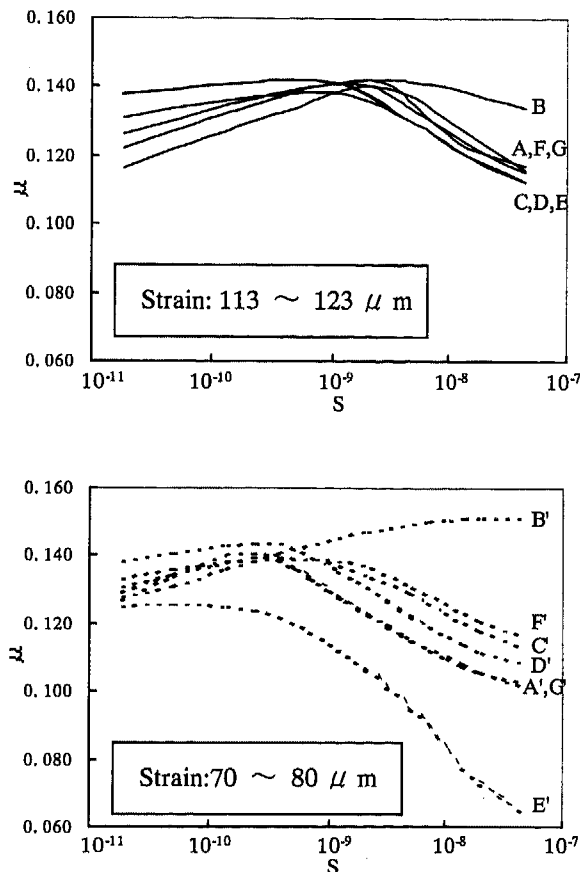

Fig.13 The Streibeck Diagram Classified according to the Strain

4.2 FRICTION VIBRATION CHARACTERISTICS

Black plots in the Streibeck Diagram of Fig.12 means the data was observed with occurrence of friction vibration. Figure 5 shows the torque trace with friction vibration. There is no vibration where the curve has positive slope. The vibration starts to occur around the maximum of the curve where the slope changes from positive to negative. This means friction materials, which have positive slopes on the μ-S curve, are effective in preventing vibrations. In this study, friction material B' is the most effective paper to prevent vibrations.

5. Conclusion

To summarizes the results:

(1)Friction materials, which have positive slope on the μ-S curve in the Streibeck Diagram, effectively improve the slip characteristics. The characteristics of fillers contribute to the slope. μ-S curves can be classified into three types by the effect of fillers.

μ – S curve	filler
	abrasive powder
	carbon group fibers phenol group fibers, carbon group powder
	solid lubricant phenol group powder

(2)The abrasive powder is effective in improving the slip characteristics of friction materials, because the fillers have the shape stability to withstand shear force, load and temperature.

(3)The abrasive fillers work more efficient by using less compliant paper. The friction force created by the fillers increases as shear force of oil film decreases. This phenomena is caused by the formation of a thin boundary lubrication oil film. The oil film formation is affected by the strain of paper. The fillers, like solid lubricant or phenol group powder, affect the slip characteristics of friction material so as to make more negative slope. Therefore, it is very important to understand the characteristics of the fillers to improve the slip characteristics.

We think the amount of abrasive fillers used in the wet friction materials will increase to the slipping clutch applications.

ABSTRACT

The physical and chemical properties of a mineral-based (Fluid-M) and a partial-synthetic-based (Fluid-PS) automatic transmission fluid were compared by the analyses of Gel Permeation Chromatography (GPC), Thermogravimetry (TG), Fourier Transform Infrared Spectroscopy (FTIR), Nuclear Magnetic Resonance (NMR), Gas Chromatography (GC), viscometry, thermo-oxidative stability, torque response curve shape and metal-to-metal wear preventive characteristics. The effects of various properties of Fluid-M and Fluid-PS on wet friction material performance were investigated from the viewpoints of compressibility, durability, tensile strength, surface interactions and friction-pressure-speed-temperature characteristics. Friction material specifications for partial-synthetic fluid applications will be different from those for mineral-based fluid applications.

GPC showed that Fluid-PS has a higher concentration and a lower molecular weight of VI Improver than Fluid-M. Chemical analyses indicated major differences in the detergent, anti-wear and anti-oxidant additive packages of Fluid-M and Fluid-PS. Thermal oxidation tests indicated different degradation paths for the fluids. Both fluid formed acid, ketone, and ester. However, Fluid-M showed more tendency to polymerize to diester or polyester than Fluid-PS. Fluid-PS reduced friction and wear in metal-to-metal contacts in 4-Ball tests as compared to Fluid-M. The less metallic wear in Fluid-PS was explained with the superior viscometrics and anti-wear additive characteristics of the fluid. Fluid-M and Fluid-PS had similar torque response curve performance in SAE tests at low temperatures. However, Fluid-PS showed an increasing friction with decreasing speed (negative μ-v slope) whereas Fluid-M showed a positive μ-v slope at high temperatures and low speeds. Hence, Fluid-PS tended to cause more "shudder" at high temperatures, especially with rigid friction materials. The factors contributing to the negative μ -v slope in Fluid-PS are the narrow molecular weight distribution of the synthetic base oil, and the detergent free additive package of the fluid. In general, the friction materials wetted with Fluid-PS had less compressibility than the ones wetted with Fluid-M. The difference in compression modulus in the fluids were explained with the differences in base oil type and VI improver package of the fluids. Fluid-PS' tendency to increase the rigidity of a wet clutch system can be compensated by tailoring the compressibility of friction materials.

INTRODUCTION

Original Equipment Manufacturers (OEM) design their new Automatic Transmission Fluid (ATF) specifications for better fuel economy and longer fluid life. The new MERCON®V specification for automatic transmission fluids has been announced recently (1). MERCON®V specification requires superior viscometry, higher shear, and oxidative stabilities, and less metal-to-metal wear than the current MERCON® specification (2). Similar trends are expected in the new DEXRON® and overseas specifications (3). For better fuel economy, new generation ATFs are required to provide high friction coefficients during clutch engagements, and low drag losses during freewheeling. Sub-zero temperature-drag losses can be reduced by increasing the fluidity of ATF at low temperatures. High friction coefficients and little metal-to-metal wear can be achieved with synthetic lubricants and effective anti-wear additives. Synthetic-based fluids meet most of the requirements of low pour point, high viscosity index, high shear viscosity, and high oxidative stability. However, synthetic-based fluids are

* Author to whom correspondence should be addressed.

considerably more expensive than the mineral-based fluids. A necessity to compromise between the performance and cost leads to partial-synthetic fluids.

The performance of a wet clutch system depends on the compatibility of ATF with the friction material and the metal mating surface. The study of physical and chemical interactions of ATFs and friction materials is a formidable task mainly due to the complexity and secrecy of the formulations of ATFs and friction materials. Nevertheless, the design of better wet clutch systems requires a solid understanding of the interaction phenomena. Recently, there is a trend to use partial-synthetic based ATFs because of their superior viscosity characteristics. The interactions of various friction materials with a mineral-based commercial ATF and a partial-synthetic-based commercial ATF were studied in this research so that an informed selection of friction materials for these fluids can be made. The systematic approach of the research and general discussions of ATF and friction material properties are of interest to all OEMs and component suppliers. The physical and chemical properties of Fluid-M and Fluid-PS were compared by the analyses of viscometry, thermo-oxidative stability, and metal-to-metal wear preventive characteristics. Furthermore, effects of Fluid-M and Fluid-PS on wet clutch performance were investigated from the viewpoints of compressibility, durability, and friction-pressure-speed-temperature (μ -P-v-T) characteristics. The difference in compression modulus in the fluids was explained with the differences in base oil type and VI improver package of the fluids. The effects of base oil type, VI improver, friction modifier, detergent, dispersant and antiwear additives on the torque curve shape were also discussed.

EXPERIMENTAL METHODS

The properties of fluids were analyzed by viscometry, Inductively Coupled Plasma (ICP), Fourier Transform Infrared Spectroscopy (FTIR), Gas Chromatography (GC), Gel Permeation Chromatography (GPC), Nuclear Magnetic Resonance Spectroscopy (NMR), Thermogravimetry (TG), and mechanical tests. Mechanical tests included 4-Ball Wear Tests, compressibility tests, and SAE No.2 Test Machine tests. Two types of tests were run with the SAE No.2 Test Machine: durability test and μ -P-v-T test. The fluid viscosities were measured at 40°C and 100°C with a capillary viscometer, then, viscosity index was calculated. High temperature-high shear viscosity was measured with a tapered bearing simulator according to ASTM D4683. Spectrochemical analysis was done with the Spectroflame ICP module. FTIR spectra were obtained with 200 scans at 4 cm^{-1} resolution. The spectroscopic measurements of fluids were taken with a KBr cell of 0.2 mm fixed path length. GC was used for the identification and quantification of the synthetic portion of Fluid-PS. The GC system consisted of a Varian 3400 instrument equipped with a flame ionization detector and Star Workstation. GPC analysis was done to determine the molecular weight distribution of the fluids. The GPC system was equipped with Waters 610 isocratic solvent delivery system and a Waters 410 refractive index detector. The GPC analyses were conducted with four columns having the exclusion limits of 1500, 5000, 20000, and 400000 molecular weight. A GPC calibration curve was obtained with nine narrow standard samples of polystyrene and polymethylmethacrylate with molecular weights ranging from 200 to 375000 dalton.. NMR analyses were done with ^{31}P and ^{13}C isotopes on a Varian UNITYplus 400 system.

High resolution thermogravimetry was done with a TA-2950 apparatus. The heating rate was 200°C/min up to 100°C, then it was 20°C/min up to 950°C when no derivative was sensed. In high resolution TG, heating is switched to a very small temperature increase when a derivative is sensed. A flow of air and nitrogen was supplied to the sample chamber at a rate of 100ml/min. Wear preventive characteristics of the fluids were tested with a four-ball machine according to ASTM D2266 with one repetition. The submerged static compressibility tests of friction materials in ATFs were done after a 5-minute soaking at 93°C. Compressive load was applied in a mechanical test machine (MTS 810 Axial Test Machine) for 60 seconds before the displacement was measured. The load was removed for 60 seconds, and permanent compression set was measured. Then, the compression load was stepped up to the next level. Displacements and compression sets were measured at 11 load steps from 0.35 MPa to 10.35 MPa. A graphical representation of the test procedure is presented in Figure 1. The μ-P-v-T tests were run at four temperatures. At each temperature the speed and pressure were increased simultaneously in four steps as presented in Table 1. The durability tests were carried out in a SAE No.2 Test Machine with two friction plates

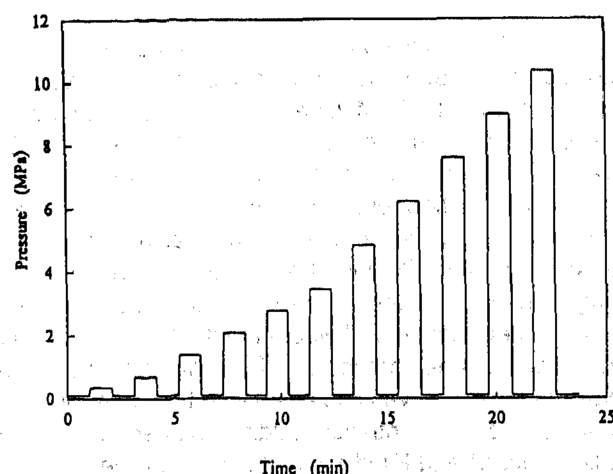

Figure 1. Static-stepwise-compression test procedure

Table 1. μ-P-v-T test procedure for SAE No. 2 Test Machine. The following procedure is repeated at 30°C, 80°C, 100°C and 120°C. There are 3 friction plates and 4 separator plates in a clutch pack Friction plate lining dimensions are OD/ID (mm): 126/106.

Level	Rpm	Pressure (kPa)	Inertia (Nms^2)	Energy (J)	Number of cycles
A	800	190	0.348	1220	50
B	1400	380	0.348	3750	25
C	2600	760	0.348	12900	25
D	3600	1140	0.348	24800	25

and three separator plates and with 1 liter of ATF. The inner and outer diameters of friction plates were 104 mm and 126 mm respectively. The absorbed energy was 36946 J and the energy density was 1.66 W/mm^2 at each engagement cycle. Thirty ml of oil sample was collected at 500 cycles, and the rest of the oil was collected at the end of the durability tests for chemical analyses.

The thermo-oxidative stability of pure ATFs and ATFs mixed with various resins was studied with an in-house developed test. The resins were cured and ground before the catalytic thermal oxidation tests. One part of resin was mixed with two parts of ATF, by weight. Then, the mixture was heated up to 150°C and held at that temperature for 300 hours. A constant air flow of 3 l/min was supplied to the mixture through a capillary tube. The mixture was continuously stirred during the heat tests. ATF was separated from resin by filtering, solvent washing, and oven drying after the thermo-oxidation tests. The residual ATF and resin were analyzed by FTIR and TG.

RESULTS

ANALYSES OF THE MINERAL AND THE PARTIAL-SYNTHETIC FLUIDS - The physical and elemental properties of Fluid-M and Fluid-PS are listed in Table 2. The viscosity characteristics of the fluids are quite different. Fluid-PS has a higher viscosity index and a high-temperature-high-shear viscosity than Fluid-M. The elemental analysis showed significant differences in the additive packages of the fluids. Fluid-PS has more phosphorus but less boron and sulfur than Fluid-M. Fluid-M has a high concentration of calcium and sulfur. Since alkylsulfonates are frequently added into oils as detergent additive, Fluid-M probably contains calcium sulfonate which commonly acts as a buffer. The total base number (TBN) of Fluid-M is significantly higher than the TBN of Fluid-PS supporting the presence of an overbased-calcium sulfonate in Fluid-M (Table 2). Fluid-PS does not have any calcium and has a lower concentration of sulfur. Phosphorus-, sulfur-, and boron-containing additives are frequently added to oils as anti-wear additives. Both fluids have a very small amount of silicon (5-6 ppm). Silicon-containing additives are added as anti-foaming agents. Fatty acids are added into oils as

friction modifiers. The amount of fatty acids in the fluids was determined according to the modified Twitchell method, which is described in Reference 4. The carboxylic acid concentrations are 2.8% and 2.7% in Fluid-M and Fluid-PS respectively. At this moment, it is not known whether there were other kinds of friction modifiers in the fluids.

GPC analysis showed that Fluid-M is a hydrocarbon based fluid with a broad Molecular Weight Distribution (MWD) centered at 483 dalton (Figure 2). On the other hand, Fluid-PS is a blend of a narrow MWD and a broad MWD base stock (Figure 3). The narrow and broad MWDs are characteristic of synthetic and mineral base oils, respectively. The synthetic base stock has two narrow bands: an intense peak centered at 600 dalton, and a small peak centered at 770 dalton. The synthetic base of the Fluid-PS was identified as polyalphaolefin by

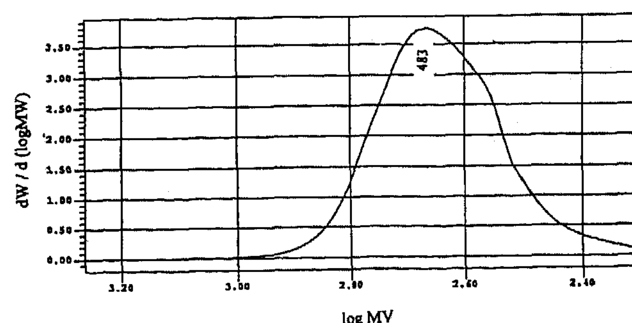

Figure 2. Molecular weight distribution of Fluid-M by GPC.

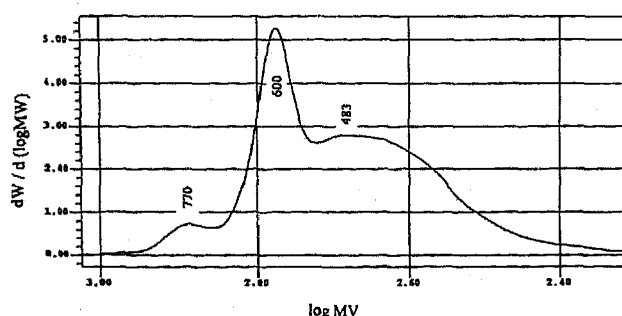

Figure 3. Molecular weight distribution of Fluid-PS by GPC.

GC and quantified as 20.4% decene dimer and 2% decene trimer in the entire fluid. Probably 600 and 770 dalton peaks in the GPC chromatogram correspond to decene dimer and decene trimer, respectively. GPC chromatograms have also indicated that both fluids have a high molecular weight and a medium molecular weight polymer which are probably the viscosity index improver and the dispersant, respectively. The molecular weight of the heavier polymer is about 42000 in Fluid-PS and 165000 in Fluid-M. The molecular weight of the dispersant is about 5000 in both fluids. The polymer fractions which were eluted from the GPC columns were deposited on a Germanium disk and analyzed by FTIR. The VI improver in Fluid-PS has a very similar spectrum to that of polyhexadecylmethacrylate. Since the VI improver amount in Fluid-M was quite small, the signal-to-noise ratio of the infrared spectrum of the fractionate was not very good. Nevertheless, FTIR spectrum of VI improver of Fluid-M showed peaks at 1730 cm^{-1}, 1467 cm^{-1}, 1451 cm^{-1}, 1221 cm^{-1} and 1161 cm^{-1} which corresponded to polyalkylacrylates or polyalkylmethacrylates. Carbon NMR spectrum of Fluid-M suggested that VI improver on Fluid-M is probably a polyalkylacrylate. The FTIR spectrum of the 5000 molecular weight polymer matched that of the polyisobutylene esters, which are added to ATFs as dispersants. Carbon NMR confirmed the presence of polyisobutylene structure in both fluids in equal amounts.

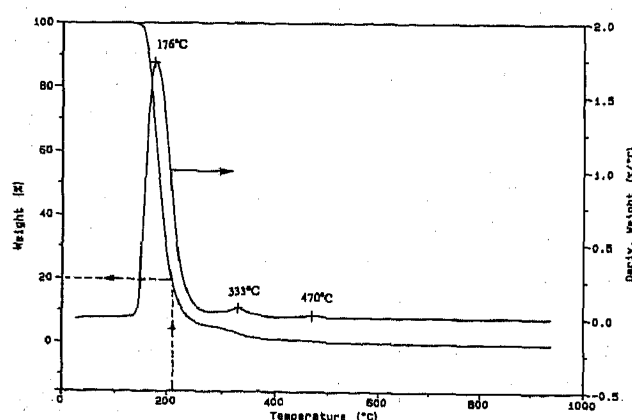

Figure 4. TG graph of Fluid-M.

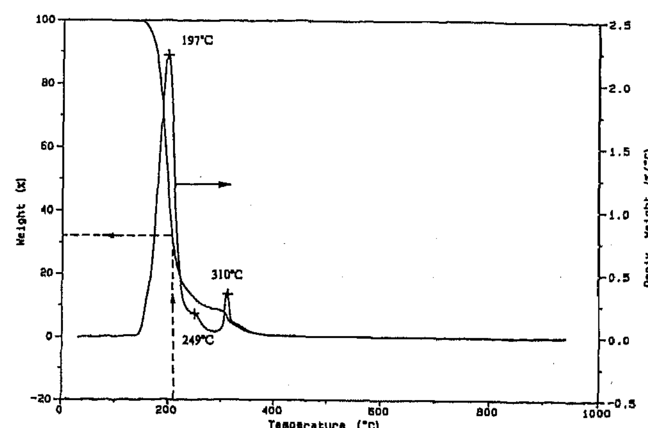

Figure 5. TG graph of Fluid-PS.

The interfacial temperatures between the separator plate and friction plate during a clutch engagement can reach several hundred degrees centigrade (5). The applied pressure in a wet clutch is on the order of a few MPa which is not high enough to prevent ATF from evaporation, hence, during each engagement, some portion of ATF evaporates readily. Therefore, it is very important to know the temperature-weight loss characteristics of an ATF, in order to understand its wet clutch performance. High resolution TG analysis of Fluid-M and Fluid-PS indicated major differences in the weight loss versus temperature characteristics of the fluids. TG derivative curves, shown in Figures 4 and 5 for Fluid-M and Fluid-PS, respectively, indicate that the peak temperature of the weight loss curve of Fluid-PS is higher than that of Fluid-M. However, Fluid-PS has a narrower and less homogeneous weight loss distribution than Fluid-M. The TG derivative curve of Fluid-PS skewed towards high temperature with a peak located at 197°C. The peak width at half the height of the peak of Fluid-PS, ranges from 177°C to 210°C, whereas, that of Fluid-M ranges from 155°C to 210°C with a peak located at 176°C. This indicates that during a clutch engagement, Fluid-PS will remain liquid longer than the Fluid-M at the interface. However, the rate of evaporation (% weight loss per degree centigrade) of Fluid-PS will be approximately twice as high as that of Fluid-M in the temperature range of 180°C and 210°C.

The TG curve of Fluid-PS has a shoulder centered at 249°C. The shoulder is probably due to that part of the synthetic base oil, which has a narrow molecular weight distribution centered at 770 molecular weight, as shown in Figure 3. High resolution TG also showed that Fluid-PS has about 9% VI improver, which was lost in a narrow temperature range centered at 310°C. Fluid-M has about 3% VI improver, which evaporates and/or degrades in a broader temperature range centered at 333°C. Furthermore, Fluid-M contains 1% of an additive which is lost at 470°C. This may be an inorganic material such as calcium sulfonate. Fluid-PS does not have this additive.

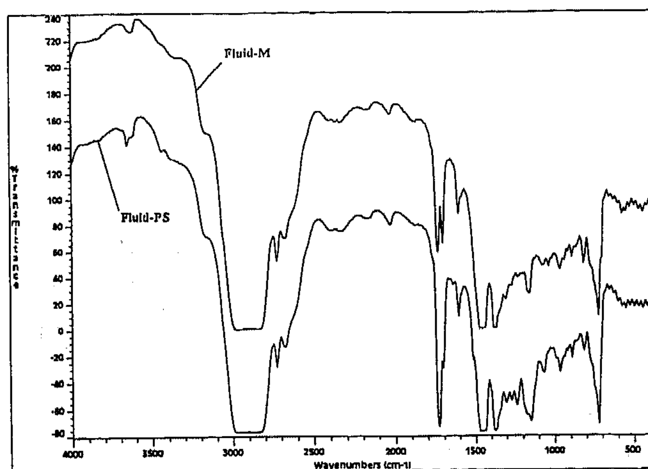

Figure 6. FTIR spectra of Fluid-M and Fluid-PS.

The composition of the residual fluids at 210°C of TG tests gives an idea about the homogeneity of the residual fluids. Here, homogeneous means "composed of the same kind or nature." There remains 20% of Fluid-M, and 26% of Fluid-PS as residuals at 210°C. The derivative weight loss curves suggest that the VI improvers (333°C and 310°C bands) and the inorganic additive (470°C band) will remain in the liquid phase at 210°C (Figures 4 and 5). The residual Fluid-M at 210°C consists of 15% VI improver, 4% inorganic additive, and 81% base oil and other additives. On the other hand, the residual Fluid-PS at 210°C is less homogeneous: 35% VI improver, and the rest are mineral base oil, synthetic base (decene dimer and decene trimer) plus other additives. Obviously, the residual of Fluid-M is more homogeneous than the residual of Fluid-PS at 210 °C.

FTIR analysis of Fluid-M and Fluid-PS indicated that Fluid-PS has a much stronger peak at 1740 cm^{-1} than Fluid-M (Figure 6). Moreover, Fluid-PS had stronger peaks from 1000 cm^{-1} to 1300 cm^{-1} than Fluid-M. The peak of 1740 cm^{-1} corresponds to the carbonyl vibrations of an ester. Esters are frequently used to improve additive solubility and/or elastomer compatibility. Ester linkages can also be found in VI improvers and dispersants. The FTIR finding is consistent with the GPC and TG data in that Fluid-PS has considerably more VI improver than Fluid-M. Furthermore, Fluid-PS has a sharp peak at 3650 cm^{-1}, unlike Fluid-M. Presence of a 3650 cm^{-1} peak in Fluid-PS indicates there is a hindered phenol-type antioxidant in Fluid-PS, which was also confirmed by Carbon NMR.

Four-Ball-Wear Tests showed that the friction and wear of sliding steel balls were reduced considerably in Fluid-PS, as compared to Fluid-M. The additives of phosphorus and boron chemistry are blended into automatic transmission fluids to reduce wear in metal-to-metal contacts. The concept of boundary lubrication suggests that the anti-wear additives function by forming protective surface films over the sliding surfaces to

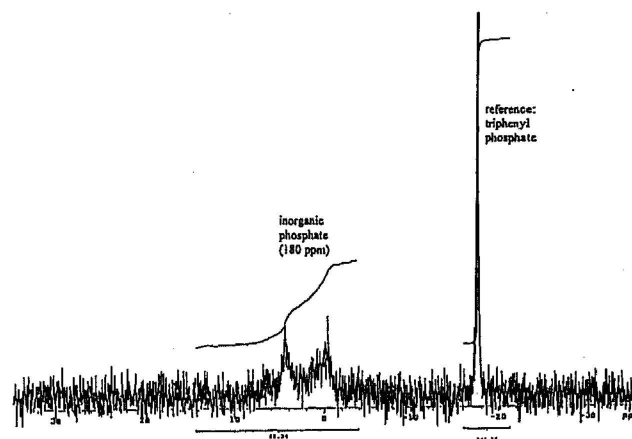

Figure 7. ^{31}P-NMR spectrum of Fluid-PS.

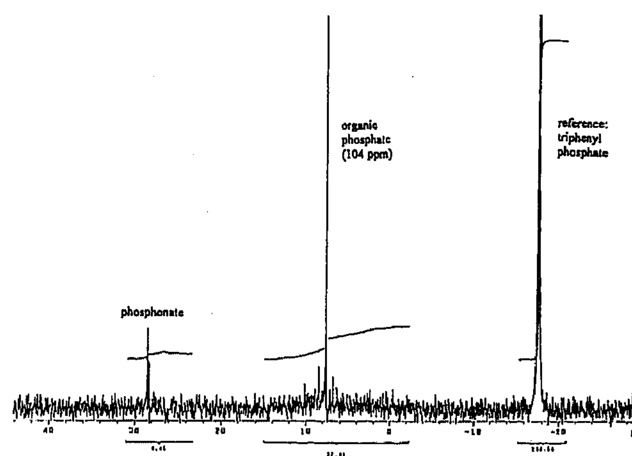

Figure 8. ^{31}P-NMR spectrum of Fluid-M

reduce wear (6,7). The chemistry of phosphorus anti-wear additive affects the durability of protective films. Phosphorus NMR analysis of the fluids yielded that Fluid-PS has an inorganic phosphate (Figure 7), whereas, Fluid-M has both organic phosphate and phosphonate (Figure 8), as anti-wear additives. The fluid samples were spiked with triphenylphosphate to quantify the phosphorus concentrations in the fluids. The phosphorus concentrations of the fluids measured by NMR, 104 ppm and 180 ppm for Fluid-M and Fluid-PS, respectively, match the ones obtained by ICP analysis (Table 2).

THERMAL OXIDATION TESTS OF THE MINERAL AND THE PARTIAL-SYNTHETIC FLUIDS - Thermal oxidation tests showed that Fluid-PS and Fluid-M follow different oxidation paths. The FTIR spectra of the fresh fluids were subtracted from those of the tested fluids to observe the changes that occurred in the fluids during the thermal oxidation tests. Figures 9 and 10, the subtraction spectra of Fluid-M and Fluid-PS, show the presence of three carbonyl groups: 1691 cm^{-1}, 1726 cm^{-1}, and 1782 cm^{-1} bands. The thermal oxidation products of a mineral base oil were identified as ketone, acid (1695 cm^{-1}), ester (1734 cm^{-1}), and diester (1778 cm^{-1}) according to Figure 8 of Reference 8. The small

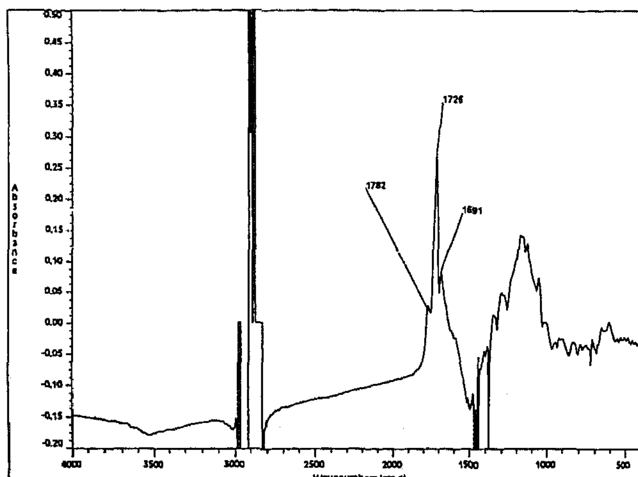

Figure 9. FTIR subtraction spectrum: (Fluid-M after thermal oxidation test) - (Fresh Fluid-M).

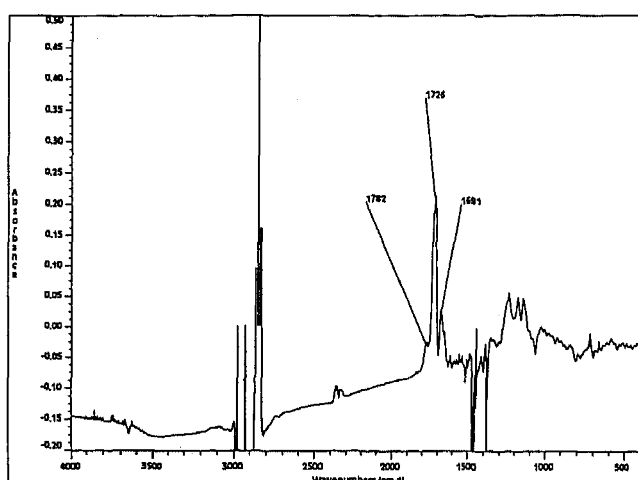

Figure 10. FTIR subtraction spectrum: (Fluid-PS after thermal oxidation test) - (Fresh Fluid-PS).

shifts (4 to 8 cm^{-1}) in peak locations between this study and Reference 8 is negligible, and may be due to the instrumentational differences between the laboratories, and the compositional differences between the fluids (formulated fluids versus base oil). During the thermal oxidation tests, both Fluid-PS and Fluid-M formed acid, ketone and ester products (1691 cm^{-1} and 1726 cm^{-1} bands). However, Fluid-M formed more diester (1782 cm^{-1}) than Fluid-PS did. In catalytic thermal oxidation tests, various commonly used wet clutch resin chemistries such as phenolic, modified phenolic, and silicon resins were added into the fluids to see the effects of various resins on the degradation of the fluids. As an example, Figures 11 and 12 show the effect of phenolic resin on the carbonyl group formation in Fluid-M and Fluid-PS. As compared with Figures 9 and 10, the diester peak intensity in Fluid-M and acid, ketone, ester peak intensities in Fluid-PS increased when the fluids were tested in the presence of the resin. The diester formation in Fluid-M and the acid, ketone, ester formation in Fluid-

PS were increased more or less by any kind of resin tested.

MECHANICAL TESTS IN THE MINERAL AND THE PARTIAL-SYNTHETIC FLUIDS - Eight different friction materials were compression tested in Fluid-M and Fluid-PS. Figure 13 shows the static compression-displacement and permanent compression set behavior of a friction material in Fluid-M. The curve on the right is the displacement under 60 seconds of compression and the curve on the left is the permanent-compression-set measured 60 seconds after the load is reduced to 100 kPa. Figure 14 shows the compression curves of the same material in Fluid-PS. The slope of a compression-displacement curve is defined as the compression modulus. Due to the nonlinear shape of the compression-displacement curves of the friction materials, it is more suitable to define two compression moduli: one for the low pressure region, from 0 to 2 MPa,

and one for the high pressure region from 2 MPa to 10.4 MPa. The compression moduli data presented in Table 3 indicate that, in general, friction materials showed higher rigidity in Fluid-PS than in Fluid-M. The low and high pressure moduli were increased 14.2% and 7.4%, respectively, in Fluid-PS as compared to Fluid-M for all the materials tested. The compression set was also affected by the kind of fluid. In general, friction materials showed less compression set in Fluid-PS than in Fluid-M.

Friction materials with a range of compressibility characteristics were tested for μ-P-v-T characteristics in a SAE No.2 Test Machine. Low and high temperature frictional torque curves for two fluids and two of eight friction materials tested, are shown in Figures 15 and 16. Torque curves of Friction Materials #1 and #8 represent compressible and rigid friction materials, respectively. Each curve was of the last cycle of level C in the μ-P-v-T test procedure (Table 1). The other levels of the test procedure showed similar trends. At level C, the speed of sliding decreased from 2600 rpm to 0 rpm in about 1 second during an engagement, with an applied pressure of 760 kPa. For a smooth engagement, descending torque curve shape with descending speed is desirable. The ascending torque curve shape towards the end of an engagement is commonly referred to as a rooster tail effect. When the coefficient of friction increases with decreasing speed, stick-slip conditions occur between friction plates and separator plates, which may result in vibrational shudder. Hence, the rooster tail effect is not desirable. In μ-P-v-T tests, Fluid-M and Fluid-PS had similar torque curve shapes at low temperatures: a flat or slightly descending initial torque shape with a slight

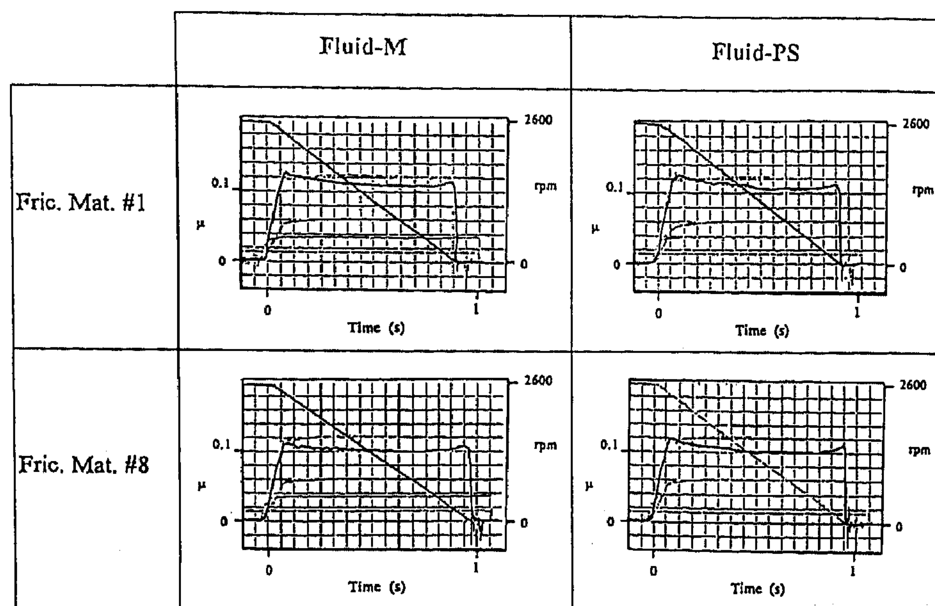

Figure 15. Torque curves of a compressible material (Fric. Mat. #1) and a rigid material (Fric. Mat. #8) in Fluid-M and Fluid-PS at 30°C.

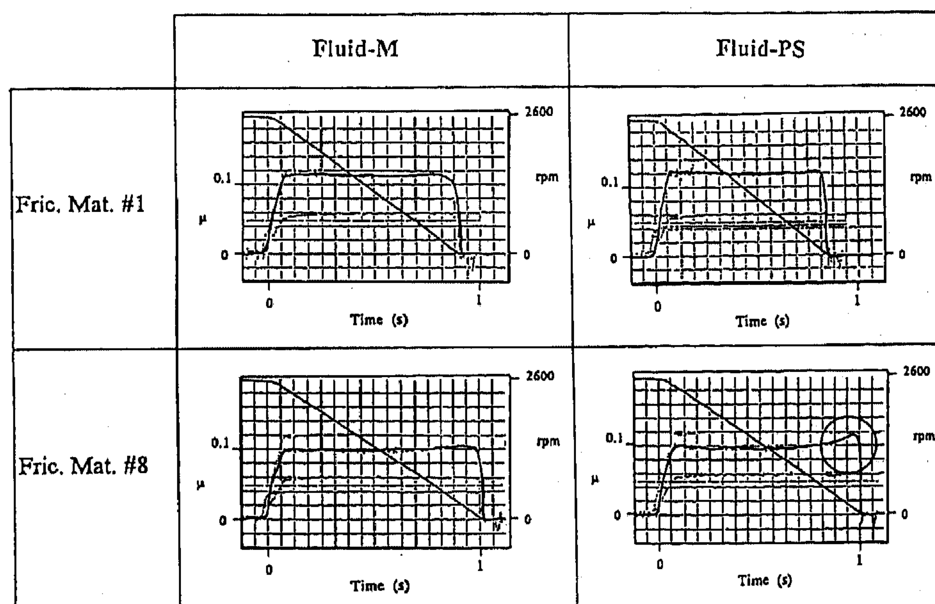

Figure 16. Torque curves of a compressible material (Fric. Mat. #1) and a rigid material (Fric. Mat. #8) in Fluid-M and Fluid-PS at 120°C. The rooster tail effect in Fluid-PS is circled.

rooster tail near the end of engagement (Figure 15). At high temperatures such as 120°C, however, Fluid-PS caused large rooster-tails especially with rigid friction materials such as Fric. Mat. #8, while Fluid-M caused small or no rooster tails (Figure 16). The least negative μ–v relationship (i.e., the smallest rooster tail) in Fluid-PS was obtained with a low modulus (i.e. highly compressible) friction material such as Fric. Mat. #1. The low modulus materials such as Fric. Mat. #1, generated higher friction coefficients than the high modulus materials such as Fric. Mat. #8, in both fluids. High friction coefficients during a clutch engagement are desirable because high coefficients provide high torque transmission capability.

Friction materials with various degrees of compressibility were tested for high-energy-high-pressure durability in Fluid-M and Fluid-PS in an SAE No.2 Test Machine. The durability test conditions are summarized in Table 4. The applied pressure on the friction plates was 1295 kPa. The failure criterion was a 2 mm displacement of the pressure apply piston. At least ten different friction material compositions were subjected to durability tests in both fluids. The number of

Number of cycles	5100, or to failure

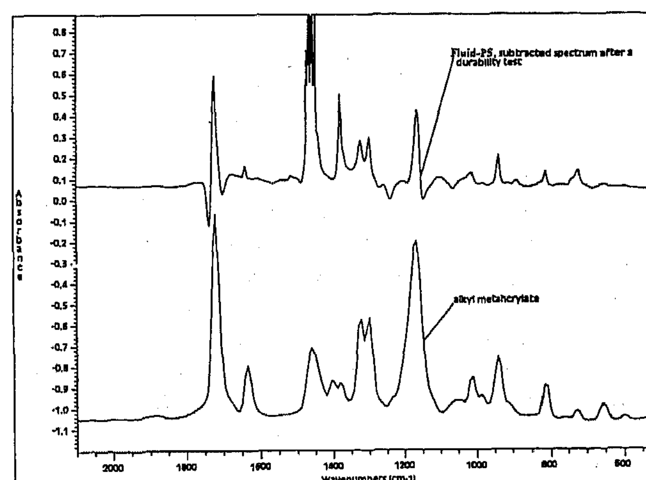

Figure 19. The differential infrared spectrum of a residual Fluid-PS matches the infrared spectrum of an alkylmethacrylate.

cycles to failure ranged from 300 to 5100 depending on the friction material-fluid combinations. Since the number of cycles to failure depends on the friction material-ATF combination, fluid samples were not only collected at the end, but also at 500 cycles of each durability test, in order to do a one-to-one comparison of the fluid degradation. In general, the friction materials with higher compressibility lasted longer in durability tests in both fluids. Another important observation was that each fluid showed different but consistent degradation characteristics, regardless of the type of friction material used in the durability tests. As examples of the fluid degradation characteristics, Figures 17 and 18 show the differential FTIR spectra of Fluid-M and Fluid-PS after the durability testing. An unspecified commercial material used in the tests shown in Figures 17 and 18 lasted to comparable cycles in both fluids: 4200 cycles in Fluid-M and 3700 cycles in Fluid-PS. The subtraction spectra between the tested and fresh fluids indicated that the degradation of Fluid-M is negligible during the SAE tests, however the degradation increases with the number of engagement cycles as evidenced in differential FTIR spectra between 500 cycles and 4200 cycles in Figure 17. The subtraction spectra of tested Fluid-PS indicated an increase in the intensity of peaks located at 1730 cm^{-1}, 1647 cm^{-1}, 1300 cm^{-1}, 1172 cm^{-1}, 1020 cm^{-1}, 944 cm^{-1}, 893 cm^{-1} and 817 cm^{-1} (Figure 18). A library search on these bands resulted in a 85% goodness of fit with the bands of polyalkylmethacrylates (PAMA) which is the VI improver additive (Figure 19). The GPC chromatogram of the tested fluids showed that the VI improver molecules in Fluid-PS were considerably fragmented during the durability tests. Some fragments may oxidize. The fragmentation of the PAMA molecules followed by an oxidation of some of the fragments causes a small shift in the infrared peak locations and results in incomplete subtraction of PAMA peaks in the differential FTIR spectrum of Fluid-PS. The fragmentation of PAMA molecules increased with the increasing number of

engagements in Fluid-PS (Figure 18). Since the fragmentation of VI improver happened with any kind of friction material tested, the cause of fragmentation was physical, namely the mechanical shear rather than a chemical effect. Since the VI improver concentration is considerably higher in Fluid-PS than in Fluid-M, the fragmentation of VI improver was more significant in Fluid-PS than in Fluid-M.

DISCUSSION

The majority of wet clutch friction materials used in automotive applications today is polymeric composite materials saturated with thermosetting resins. Polymeric friction materials are developed with a fundamental understanding of material-friction characteristics and basic ATF-friction material interactions. In order to compare the wet clutch performance of a mineral-based ATF and a partial-synthetic-based ATF, some important characteristics of the fluids were first identified. Then, the fluids were subjected to a series of mechanical tests with various kinds of friction materials. The following paragraphs discuss the important performance differences between Fluid-M and Fluid-PS.

Fluid-PS has higher viscosity index and high-temperature-high-shear viscosity than Fluid-M. Fluid-PS also has much lower viscosity at sub-zero temperatures. High fluidity at low temperatures reduces drag loss in disengaged clutches at sub-zero temperatures, hence, contributing to fuel economy. A high concentration of VI improver, in addition to the 22.4% synthetic base fluid, is responsible for the superior viscosity characteristics of Fluid-PS. Superior viscosity characteristics contribute to a low level of metal-to-metal wear because a high viscosity index and high shear viscosity provide better fluid film formation capabilities for an extended range of temperatures in elastohydrodynamic conditions. When the sliding surfaces can not be separated by a lubricant film due to severe operating conditions such as low speed, high pressure, and high temperature, the asperity interaction is inevitable. When there is appreciable asperity contact, as in the case of the 4-Ball tests, the anti-wear additives react with the exposed nascent metal surfaces and form protective surface films. The protective ability of surface films formed from a phosphate-type anti-wear additive in a boundary lubrication regime, was documented earlier (6,8). Less metallic wear in Fluid-PS as compared to Fluid-M may be an indication of the relative effectiveness of phosphate and phosphonate type antiwear additives, which are used in Fluid-PS and Fluid-M respectively.

High concentrations of calcium and sulfur in Fluid-M suggest that there is probably calcium sulfonate in Fluid-M, added as a detergent. Having a basic character, calcium sulfonate also acts as a buffer against increasing the acidity of degrading oil. Furthermore, it follows from the thermal oxidation tests that in the presence of calcium sulfonate, there is a tendency to polymerize the degradation products to diester and to form sludge. The polymerization and sludge formation is not desirable because they may plug the pores of the friction material. Other evidence showed that SO_3 may form from metal sulfonates upon degradation, and be adsorbed on the sliding surfaces, thereby, reducing coefficient of friction (9). On the other hand, the formation of ketones, acids and esters in Fluid-PS may affect the fiber-resin bond strength in friction materials in the long term. The long-term effects of fluid's degradation products need further investigation. Fragmentation of polyalkylmethacrylate molecules in Fluid-PS is not desirable. The fragmentation of VI improver not only changes the fluid's viscosity characteristics but may also cause formation of alkylmethacrylate free radicals, which help to initiate degradation of the fluid. Furthermore, if the alkyl methacrylate fragments oxidize, they may no longer be chemically inert, but interact with the friction material and with the additives of the fluid.

It is the compressibility of a wet clutch system which helps absorb vibrations and allow weeping of ATF through pores during engagements. A wet clutch system with Fluid-PS behaves more rigidly than a system with Fluid-M. One explanation for this behavior lies both with the branched structure of the polyalphaolefin molecules, and with the differences in concentration and molecular weight of the VI improvers of Fluid-PS and Fluid-M. It was reported that the VI improver molecules may orient themselves under pressure if the molecules are longer than a threshold value. The onset of molecular orientation lies in the range of 10000 to 100000 dalton for most fluids (10). Having long molecular chains heavier than 100000 dalton, the VI improver molecules of Fluid-M may reversibly orient themselves under pressure, thereby, contributing to the compressibility of the friction material-ATF system. On the other hand, having a large amount of shorter chain molecules, the VI improver of the Fluid-PS shows stronger resistance to orientation under pressure, hence, increasing the rigidity of the system. Furthermore, it will often be more difficult for the branched PAO molecules of the partial-synthetic fluid to get in and out of the pores of the friction material than for the linear molecules of the mineral fluid. The fluid penetration becomes more difficult when there is a large concentration of VI improver in the fluid, than when there is not. At this moment, it is not known whether the rigidity is also affected by the rest of the additives of the fluid or not.

The torque curve shape in an engagement is affected by the type of base oil/VI improver combination, and/or by the type and ratios of friction modifier, dispersant, detergent, and anti-wear additives. Since the type and ratio of dispersant additive present in the Fluid-M and Fluid-PS are very similar, the cause of undesirable torque curve shape with Fluid-PS at high temperatures, can be explained by the narrow molecular weight distribution of the partial-synthetic base oil, higher concentration of VI improver, absence of calcium

sulfonate detergent additive, presence of inorganic phosphate additive and type of friction modifier which is not known. During an engagement, the interfacial temperatures easily reach several hundred degrees centigrade. Furthermore, the interfacial temperatures keep increasing from the start of the engagement to the end of engagement. Remember that the rate of evaporation of Fluid-PS is twice as high as that of Fluid-M in the temperature range of 180°C and 210 °C. The rapid evaporation of partial-synthetic base oil with increasing interfacial temperature leaves behind a highly inhomogeneous, high molecular weight fluid, which may cause the higher friction near zero sliding speed. Secondly, Scanning Electron Microscope/Electron Diffraction X-ray analysis of the friction material surfaces indicated the presence of a considerable amount of Ca and S on the surfaces after durability tests in Fluid-M, but not in Fluid-PS. Furthermore, phosphorus concentration on friction material surfaces run in Fluid-PS, was slightly higher than that in Fluid-M. Obviously, the surface species adsorbed from the oil additives, which may affect the torque curve shapes, have a different composition in Fluid-M and in Fluid-PS. The reduction in rooster tail with a compressible friction material may be explained by the weeping of the cooler ATF from the pores of friction material to the interface under compression. Furthermore, a compressible material dampens the shudder effectively, resulting in a smaller rooster tail. The high rigidity in Fluid-PS can be accommodated by designing more compressible friction materials.

CONCLUSIONS

The interactions of a mineral-based ATF and a partial-synthetic based ATF with various kinds of friction materials, were investigated. Friction material/ATF systems showed marked performance differences in mechanical and thermal-oxidation tests. The compressibility and torque response curve were greatly affected by the type of fluid and the type of material. Partial-synthetic fluid has many superior characteristics over mineral fluid such as good metallic wear prevention, excellent low temperature fluidity, and high viscosity index. These superior characteristics were achieved by radically different molecular weight properties and the additive package of the partial-synthetic fluid from those of the commercial mineral-based ATF. Partial-synthetic fluid may increase the performance of those components of an automatic transmission which operate in the elastohydronamic lubrication regime. However, this study has shown that the partial synthetic fluid which also contains a high concentration of VI improver and a detergent-free additive chemistry, requires a careful selection of friction material for wet clutch applications. The major findings of this study are:

1. The partial-synthetic fluid caused less friction and wear than mineral fluid did in a lubrication regime where there is appreciable metal-to-metal contacts because of its superior viscometrics and anti-wear additive characteristics.

2. The viscosity index improver molecules of the partial-synthetic fluid were fragmented during the wet clutch engagements. The thermal oxidation tests indicated acid, ketone, and ester formation in both fluids. However, in Fluid-M the degradation products polymerize to diester or polyester. The different degradation paths of the Fluid-M and Fluid-PS have different implications on the wet clutch performance.

3. Friction materials showed higher rigidity in the partial-synthetic fluid than in the mineral fluid in compression tests. The high rigidity may be caused by the branched structure of the synthetic molecules, a high concentration of VI improver, and the detergent-free additive chemistry of the partial-synthetic fluid.

4. The partial-synthetic fluid caused a much more negative friction-speed relationship near the end of an engagement (the rooster tail effect) than the mineral fluid did at high temperatures. The torque curve shape may be affected by both the detergent free-additive chemistry, and by the base oil/VI improver combination of the partial synthetic fluid. The rooster tail effect of partial-synthetic fluid was reduced considerably with a compressible friction material.

ABSTRACT

Friction performance of paper-based materials for wet clutches in automotive automatic transmissions is influenced by the entire structure of the material, which is characterized by a combination of porosity and visco-elasticity. In the clutch plate engagement process, the coefficient of friction is higher when the porosity of the material is higher.

In this paper, visco-elasticity of the material was measured by a testing apparatus which was originally designed and built. It has become clear that the compressive visco-elastic deformation increases as the porosity becomes higher.

The relationship between the compressive visco-elastic deformation of the material and the friction torque curve of the clutch plate was also analyzed. It was found that the friction torque curve of a clutch plate is influenced by the visco-elasticity of the material as well as the porosity.

1. Introduction

The friction characteristics and thermal resistance of paper-based wet friction materials are influenced by the material structure formed as a result of the combination of porosity and visco-elasticity (resiliency).

In three previous papers (1), (2), (3) by the author, the effects of porosity on the frictional performance and the thermal resistance were characterized by Stribeck Diagrams based on continuous sliding test data, and were also discussed with reference to torque curves and temperature measurements by an SAE No. 2 friction testing machine. The effects of porosity on the thermal durability of paper-based friction materials were also studied, by discussing material durability in terms of mechanical and physical property changes of the material.

In this study, the effects of visco-elasticity (resiliency) on the friction characteristics of paper-based friction materials were studied. The relationship between the compressive visco-elastic deformation of a paper-based friction material and the friction torque curve of a clutch plate from the initial to the final stage of the engagement process was analyzed.

2. Concept of Visco-Elasticity in the Engagement Process of a Wet Clutch

The entire structure of a paper-based friction material, which is characterized by a combination of porosity and visco-elasticity, has a strong influence on the tribological property existing between the sliding surfaces of the friction material and the mating steel plate. Visco-elasticity and porosity are considered to be the two important factors that control the friction performance of the material. Fig. 1 shows the concept of visco-elasticity and porosity of a paper-based friction material. Assuming that the figure shows the section of a clutch plate, the porous material

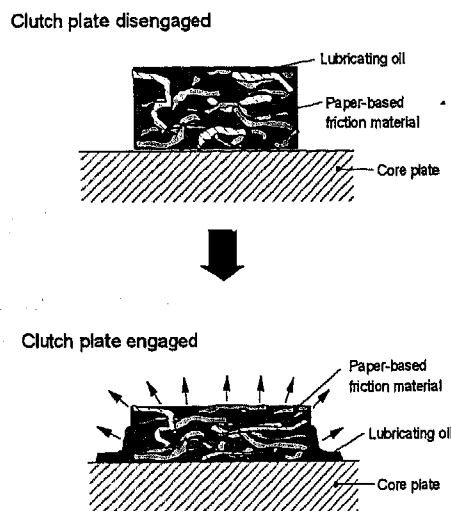

Fig. 1 Concept of Visco-Elasticity and Porosity

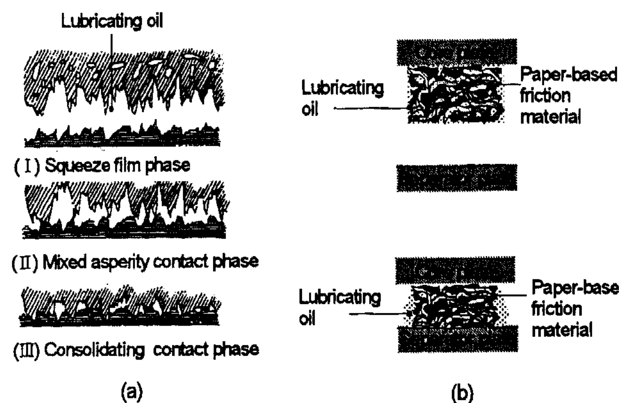

Fig. 2 Concept of Engagement Model

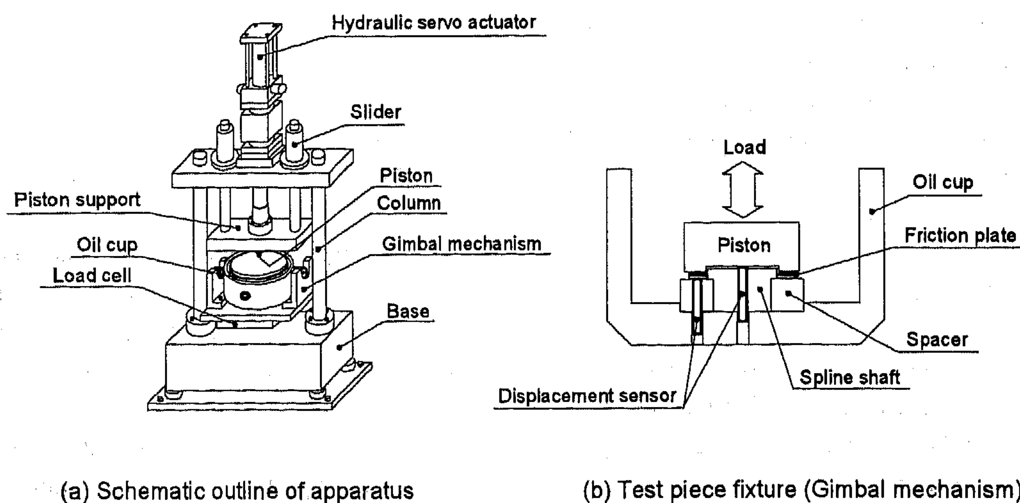
is filled with lubricating oil, when a clutch plate is disengaged. When a clutch plate is engaged, the porous material is visco-elastically deflected (compressive deformation), and the lubricating oil is squeezed out of the material.

The behavior of the lubrication in the engagement process of a wet clutch and a wet brake is considered to be divided into three phases, that is, squeeze film phase, mixed asperity contact phase and consolidating contact phase, as shown in Fig. 2 (a) (4), (5). The porous material becomes filled with lubricating oil, when the clutch is disengaged. When the clutch is engaged, the porous material becomes visco-elastically deflected, and the lubricating oil is squeezed out of the porous material, as shown in Fig. 2 (b).

3. Experiment

3.1 Measuring Apparatus of Compressive Visco-Elastic Deformation

In order to investigate the visco-elastic behavior at the surface of paper-based friction materials during a practical clutch plate engagement, a special measuring apparatus was designed and built, as shown in Fig. 3. Fig 3 (a) shows the schematic outline of the apparatus. The test piece is installed on the spline of the oil cup. The piston and the test piece, which is bonded a paper-based friction material, can



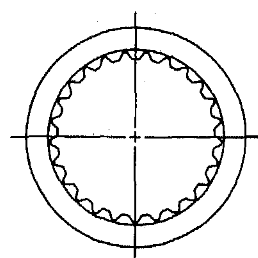


Fig. 3 Measuring Apparatus of Compressive Visco-Elastic Deformation

be made to fully contact each other by a Gimbal mechanism without any unbalance, as shown in Fig. 3 (b). The test piece is a practical clutch plate as shown in Fig. 4. It is a bonded paper-based friction material on one side only. The load is applied by hydraulic servo actuator, and is measured by a load cell equipped under the Gimbal mechanism. Compressive visco-elastic deformation is measured by displacement sensors installed in the oil cup.

In order to eliminate the influence of core plate flatness on the deformation measurement, the displacements between core plate and spacer are measured at and averaged from three places on the circumference of the plate.

The entire deformation is measured by the displacement sensor located at the center of piston. The deformation of a paper-based friction material is computed by subtracting the displacement between core plate and spacer from the entire deformation.

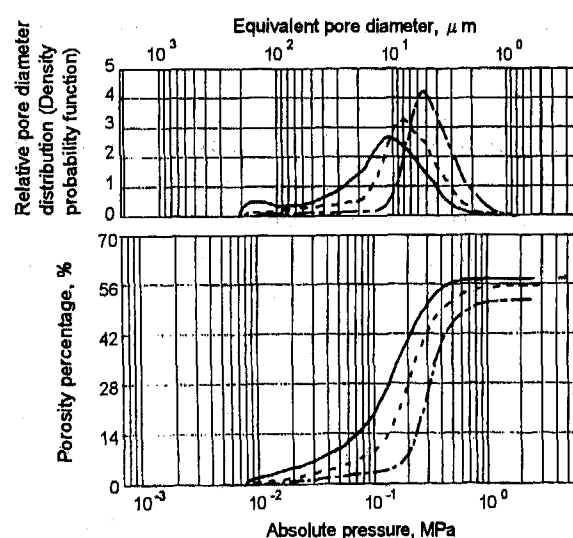
3.2 Relationship between Porosity and Compressive Visco-Elastic Deformation



As for the test results based on friction torque curves obtained by an SAE No. 2 friction testing machine using the sample paper-based friction materials (whose porosities were varied), it was found that the coefficient of friction is higher when the porosity of a material is higher (1), (2), (3).

In order to vary only the porosity while keeping the ingredients almost constant in the paper-based friction material, the fibers of the sample materials were supplied with different degrees of fibrillation treatment. Fibrillation is a refining process used in manufacturing paper that makes fibers fluffy. Fig. 5 (a) shows a picture of fluffed fibers (fibrillation) and unfluffed fibers.

The porosities measurement results of materials with the same ingredients are shown in Fig. 5 (b). The pore diameter, pore diameter distribution and porosity percentage were measured by a mercury intrusion porosimetry method (6). Using the porosimeter, mercury penetrates the lining piece as the pressure is increased. As the volume of penetrated mercury is directly read, porosity percentage at each pressure can be continuously plotted, if the volume of a sample is known. The lower graph in Fig. 5 (b) shows the relationship between porosity percentage and absolute pressure (MPa). The upper graph in Fig. 5 (b) is the derivative curve of the lower graph, from which the equivalent pore diameter (μm) and the

(a) Structure of material

(b) Pore diameter and porosity

Fig. 5 Porosity Measurement Result of Sample Material

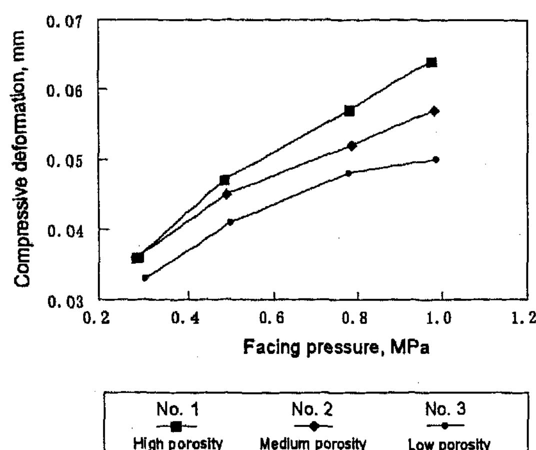


Fig. 6 Relationship between Facing Pressure and Compressive Deformation

relative pore diameter distribution can be determined. The pore diameter as well as the porosity percentage of sample material is arranged in a descending order: No. 1 > No. 2 > No. 3. The sample material No. 1, which received the lowest degree of fibrillation, has the highest porosity, and the sample material No. 3 with the highest degree of fibrillation has the lowest porosity. The fibers in raw papers have a tendency to be oriented to flow in the prescribed direction during the paper manufacturing process. However, the pore size distribution and the orthotropy of the material are not changed circumferentially, because the friction material is stamped out in a round shape from the raw paper sheet.

These sample materials No. 1, No. 2 and No. 3 were bonded to practical clutch plates to make the test pieces, as described in section 3.1. Compressive visco-elastic deformation of each sample material was measured while immersed in ATF (Dexron II Type) by the measuring apparatus shown in Fig. 3.

The relationship between facing pressure and compressive deformation for each sample material is shown in Fig. 6. It is presumed that the compressive deformation in Fig. 6 includes permanent (plastic) deformation, to some extent. However, since the facing pressure is not higher than 1.0 MPa, it can be said that the compressive deformation is mostly elastic. The compressive deformation of a paper-based friction material increases as the porosity of the material becomes higher. It is clear that increased deformation functions effectively to raise the coefficient of friction, which will be discussed later.

3.3 Experimental Procedure

The visco-elasticity of a paper-based friction material is dependent on the basic ingredients in the raw paper and the kind of resins. In order to vary the visco-elasticity while keeping the ingredients almost constant in a paper-based friction material, the sample materials were made by changing the compression rate during the clutch plate bonding process and by changing the volume percentage of resin. As the same kind of resin was used, the ingredients of the sample materials are identical. However, the ingredient percentage of the sample materials are different because the volume percentage of resin was varied.

Five kinds of sample materials, whose visco-elasticity are different, were made as shown in Table 1. As for the volume percentage of resin, Low (a) is about 15%, Medium (b) is about 30%, and High (c) is about 40%. Porosity was measured by a mercury intrusion porosimetry method. The average pore diameter of a porous body is determined by Eq. (1), using the data measured by a mercury intrusion porosimetry method (6).

$$D_{ave} = \frac{2V_{max}}{S_{max}} \quad (1)$$

where:

D_{ave} : Average Pore Diameter (μ m)

V_{max} : Total Micropore Volume (cm^3/g)

S_{max} : Total Micropore Specific Surface Area (m^2/g)

V_{max} is the total volume of the penetrated mercury, and S_{max} is the total specific surface area of the penetrated mercury.

The apparent density is determined by Eq. (2), and the real density is computed by Eq. (3).

$$\rho_a = \frac{W}{V} \quad (2)$$

where:

ρ_a : Apparent Density (g/cm^3)

W : Measured Sample Material Weight (g)

V : Measured Sample Material Volume (cm^3)

Table 1 Properties of Sample Materials

Compressive visco-elastic deformation of each sample material is measured by the method as described in section 3.1. Friction torque curve of each sample material is obtained by a modified SAE No. 2 friction testing machine, of which the schematic outline of the test piece fixture is shown in Fig. 7. Standard SAE No. 2 friction testing machine was modified so that the friction torque curve of the 70 mm outside diameter plate bonded a paper-based friction material on one side only, could be obtained. Therefore, the friction torque curve of the very plate, whose compressive visco-elastic deformation was measured, could be obtained by this modified SAE No. 2 friction testing machine. Test condition is shown in Table 2. Friction torque curve is measured after 200 engagement cycles.

Table 2 Test Condition by a Modified SAE No. 2 Friction Testing Machine

Rotating speed	2380 rpm

Oil temperature	100 ℃
Oil volume	0.0008 m^3 (0.8 L)
Total energy absorbed	0.6 kJ
Number of friction surface	1

4. Results and Discussion

4.1 Compressive Visco-Elastic Deformation

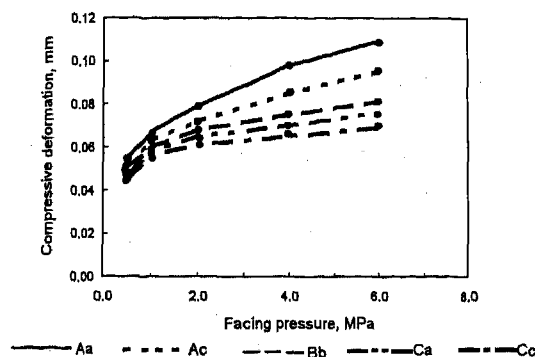
As described in section 3.2, three identical quality materials (identical ingredients, identical ingredient percentage, but with different porosities) were made, in order to study the influence of paper-based friction material porosity on the performance of a wet clutch (1), (2), (3).

As for the sample paper-based friction material whose porosities were varied, the relationship between compressive visco-elastic deformation and the facing pressure received is shown in Fig. 6. The data were obtained by the sample materials No. 1, No. 2 and No. 3 whose porosities are different. The porosity measurement result is shown in Fig. 5. It can be understood that the compressive deformation of a paper-based friction material increases as the porosity

of the material becomes higher.

Visco-elasticity of a paper-based friction material varies with porosity change. Porosity is a comprehensive term that includes three aspects: porosity percentage, pore diameter, and pore diameter distribution. At present, there is no known method to independently change the visco-elasticity of a paper-based friction material without either changing the porosity or the material composition.

Therefore, the sample materials whose properties are shown in Table 1, were made, by the method described in section 3.3, with a view to making the sample materials having different visco-elasticity property but retaining the porosity percentage approximately constant for Ac, Bb and Ca (but the pore diameters are different). Compressive visco-elastic deformation of those sample materials was measured while immersed in ATF (Dexron II type) by the measuring apparatus shown in Fig. 3. The relationship between facing pressure and compressive deformation for each sample material is shown in Fig. 8. By the use of two test pieces each, the compressive deformation was measured, changing the measurement position three times randomly in the circumferential direction. Finally, the average value of each set of six measurements was plotted.



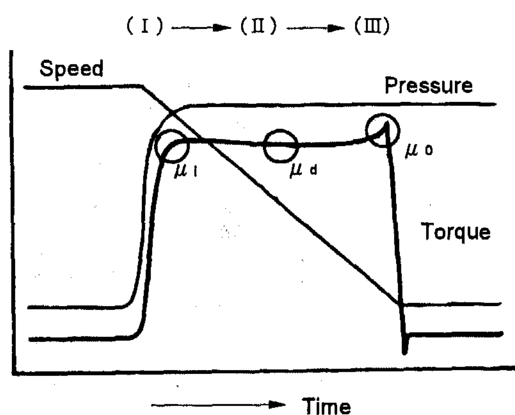


Fig. 8 Relationship between Facing Pressure and Compressive Deformation of Each Sample Material

The compressive visco-elastic deformation of the sample material is arranged in descending order: Aa > Ac > Bb > Ca > Cc. The compressive visco-elastic deformation is a function of density (Apparent density, Real density) and porosity (Pore diameter, Pore diameter distribution, Porosity percentage), provided the ingredients of the paper-based friction material are identical. A more detailed study, however, is necessary to clarify this relationship.

4.2 Friction Torque Curves

The behavior of the lubrication during the engagement process of a wet clutch and a wet brake is discussed based on the concept of three phases, that is, squeeze film phase, mixed asperity contact phase, and consolidating contact phase (4), (5). Moreover, when torque curves obtained by an SAE No. 2 friction testing machine are discussed, three modes of friction coefficient are used, namely, the coefficient of friction near the initial stage of the engagement process: μ_i, the coefficient of friction during sliding: μ_d, and the coefficient of friction in the final stage of the engagement process: μ_0, as shown in Fig. 9 (1), (2).

A comparison of torque curves due to porosity change (sample materials No. 1, No. 2 and No. 3) at the facing pressures of 0.5 MPa and 0.8 MPa is shown in Fig. 10. The sample friction plate is a non-grooved plate having splines on the inner diameter. The outside diameter, inside diameter and thickness of the facing are 127 mm, 102 mm and 0.5 mm, respectively. Test conditions are shown in Table 3. Coefficient of friction was measured after 200 engagement cycles. The coefficients of friction (μ_i and μ_d) are higher when the porosity (the porosity percentage and pore diameter) of a material is higher, and as a result, torque curves are held at higher levels. The same results were obtained at the facing pressures of 0.3 MPa and 1.0 MPa (1), (2). The higher porosity material removes the oil film more effectively in the sliding area where boundary lubrication and hydrodynamic lubrication exist at the same time (mixed-lubrication), and it increases boundary friction, thus resulting in a rise of the coefficient of friction (1), (2), (4), (5), (7), (8), (9).

μ_I : Initial dynamic coefficient of friction
μ_d : Medial dynamic coefficient of friction
μ_o : Final dynamic coefficient of friction

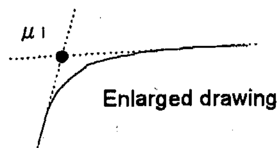

Fig. 9 Definition of μ_I, μ_d and μ_o

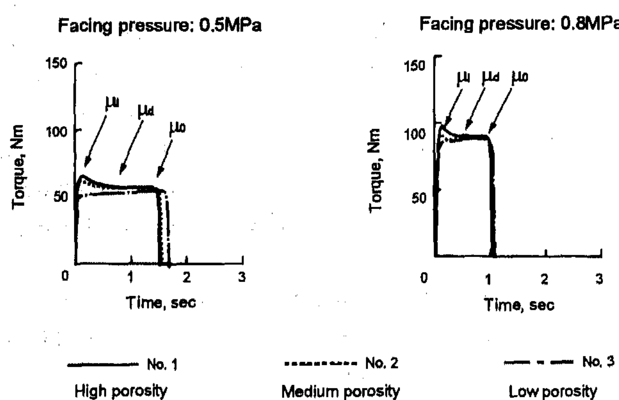

Fig. 10 Torque Curves of Friction Materials with Different Porosity

As described in section 3.2 and 4.1, the compressive visco-elastic deformation of a paper-based friction material increases as the porosity of the material becomes higher. It is clear that this deformation increase functions effectively so as to remove the oil film between the sliding surfaces.

When a wet clutch or a wet brake is engaged, a paper-based friction material actually receives a visco-elastic deformation in the shearing direction as

Table 3 Test Conditions

Tester	SAE No. 2 Friction testing machine
Rotating speed	3478 rpm
Inertia	0.245 kg · m^2
Facing pressure	0.5 MPa, 0.8 MPa
Lubricating oil	ATF (Dexron II Type)
Oil temperature	100 ℃
Oil volume	0.0007 m^3 (0.7 L)
Total energy absorbed	16.26 kJ
Number of friction surface	4

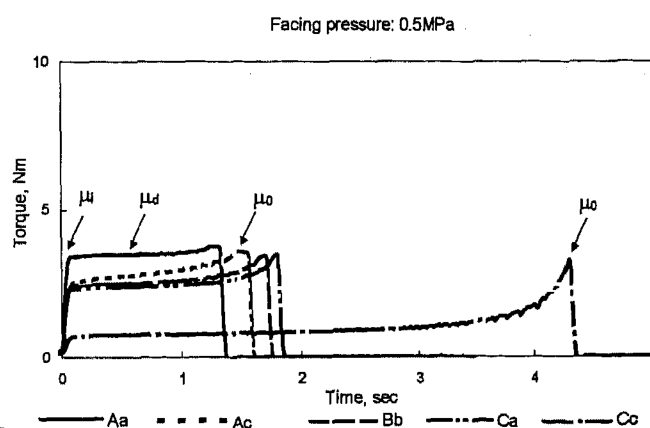

Fig. 11 Torque Curves of Friction Materials with Different Visco-Elasticity - 1

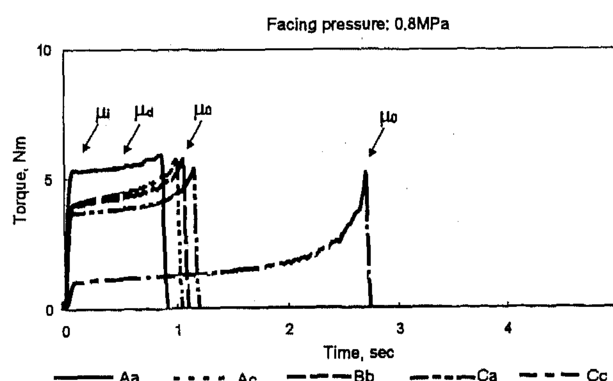

Fig. 12 Torque Curves of Friction Materials with Different Visco-Elasticity - 2

well as undergoes the compressive visco-elastic deformation. In this study, we paid close attention to the compressive visco-elastic deformation.

Friction torque curves of the sample materials, Aa, Ac, Bb, Ca and Cc were obtained by a modified SAE

No. 2 friction testing machine, as described in section 3.3. Comparisons of torque curves due to compressive visco-elastic deformation change at the facing pressures of 0.5 MPa and 0.8 MPa are shown in Fig. 11 and Fig. 12. The coefficients of friction (μ_i and μ_d) are higher when the compressive visco-elastic deformation of a material is higher, and as a result, torque curves are held at higher levels. It can be understood that the material whose compressive visco-elastic deformation is higher, removes the oil film more effectively in the sliding area where boundary and hydrodynamic lubrication co-exist and it increases boundary friction, thus resulting in a rise of the coefficient of friction. Fig. 13 shows the real contact area of the sample materials, Aa, Ac, Bb, Ca and Cc. After 200 engagement cycles, the real contact area of each sample was observed at the facing pressure of 0.8 MPa by the special testing machine (10), shown in Fig. 14. Fig. 13 is a photograph of the real contact area under stationary state. The real contact area does not change when sliding exists between the two surfaces (< about 0.5 m/sec) (10).

Facing pressure: 0.8 Mpa

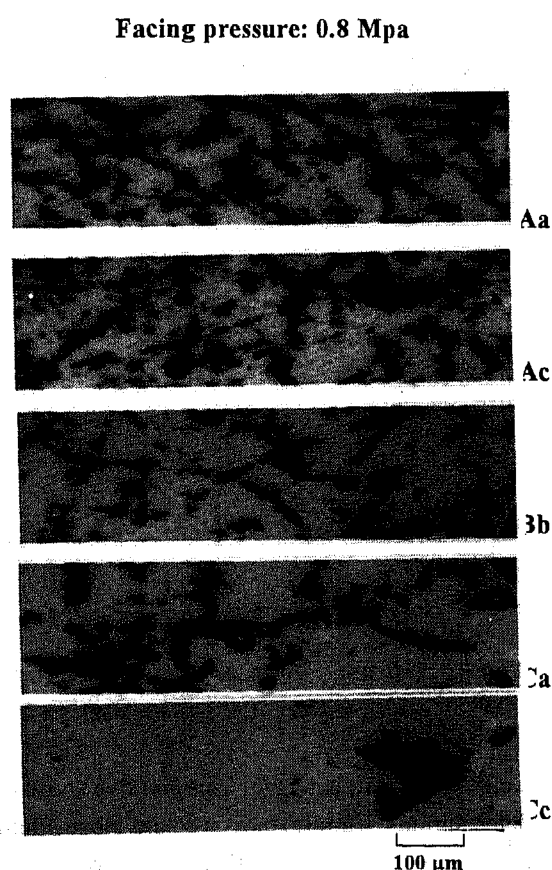

Fig. 13 Photograph of Real Contact Area

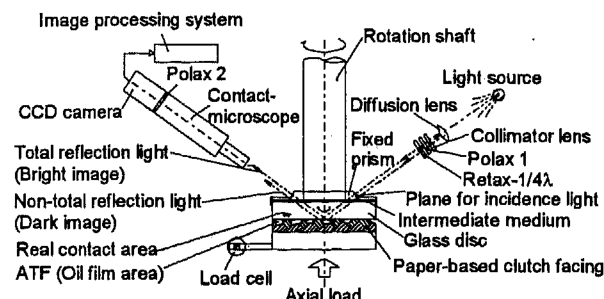

Fig. 14 Scheme of the Visualizing Apparatus

The real contact area percentage of the sample material, Aa was measured to be about 38 %, the percentage decreased in the order of Aa > Ac > Bb > Ca > Cc, and the real contact area percentage of Cc was about 16 %. The number of the real contact points decreased in the following order: Aa > Ac > Bb > Ca > Cc. Moreover, the uniformity of the contact was lost in the same order. These facts are considered to be important evidence especially in mixed asperity contact phase and consolidating contact phase, that the material having higher compressive visco-elastic deformation removes the oil film more effectively and increases boundary friction, thus resulting in a raise of the coefficient of friction.

At present, there is no known method to independently change the visco-elasticity of a paper-based friction material without either changing the porosity or the material composition. Therefore, it is difficult to determine which influence is higher, porosity or compressive visco-elastic deformation, in raising the coefficient of friction. The porosity percentages of the sample materials, Ac, Bb and Ca are at the same level, and the coefficients of friction, μ_i and μ_d of the sample materials are arranged in a descending order: Ac > Bb > Ca (The compressive visco-elastic deformation is in the same order: Ac > Bb > Ca). Therefore, it can be said that these phenomena are due to the pure influence of the visco-elasticity, but the phenomena might be due to the influence of pore size difference, because the average pore diameter and maximum existing pore diameter of the sample materials are arranged in a descending order: Ac > Bb > Ca. Further study, however, is

necessary to clarify this subject.

5. Concluding Remarks

Visco-elasticity and porosity are considered to be the two important factors that control the friction performance of a paper-based friction material. In the clutch plate engagement process, the coefficients of friction (μ_i and μ_d) are higher when the porosity of a material is higher. The higher porosity material removes the oil film more effectively in the sliding area where boundary and hydrodynamic lubrication co-exist, and it increases boundary friction, thus resulting in a rise of the coefficient of friction. It is presumed that the oil on the sliding surface penetrates into the material more effectively when the porosity of a material is higher. This fact is based on various kinds of data obtained by testing with a continuous sliding type test machine and an SAE No. 2 friction test machine.

As for the test results, the compressive visco-elastic deformation of a paper-based friction material increases as the porosity of the material becomes higher. This increase in deformation functions effectively to raise the coefficient of friction.

Using sample materials that consist of the same ingredients but different visco-elasticities, a comparison of torque curves due to compressive visco-elastic deformation change at the facing pressures of 0.5 MPa and 0.8 MPa was made. The coefficients of friction (μ_i and μ_d) are higher when the compressive visco-elastic deformation of a material is higher, and as a result, torque curves are retained at higher levels. The material whose compressive visco-elastic deformation is higher, removes the oil film more effectively in the sliding area where boundary and hydrodynamic lubrication co-exist and it increases boundary friction, thus resulting in a rise of the coefficient of friction. These phenomena were confirmed by the observation of the real contact area of the sample materials.

Abstract

A theoretical model for predicting the life cycle of a friction material used in wet friction clutches has been developed and verified. For a given friction material, the degradation mechanism can be identified by performing a Thermal Gravimetric Analysis (TGA) on the samples of worn friction materials. The samples are taken from the friction plates after they undertake various periods of the continuous slip experiments on the full-pack test machine. The degradation rate constants are obtained by performing the TGA experiments on the samples from the continuous slip experiments with different input powers and interface temperatures. The degradation for a dynamic engagement cycle is calculated by integrating the degradation rate with the temperature history near the friction interface as a function of time. The temperature history is predicted by the Borg-Warner computer model for the engagement of a wet clutch [1], which has been verified experimentally. The predicted thermal degradations agree with the experimental measurements on the worn friction samples from the dynamic engagements. This work illustrates that the degradation of wet friction materials in a wet friction clutch can be predicted by a theoretical model using temperature history near the friction interface.

Introduction

The wet disc clutch used in automatic transmissions consists of multiple separators, friction plates, and other components as illustrated in Figure 1. The key element in the clutch pack is the friction plate, made of a low carbon steel core plate with friction materials bonded on each side. A typical clutch pack configuration as shown in Figure 1 contains five separator plates and four friction plates. The friction plates are splined to the input shaft while the separator plates are lugged to the clutch housing. The function of a clutch pack is to transmit torque from a driving to a driven member when shifting from one gear to another. During engagement (shifting) the separator plates and friction plates are forced together by pressure, and the kinetic energy is converted to heat at the interfaces. The time for the relative rotating speed to reach zero is called the stop time, which is typically less than a second.

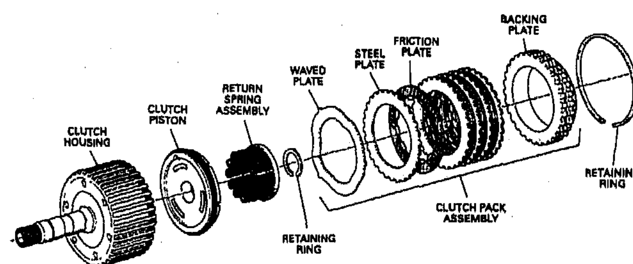

Figure 1: Schematic of Automatic Transmission Clutch Pack

During the engagement of wet clutches, a large amount of friction heat is generated at the separator-friction plate interface in a short time.

† To whom all correspondence should be addressed to.

The separator absorbs most of the heat and the friction plate (friction material and core plate) receives much less heat, due to the low conductivity of friction material. This results in a non-uniform temperature distribution in the axial direction in the friction material, i.e. large temperature gradient across the thickness of friction materials. The temperature rise at the interface during engagement is determined by the input energy, and physical and processing parameters. The temperature history near the friction interface is important, since it determines the performance characteristics, and especially, the thermal degradation rate of friction material.

The degradation of friction materials has been the subject of several investigations [2, 3, 4]. However, all the previous works to authors' knowledge were experimental in nature, and theoretical work is lacking. In order to predict the life cycle of friction materials for a given application, it is necessary to understand theoretically the mechanism and rate of material degradation. The life of a paper-based friction material is affected by both the thermal degradation (carbonization) and mechanical degradation (wear). The thermal degradation of a friction material is the major factor for determining the life cycle under the normal engagement of a wet clutch due to the high temperature environment at the friction interface, caused by the friction heat generated during clutch engagements. After the friction material is thermally degraded to a certain extent, the friction characteristics will be changed dramatically and its performance will suffer. Generally, the least heat resistant composition in the friction material will be degraded first at elevated temperatures.

The objective for this work is to predict the thermal degradation of friction materials during the dynamic engagement of wet clutches for any given condition. To achieve this goal, the mechanism of thermal degradation and its rate constants need to be determined. The temperature history near the friction interface during the dynamic engagement, as computed by the thermal model [1], has to be accounted for when calculating the cumulative degradation. In this paper a model that predicts the thermal degradation of friction material is presented, and the comparisons between experimental measurements and model predictions of thermal degradation are illustrated.

Degradation Mechanism

Borg-Warner Automotive produces many types of friction materials, consisting of different constituents for various applications. For this study a production friction material with low heat resistance was selected for the sake of saving experimental time, since it may take over 10,000 engagement cycles for a friction material with high heat resistance to degrade a measurable amount. A TGA experiment of the raw friction material under a high resolution temperature ramp condition can be utilized to determine the percentages of cellulose fibers and inert components. The inert components are those that start to degrade after all cellulose fibers are carbonized. Figure 2 illustrates the sample weight loss as a function of temperature (the temperature ramp rate was set to 100°C/min for up to 300°C, and 200^oC/min for temperatures between 300°C and 950°C). The solid curve is the percentage of sample weight loss, and the dotted curve is the negative gradient of weight loss percentage. The gradient peak at lower temperatures corresponds to the maximum rate of cellulose degradation, and the second peak corresponds to that of inert contents. This figure indicates that cellulose fibers start to carbonize near 200^oC and finish the degradation at 420^oC under the TGA testing condition. It also reveals that the weight percentage of cellulose fibers for this material is 31.2%.

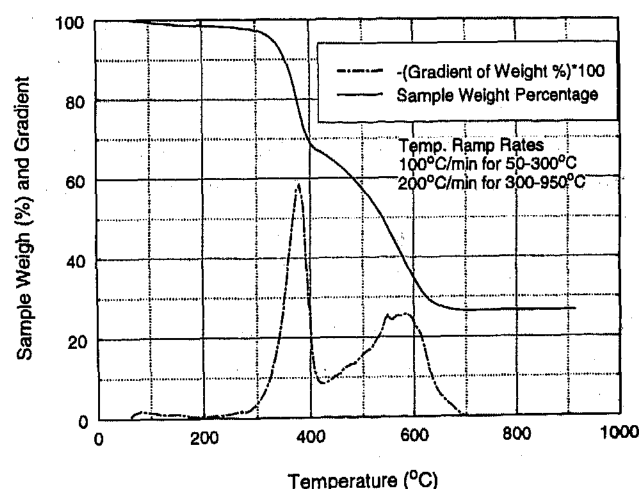

Figure 2: Weight Loss of Friction Material by TGA Analysis at Temperature Ramp Mode

Cellulose fiber is the least heat resistant component in this friction material. As cellulose fibers

encounter the high interface temperature during the repeated clutch engagements, they carbonize. The cellulose fibers undergo a chemical reaction and the interwoven fibers become brittle pieces of carbon after carbonization. After the carbonization reaches a certain degree, the friction material loses strength and small chunks of material at the surface may be pulled away.

The degradation amount/life cycles depends on the degradation rate and temperature history. The degradation mechanism and degradation rate need to be determined first. The degradation of friction material is a simple chemical reaction. We can first assume that the degradation is a n-th order reaction, and then determine the n value.

For a n-th order degradation, its reaction rate can be expressed as:

$$\frac{dW}{dt} = -kW^n \tag{1}$$

where W is the concentration of cellulose fibers (weight per unit volume), t is time, and k is the rate constant, which is a function of temperature and activation energy:

$$k = k_0 \exp\left(-\frac{E}{RT}\right) \tag{2}$$

where k_0 is the reaction rate constant, E is the activation energy of reaction, R is the Boltzmann constant, and T is temperature in °K. For example, for a first order reaction $n = 1$, and for a zeroth order reaction $n = 0$.

For a zeroth order degradation at the isothermal condition (constant temperature), by solving EQ (1) we obtain:

$$\frac{W}{W_0} = 1 - \frac{kt}{W_0} \tag{3}$$

where W_0 is the initial cellulose concentration, and t is the time duration of degradation at the isothermal condition.

Similarly, for the first order degradation at the isothermal condition, we obtain:

$$\ln\left(\frac{W}{W_0}\right) = -kt \tag{4}$$

Similar expressions can be derived for other orders of reaction ($n < 0$ and $n > 1$). However, there are more fundamental reasons for the zeroth and first order reactions.

If the degradation mechanism is a zeroth order, the plot of (W/W_0) vs t at various durations of experiments should be linear, where W is the cellulose weight per unit volume at time t. If the mechanism is a first order, the plot of $\ln(W/W_0)$ vs various t should be linear. Figure 3 shows the weight loss ratio W/W_0 as a function of time for the zeroth and first order degradations. The rate of zeroth order degradation is independent of cellulose concentration, and the rate of its weight change is constant. For a first order degradation, the rate of degradation depends on the concentration of cellulose fibers, and the rate of degradation decreases as the cellulose concentration decreases.

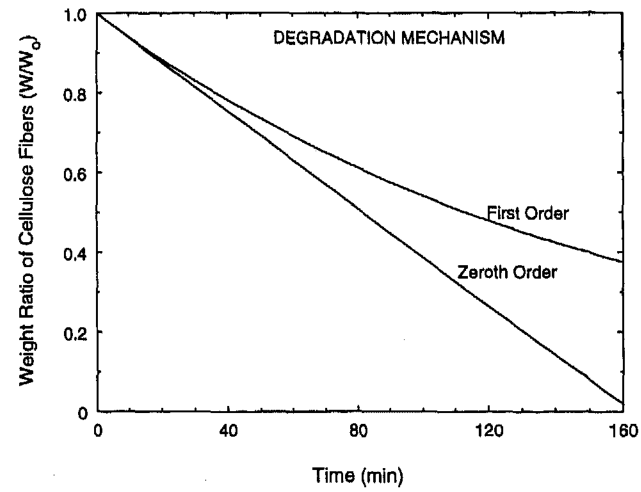

Figure 3: Degradation Mechanism of Friction Materials: Zeroth and First Order

The weight loss of cellulose fiber as a function of time under the isothermal condition can be measured from TGA experiments of new samples of friction material in a nitrogen or oxygen environment, or by measuring the cellulose content of the friction material after it undergoes the continuous slip test on the full-pack test machine. Under the continuous slip test, a constant power is supplied to the clutch pack and the temperature field reaches a pseudo-steady value in a short period of time (typically less than 1 minute) after the test starts. The tests typically run for more than 10 minutes. The temperature gradient across the thickness of the friction material is small at the pseudo-steady state. Thus, the temperature field exposed to the friction mate-

rial at the interface can be considered isothermal.

The weight loss of cellulose fiber under the continuous slip test best imitates the normal operating conditions of friction material in a clutch engagement. The detailed procedure and the experimental results of the continuous slip tests can be found in Twaddell's work [5]. Since the cellulose-to-inert ratio on the new friction material is not perfectly uniform, the average cellulose-to-inert ratio needs to be determined first. Ten samples were measured for the baseline cellulose-to-inert ratio with an average of 1.243±0.04, which is needed to determine the cellulose ratio W/W_0 on the worn materials. For each continuous slip test, eight samples of friction material were made by slicing a very thin layer (0.15mm) of friction material next to the friction interface. These samples were analyzed by the TGA to determine the cellulose-to-inert ratio, and the average ratio was calculated to obtain a mean value. From the baseline average cellulose-to-inert ratio and the average degraded cellulose-to-inert ratio, the cellulose weight ratio W/W_0 after degradation of time t is obtained. The cellulose ratio W/W_0 at various durations was obtained by measuring the samples from each corresponding continuous slip test.

Figure 4 shows the experimental results of $\ln(W/W_0)$ vs slip time for interface temperature of $260°C$. The temperature was measured by inserting a miniature thermocouple into the middle point between the separator ID and OD at its half thickness location. The temperature at this location should be very close to the temperature at the friction interface under the continuous slip condition because of the large thermal conductivity of steel and the pseudo-steady temperature distribution. If the degradation is a first order reaction, the experimental results (symbols in Figure 4) from various slip times should appear as a straight line in a logarithm scale. The best fit for the data (solid line) is reasonable except for the slip time of 60 minutes (relative error of W/W_0 between the fit and data is 9.9%). The W/W_0 ratios, from the same experimental data but plotted in a linear scale are illustrated in Figure 5 with the maximum relative error being 3.5%. If the degradation is a zeroth order reaction, all the experimental data should regress to a straight line. It is clear from Figures 4 and 5 that a zeroth order reaction represents the degradation mechanism better than the first order reaction. The degradation data obtained from the samples of continuous slip test under several other interface temperatures (230, 245, 275, 290, and $305°C$) also indicate that a zeroth order reaction describes the degradation mechanism better.

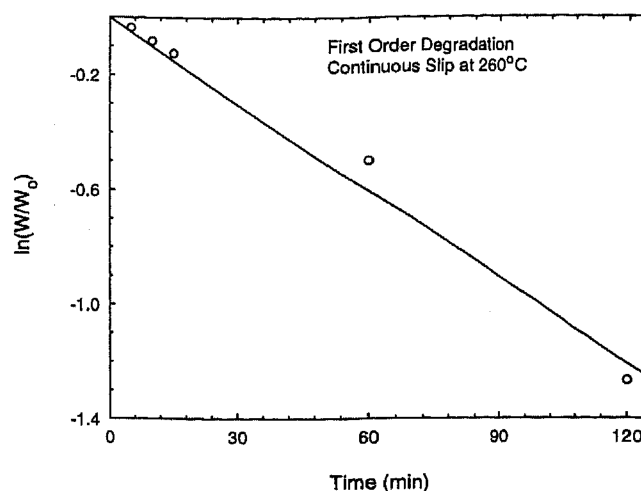

Figure 4: First Order Degradation Fit to the Experimental Weight Loss of Cellulose Fiber

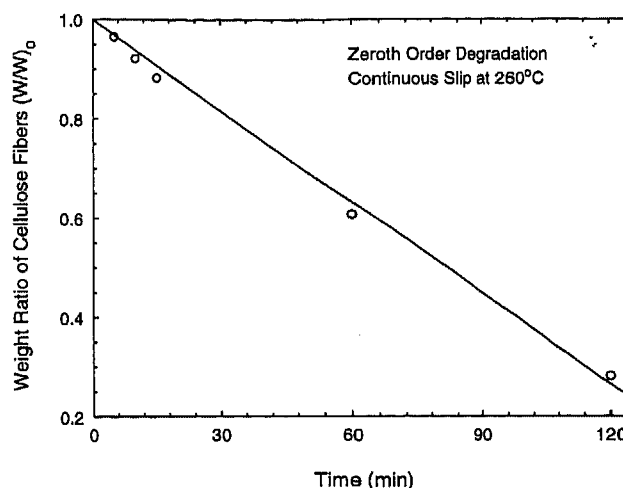

Figure 5: Zeroth Order Degradation Fit to the Experimental Weight Loss of Cellulose Fiber

For a zeroth order degradation, the slope of the W/W_0 vs time from one isothermal condition (one temperature) is the k/W_0 value for that temperature as described in EQ (3), while for the first order degradation the slope of $\ln(W/W_0)$ vs time is the k value from EQ (4). The reaction rate constant k_0 and the activation energy E of reaction can then be obtained by the least-square fitting of EQ (2) from several k values at different temperatures T.

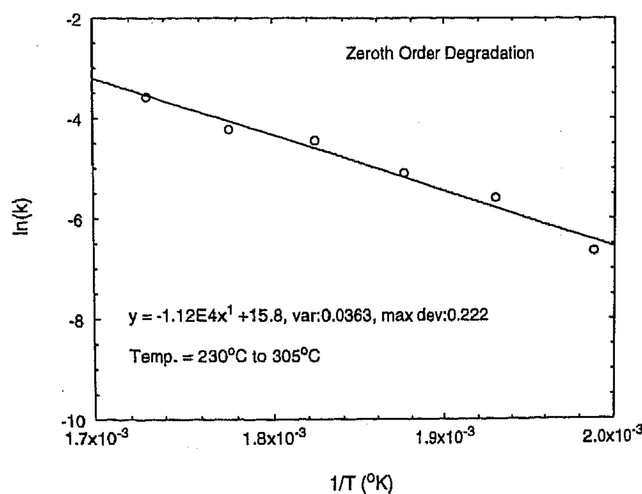

Figure 6: Determination of Rate Constant k_0 and Activation Energy E, Zeroth Order Model

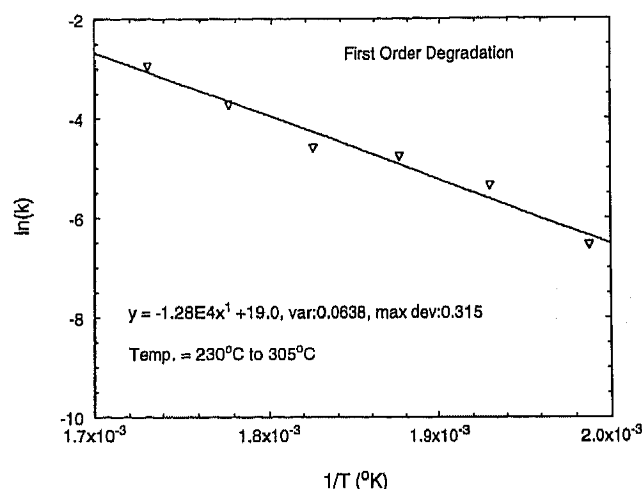

Figure 7: Determination of Rate Constant k_0 and Activation Energy E, First Order Model

Figures 6 and 7 depict the $\ln(k)$ vs $1/T$ for the zeroth order degradation and the first order degradation, respectively. The symbols are the experimental data and solid lines are the least-square fits to the experimental data. It is evident from these two figures that the least square fit for the zeroth order degradation yields smaller variance and deviation (0.0363 and 0.222, respectively) than those for the first order degradation (0.0638 and 0.315, respectively). It is then concluded that the degradation of this friction material is a zeroth order reaction with $k_0 = 1.203 \times 10^5 W_0$ (1/sec) and $E/R = 1.118 \times 10^4$ (°K).

Temperature History of Friction Material at Interface

Since the degradation rate is a strong function of temperature, the entire temperature history of friction material near the friction interface has to be accounted for when calculating the cumulative degradation during dynamic engagements. The temperature history at the interface can be measured by thermocouple (to be exact, the temperature at the separator plate can be measured). However, the temperature history of friction material below the interface cannot be measured easily since the friction plates are typically rotating. Therefore, we have to use a validated computer model [1] to obtain the necessary temperature information for evaluating the thermal degradation in the dynamic engagement situation.

Borg-Warner Automotive has developed a comprehensive and detailed mathematical model and computer software for calculating the temperature at the interface, as well as the temperature distribution as a function of time and spacial variables during the engagement cycle of a wet clutch. Many improvements and enhancements have been made since we presented this work in 1995 [1]. The model equations consist of heat balance for the separator, friction material, core plate, and Automatic Transmission Fluid (ATF) in the clearance and in the grooves. The momentum balance for ATF flow in the friction lining (porous medium) during the engagement was also considered. It has been verified by the experiments that the model can predict the temperature well during the engagement of a wet clutch [1]. Many important factors are included in the model, such as physical properties of steel and ATF as a function of temperature, non-uniform contact between separators and friction material, ATF flow into the friction material due to liquid permeability, compressibility of friction material, effects of separator splines, effects of rotational speeds, etc.

To further illustrate the capability of the thermal model, another comparison was made, as shown in Figure 8, between the model predictions and experimental measurements on the temperature history of the separator during a stable cycle of dynamic engagement. The experimental values were measured by inserting a miniature thermocouple into the middle point between the separator ID and OD

at the location of half separator thickness. The predicted values are also for the same location. It is demonstrated again that the model prediction of temperature agrees well with the experimental measurement. The physical parameters and operating conditions for the clutch configuration are shown in Table 1 with the initial rotating speed of 3000 RPM (low energy), which corresponds to one of the degradation studies for dynamic engagements. The temperature increases rapidly during the engagement stage, reaching the maximum temperature near the end of stop time. The temperature then decreases due to the heat conduction from the interface to the other parts of the clutch, and due to the heat transfer to the test machine housing at the outer and inner diameters. During the stabilization period (motor-on stage, from $t = 7.25$ sec to the end of cycle), ATF flows from the inner to outer diameter through the clearance and grooves on the friction plate, which rapidly lowers the temperature. At the end of a stable engagement cycle, temperatures reach the initial values of the previous cycle.

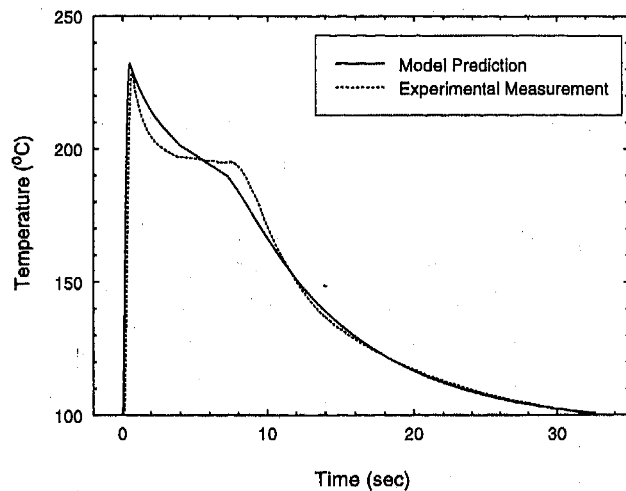

Figure 8: Model Prediction and Experimental Measurement on Interface Temperature

Figure 9 illustrates the temperature distribution across the axial thickness at the middle point of radial direction during the engagement stage (from t=0 to 0.52 sec). τ is the dimensionless engagement time ($\tau = t/t_e$, where t_e is the stop time, and $\tau = 1$ is at the end of engagement stage). The dimensionless thickness $\xi = 0$ is at the symmetric line of the separator, and $\xi = 1$ is at the symmetric line of the core plate. This figure illustrates that a large temperature gradient exists across the friction material

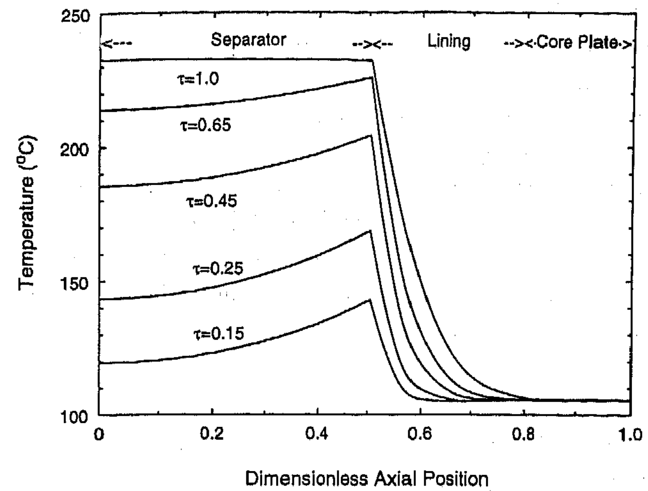

Figure 9: Temperature Distribution in Thickness Direction During Clutch Engagement

Table 1. Summary of Parameters for Dynamic Engagements

Energy Level	Low	High

Pack Clearance (mm)	1.3	1.3

(lining) between the interface and the bonding plane due to the low conductivity of friction material. The temperature profile of friction material between the interface and 0.15 mm depth from the interface is important, since the degradation amount of experiment for dynamic engagement is performed by slic-

ing a 0.15 mm thickness of friction material from the interface. The temperature history of this 0.15 mm thick friction material next to the interface needs to be accounted for when computing the cumulative degradation by the degradation model. By doing so, meaningful comparisons can be made between the experimental data and model predictions. It should be emphasized that the temperature history is a function of time, radial position, axial position, and other parameters [1].

Degradation Under Dynamic Engagement

In order to predict the degradation amount for a dynamic engagement cycle, we have to account for the temperature history of friction material as a function of time and axial locations. For a small slice of friction material at a certain radial location near the friction interface, the degradation amount for a zeroth order reaction from time t to time $t+\Delta t$ (Δt: time step from the thermal model) can be evaluated by:

$$\left(\frac{W_{t+\Delta t}}{W_t}\right) = 1 - \frac{1}{W_t}\int_0^{\Delta z}\frac{dz}{\Delta z}\int_t^{t+\Delta t} k_0 \exp\left[-\frac{E}{RT(t,z)}\right] dt \tag{5}$$

where Δz is the small thickness of friction material from the interface (slicing thickness), and $T(t,z)$ is the temperature, a function of time and axial depth from the interface. The degradation amount for this small time step Δt is:

$$\Delta W_i = W_{t+\Delta t} - W_t \tag{6}$$

The cumulative degradation for a dynamic engagement cycle is obtained by summation of all the time steps, i.e.

$$\Delta W_{cycle} = \int_0^{t_{cycle}} \frac{dW}{dt} dt = \sum_{i=1}^{N_{step}} \Delta W_i \tag{7}$$

where N_{step} is the number of time steps.

The double integration in EQ (5) needs to be evaluated efficiently and accurately, considering that there are over 200 time steps for each engagement cycle, and more than 10 divisions from the inner radius to outer radius for the degradation calculation. Several integration schemes have been tried and the Gaussian quadrature is chosen for this work because of its numerical accuracy and fast computation.

For any given two-dimensional function $f(x,y)$, the double integration by the Gaussian quadrature can be expressed by the following formula, and the numerical value of integration is exact if $f(x,y)$ can be represented by a polynomial degree of $(2n_g - 1)$:

$$\begin{aligned} P &= \int_a^b\int_c^d f(x,y)dxdy \\ &= \frac{(b-a)}{2}\frac{(d-c)}{2}\int_{-1}^{+1}\int_{-1}^{+1} f(\xi,\eta)d\xi d\eta \qquad (8) \\ &= \frac{(b-a)}{2}\frac{(d-c)}{2}\sum_{i=1}^{n_g}\sum_{j=1}^{n_g} f(\xi_i,\eta_j)w(i)w(j) \end{aligned}$$

$$\xi = \frac{2x-(a+b)}{b-a} \qquad \eta = \frac{2y-(c+d)}{d-c}$$

where n_g is the number of Gaussian points, $w(i)$ and $w(j)$ are the Gaussian weights, ξ_i, and η_j are the Guassian values. Table 2 shows the Gaussian values and Gaussian weights for $n_g = 11$.

Table 2: Gaussian Points and Weights ($n_g = 11$)

The cumulative degradation amounts from the dynamic engagement were measured on the samples of friction materials after they have been engaged for 1000, 4000, and 8000 cycles for the low energy engagement and for 1500, 2500, and 4000 cycles for the high energy engagement. The testing parameters are listed in Table 1 and the samples are taken near the inner diameter and outer diameter of the

friction plate. The sample measurements were made in a similar manner as those for the samples of the continuous slip as described earlier for determining the degradation rate. A total of sixteen samples (eight near the inner diameter and eight near the outer diameter) of friction material were taken and measured for each set of engagement cycles in order to obtain an average value.

The comparison between the experimental measurements and model predictions on the cumulative degradation is illustrated in Figures 10 and 11 for the low and high energy engagements, respectively.

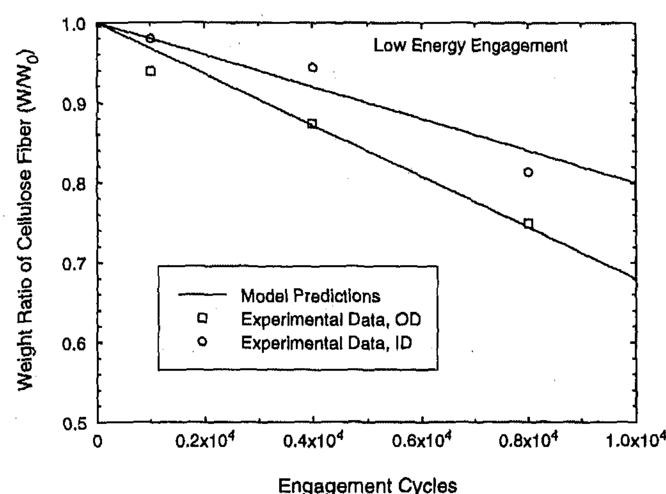

Figure 10: Model Predictions and Experimental Measurements on Cumulative Degradation (Low Energy Level)

The symbols in these two figures are the experimental measurements, with squares for the samples taken near the outer diameter and circles near the inner diameter (each symbol is the average of eight measurements). Figures 10 and 11 show that the predicted degradations of friction material agree fairly well with the experimental measurements of thermal degradation for both the low and high energy engagements, and for the samples taken from both the inner and outer diameters of friction material. The friction material close to the outer diameter degrades more than that close to the inner diameter. This is due to the fact that the temperature near the outer diameter is higher than that near the inner diameter, since more friction heat is generated near the outer diameter, and cold ATF flows from the inner diameter to the outer diameter of the friction plate. This results in the temperature near the outer diameter being higher than that near

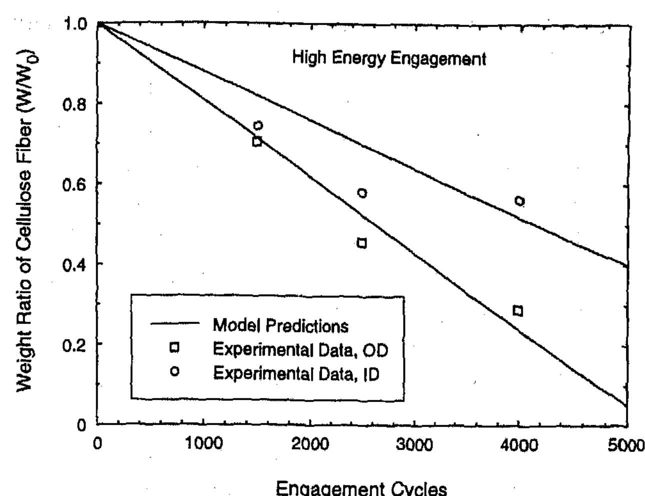

Figure 11: Model Predictions and Experimental Measurements on Cumulative Degradation (High Energy Level)

the inner diameter during engagement.

Since the prediction of the thermal degradation of friction materials involves many uncertainties, it is not expected that the model prediction will be perfect. The non-perfect agreements between the theoretical predictions and the experimental measurements shown in Figures 10 and 11 (especially Figure 11) may be due to one or more of the following factors. The degradation rate constant k_0 and the activation energy E as shown in Figure 6 are not perfectly accurate. The prediction of temperature distribution by the thermal model does not agree exactly with the experimental values. The contact between the friction plate and the separator may not be perfectly uniform, and non-uniform contact may generate locally high temperature. All these factors contribute to the slight disagreements between the model predictions and measurements. The key factor is the temperature history that friction materials encounter during the dynamic engagement. The degradation rate is an exponential function of temperature, and any inaccuracy in temperature predictions will be propagated to the degradation predictions.

Summary

A model and computer software have been developed to predict the thermal degradation of friction material after it undergoes a certain number of dy-

namic engagement cycles. The degradation mechanism for the selected friction material obeys the zeroth order reaction well. The degradation rate as a function of temperature was determined by the TGA measurement of the samples from the continuous slip test on the full-pack machine. The whole temperature profile of friction material in a thin layer close to the interface was considered when evaluating the degradation. The temperature profile was obtained by the thermal model. The experimentally measured cumulative degradations from dynamic engagements were compared favorably with the predictions of the degradation model. This model will provide useful information for engineers, and assist them to optimize the design of a clutch pack for a given application. Furthermore, the model is flexible and can be used to project material life under variable cycle conditions at any defined set of application conditions.

ABSTRACT

A new sintered composite friction material consisting of mechanically-alloyed copper-based composite powders has been developed. It has a unique microstructure of fine hard particles that are embedded in the matrix of the copper-based primary particles. This friction material reduces abrasive wear and/or seizures that are often caused by hard particles which become detached from the matrix, because the hard particles in this material are bonded tightly to the matrix even under harsh service conditions. The fine hard particles are also very useful for improving high friction force when contacting a surface material. Therefore, this new friction material provides a higher friction coefficient than the conventional material containing coarse hard particles. Furthermore, this friction material is less abrasive to the surface material than the conventional one. The new sintered composite friction material shows outstanding performance and reliability when used as a friction component in some friction devices, such as magnetic clutches in automotive air-conditioners and brake systems. The friction characteristics are bound to be superior to those of the conventional sintered copper alloy or organic material currently used for such friction components.

INTRODUCTION

In friction devices, such as magnetic clutches and brakes, good wear resistance, high friction force and high durability are required to make a more compact or smaller friction device system with high performance. As shown in equation (1), Friction force F is relative to the coefficient of friction μ of friction material and the material with higher coefficient friction has the ability to produce a friction device system with greater braking force. Furthermore, when the friction coefficient μ increases, the number of contact components n will decrease. This means that it is possible to design a more compact friction device system by using a friction material with a higher friction coefficient.

$$F=\Sigma(\mu P_i)=n \mu P \qquad (1)$$

P_i ; Pressure on each contact component

The friction material usually also requires the heat resistance because the temperature at the surface sliding against a surface material rises due to the increased friction heat when the friction coefficient increases. Furthermore, metal-based friction material is more available than a paper based or organic one when developing an advanced friction material with a higher friction coefficient.

Sintered friction material used for friction devices usually consists of hard particles such as ceramics and intermetallic compounds, and self-lubricant particles. Figure 1 shows a typical microstructure of a sintered copper-based friction material. Copper, particularly a Cu-Sn brass alloy, is often used for the base metal of sintered friction materials. Elements

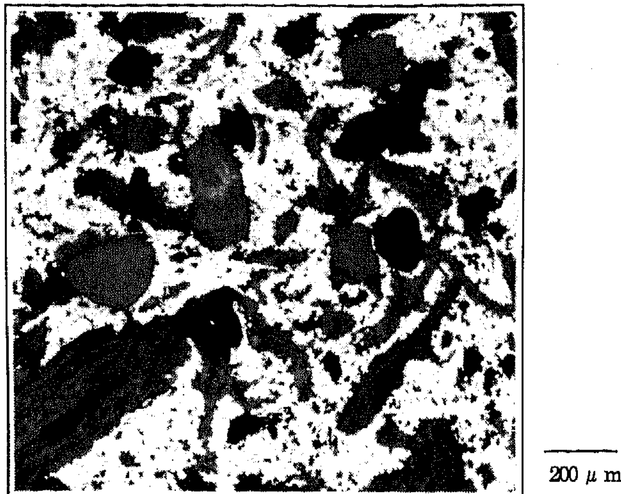

Figure 1. Microstructure of the conventional sintered friction material.

added to a copper-based alloy, such as Ni, Fe, Zn improve the mechanical and wear properties of the sintered copper alloy. A self-lubricant, such as graphite, MoS_2 ,or BN, creates lubricant films along the interfaces between the friction material and the surface, so it is easy to maintain a constant friction coefficient. Hard particles, such as SiO_2 or Al_2O_3 dispersed in the sintered material, also have an important role in improving the wear resistance and high friction coefficient when contacting a surface material. In particular, sintered friction components have poor wear resistance when the content of contained hard particles is less than the optimum range, 10~30mass%.

WEAR PHENOMENA OF THE CONVENTIONAL SINTERED FRICTION MATERIAL

Firstly, the mechanism of wear phenomenon, particularly a seizure, was analyzed in order to develop a new sintered friction material with excellent anti-wear properties. Figure 2 shows a change in the friction coefficient of the conventional sintered copper alloy using the ring-on-disk wear test under dry conditions as shown in Figure 3, using a low carbon steel (S15C) as the surface material. The sintered Cu-9%Sn+FeMo alloys, whose microstructures are shown in Figure 4, are applied to contact/friction materials in this work. FeMo intermetallics with average diameters of 60~70 μ m and

average hardness of 830mHv (micro-vickers hardness) are added as hard particles to each sintered copper alloy. The initial friction coefficient of each sintered copper alloy is a constant 0.3~0.4. The friction coefficient, however, gradually increases and finally each alloy has a high friction coefficient over 0.7 because of the seizure phenomena at the surface in which it contacts a surface material, independent of the content of FeMo intermetallics. The results of the microscopic and Scanning Electron Microstructure (SEM) analysis show that FeMo hard particles are dispersed not only at the primary particle boundaries (PPB) of the sintered friction material, but also at the contacting surface of the surface material. Furthermore, pores are observed at the contacting surfaces of each sintered material. Therefore, it is quite certain that these pores at the PPB correspond to the traces where FeMo hard particles detached from the matrix of the sintered friction material. The hard particles which detach from and cause seizure phenomena when contacting a surface material do so because of gaps between FeMo hard particles and the matrix of the primary copper particles as shown in Figure 4. Based on these results, the mechanism of seizure phenomena of the conventional sintered friction material is considered as follows. Raw powders, which consist of copper-based powders and hard particles, are consolidated into the green compact by pressing as shown in Figure 5.

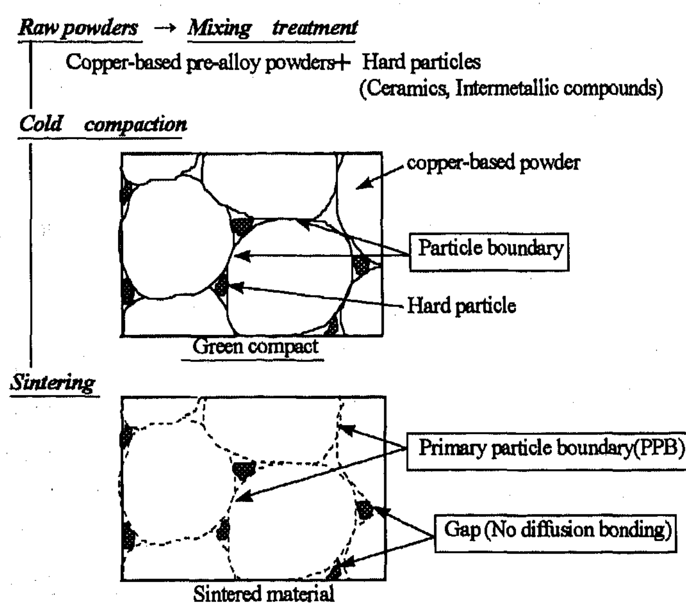

Figure 5. Procedure of the conventional sintered composite friction material.

The hard particles are dispersed at the primary copper-based powder boundaries in the compact. After sintering, however, it is impossible to provide a diffusion layer between the hard particles, such as ceramics particles and/or intermetallic compounds, and the copper-based powders because metallic diffusion bonding does not occur between them even in sintering. Therefore, as shown in Figure 6, FeMo hard particles easily detach from the matrix of the sintered friction material under severe dry conditions, such as high load or high sliding speed, because of the lack of a diffusion layer with the matrix.

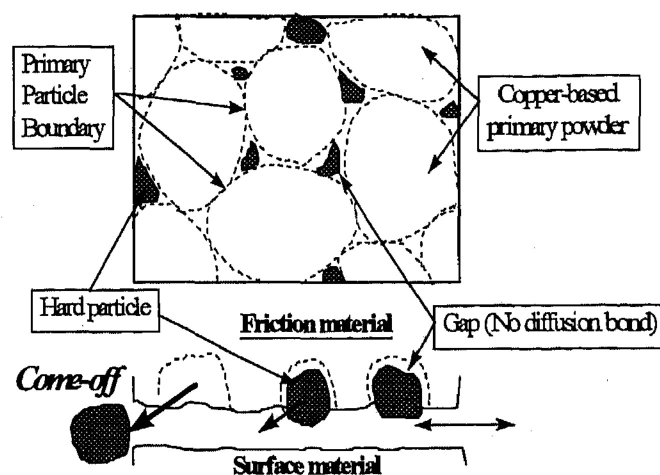

Figure 6. Schematic microstructure of a typical sintered friction material and the cross section when contacting a surface material.

That is, gaps between the hard particles and the matrix cause a poor bonding at the interface therebetween, so the hard particles easily detach from the matrix when contacting the surface material causing seizure or wear phenomena. In addition, these hard particles which detach from the matrix attack the surface material cause wear phenomena to occur at the contacting surface of the surface material as well.

ADVANCED SINTERED COMPOSITE COPPER-BASED FRICTION MATERIAL

MATERIAL DESIGN BY MECHANICAL ALLOYING PROCESS — Based on the above results, it is essential to

bond the hard particles to the matrix of the sintered friction material in order to improve the anti-seizure property, wear resistance and the stability of the friction coefficient when contacting the surface material. An ideal schematic microstructure of the sintered friction material, as shown in Figure 7 compared with the conventional one, has essentially a reaction/diffusion layer at the interfaces between hard particles and the matrix. This layer serves to bond well the hard particles to the matrix.

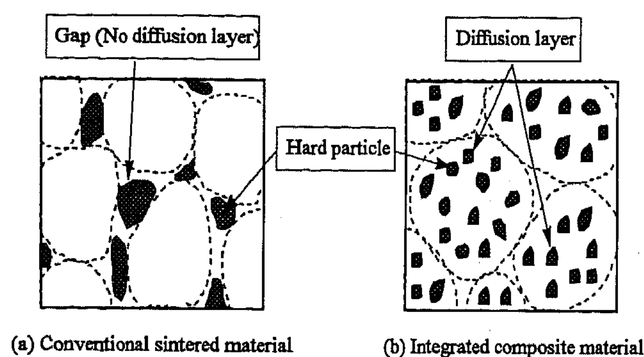

Figure 7. Ideal schematic microstructures of the integrated sintered composite friction material compared to the conventional sintered one.

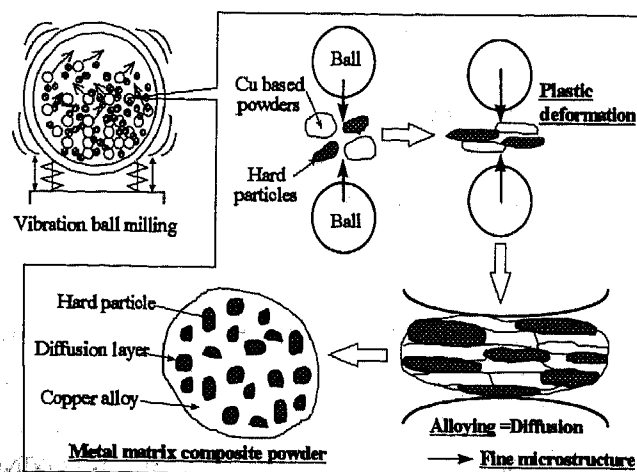
There are methods to realize this microstructure with a powder metallurgy process, such as reaction sintering or diffusion bonding, etc. In this work, a mechanical alloying (MA) process is selected to provide a reaction/diffusion layer between the hard particles and the matrix. Figure 8 shows a schematic of the MA process and the microstructure of the metal matrix composite (MMC) powders made by the MA process. Coarse hard particles ground into fine hard particles by ball milling, are dispersed in the matrix of the copper alloy based powders. They also have a diffusion layer with the matrix due to the high energy given to powders by ball milling. The new sintered friction material consists of these mechanically-alloyed MMC powders used as raw powders. Therefore, it has good ability to control seizure phenomena because FeMo hard particles have become sufficiently embedded in the matrix to resist friction with a surface material. In addition, it is possible to consider that this material has not only good anti-seizure properties but also good wear resistance, because the matrix of base copper alloy which has fine crystal microstructures produced by the MA process, is harder and stronger than that of the conventional sintered copper-based friction material.



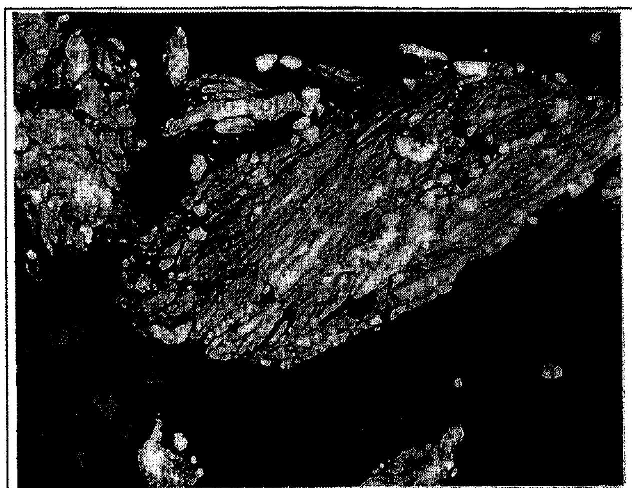


Figure 8. Schematic of the mechanical alloying(MA) process and the microstructure of a metal matrix composite(MMC) powder made by the MA process.

MICROSTRUCTURES OF METAL MATRIX COMPOSITE POWDERS AND SINTERED MATERIAL— Cu-9mass%Sn mixed powders are used for base metal alloys. FeMo intermetallics whose average diameter is 70 μ m and average hardness is 830mHv are selected as hard particles in this work. The MA conditions with a vibration ball milling device are shown in Table 1 and the milling time is used as a parameter in this work.

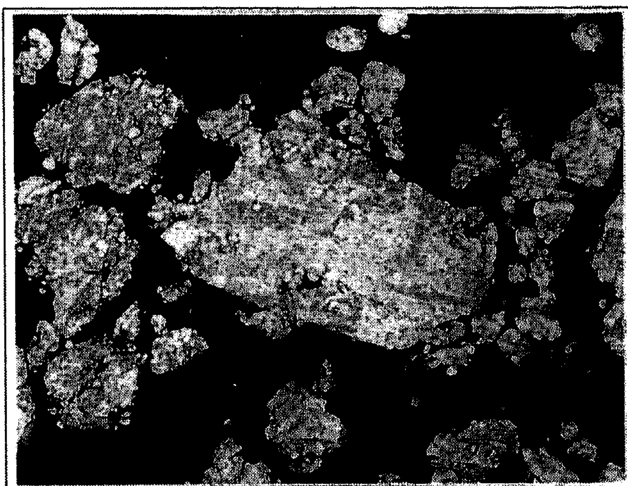

Table 1. Test conditions in mechanical alloying with vibration ball milling device.

Vibration conditions		Milling time	Powder weight	Ball weight
Frequency	Width	t	W_P	W_B
1200 rpm	8 mm	1~20 hr	800 g	8 kg

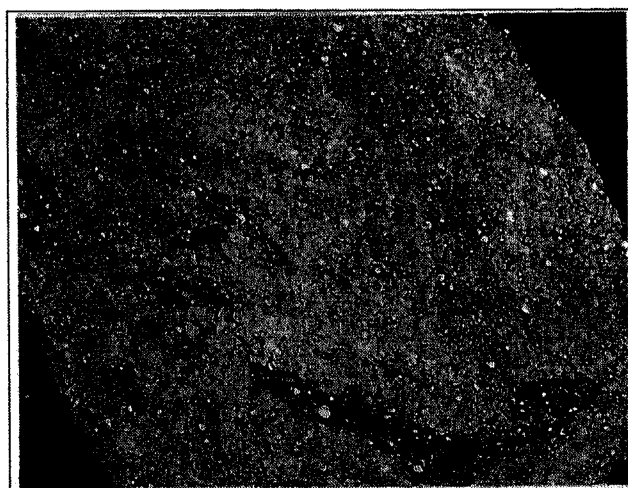

Figure 9 reveals the microstructures of MMC powders produced by the MA process at each milling time. For a milling time period under 3hrs., FeMo hard particles of a size less than about 10 μ m in a diameter, are uniformly dispersed in the matrix, although layer-like microstructures of the copper alloy are clearly observed in the matrix of powders. On the other hand, with a milling time of over 5hrs., very fine FeMo hard particles of less than 5 μ m in diameter are uniformly dispersed in the matrix, and the uniform microstructure of the copper alloy is also observed in the matrix. Figure 10 shows the

(Chemical compositions of both materials ; Cu-9%Sn+20%FeMo)

On the other hand, coarse FeMo hard particles are dispersed in the primary particle boundaries of the conventional sintered friction material and there are gaps at the interfaces between hard particles and the matrix. This is why in producing the conventional sintered friction material, the mixing treatment of raw powders makes it impossible to embed the FeMo hard particles in the matrix of copper alloy powders. Thus, this means that the MA process has the ability to realize the ideal microstructures of a sintered friction material which has excellent anti-seizure properties. Therefore, it is expected that this advanced sintered composite friction material will satisfy the requirements of good wear resistance and a constant friction coefficient under severe friction conditions.

MECHANICAL AND TRIBOLOGICAL PROPERTIES OF ADVANCED SINTERED MMC FRICTION MATERIAL — Table 2 shows the physical and mechanical properties of this new sintered composite friction material which consists of mechanically-alloyed MMC powders as raw powders, compared to the conventional one with the same chemical composition. The strength and hardness of the new sintered friction material are superior to those of the conventional one because FeMo hard particles are bonded well to the copper alloy matrix, and the matrix is strengthened by fine copper crystals.

Table 2. Physical and mechanical properties of sintered composite friction materials.

MA composite	5.96 g/cm³	207 MPa	56
Conventional	5.91 g/cm³	118 MPa	42

(Chemical compositions. Cu-9%Sn-25%FeMo)

Figure 14 shows a change in the friction coefficient of both friction materials, using a ring-on-disk wear test equipment as shown in Figure 3 under dry conditions (Pressure;0.2MPa, Velocity;10m/sec.). This advanced friction material has a higher friction coefficient with a constant 0.4~0.45, and no seizure phenomenon occurs at the surface contacting the surface material. On the other hand, the friction coefficient of the conventional material gradually increases, and finally, it reaches 0.7 with seizure phenomena. The above result reveals that the friction coefficient of the new friction material is higher than that of the conventional one in which seizure phenomena has not occurred yet. Usually, the surface area of hard particles which contact the surface material determines the friction force, and the surface area of fine hard particles contacting a surface material is larger than that of coarse ones. Therefore, this new friction material provides a higher friction coefficient than that from a conventional material made of coarse hard particles, because the finer hard particles which raw coarse particles are ground by the MA process, are dispersed in the matrix of this new friction material. Figure 15 shows the wear thickness of each sintered friction material and surface materials. In the case of this new sintered friction material, wear of both the friction material itself and its surface is very low, so this result means that a new integrated friction material has excellent anti-wear property. It is also found that no FeMo hard particles detach from the matrix at the contacting surface, using microscopic and SEM analysis. That is, hard particles are seen to be perfectly embedded in the matrix.

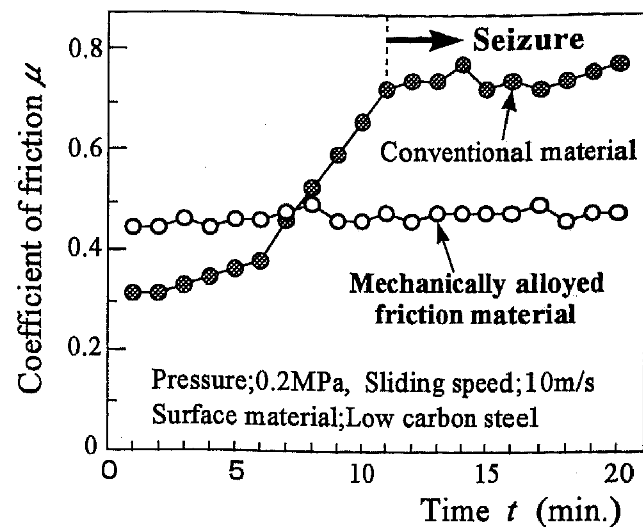

Figure 14. A change in the friction coefficient of the mechanically-alloyed sintered composite friction material and the conventional one. (Chemical composition of both materials ; Cu-9%Sn+25mass%FeMo)

APPLICATION TO A MAGNETIC CLUTCH MATERIAL IN AUTOMOTIVE AIR-CONDITIONERS

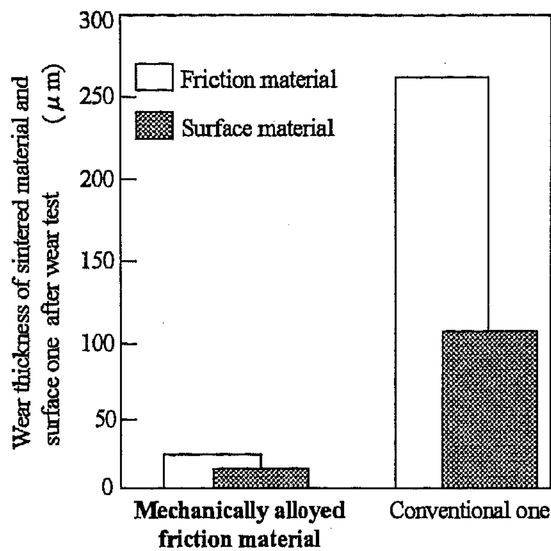

Figure 15. Wear properties of mechanically alloyed copper-based friction material compared to the conventional one.

In a magnetic clutch system, the ring-shaped friction material which is fixed on the surface of either a rotor or an armacher as shown in Figure 16, has an important role in stopping the rotation of the armacher instantaneously and synchronizing the armacher with the rotor. Therefore, friction material with a higher friction coefficient is required to produce a new magnetic clutch system with higher friction force and outstanding performance. It must also contribute to weight reduction on the magnetic clutch system.

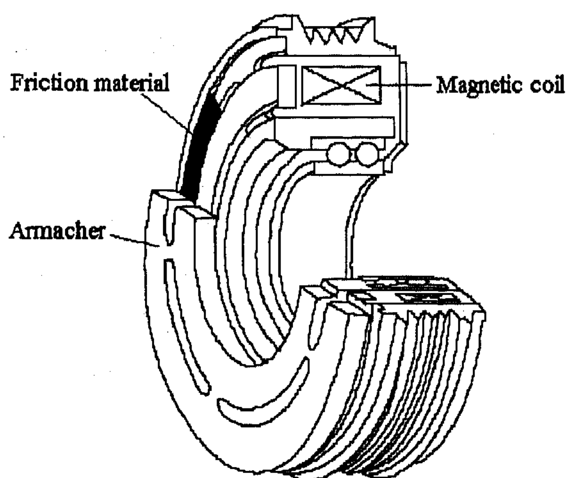

Figure 16. Schematic of a magnetic clutch system used in an automotive air-conditionaer.

That is, as mentioned in the above equation (1), a higher friction clutch material makes it possible to realize a more compact system with the same friction force because the radius of the clutch material R is smaller due to the higher friction coefficient. Good wear resistance is also necessary under more severe sliding conditions. Thus, this integrated composite sintered material with both higher friction coefficient and excellent wear resistance has good potential to realize the new magnetic clutch system with high performance.

Figure 17 shows a change in the friction coefficient of each friction material, the mechanically-alloyed composite sintered material, the conventional sintered copper alloy and an organic one in use, evaluated by a cyclic wear test simulating a magnetic clutch in an automotive air-conditioner by using Ring-on-disc wear test equipment (See Figure 3) under sliding conditions as shown in Figure 18.

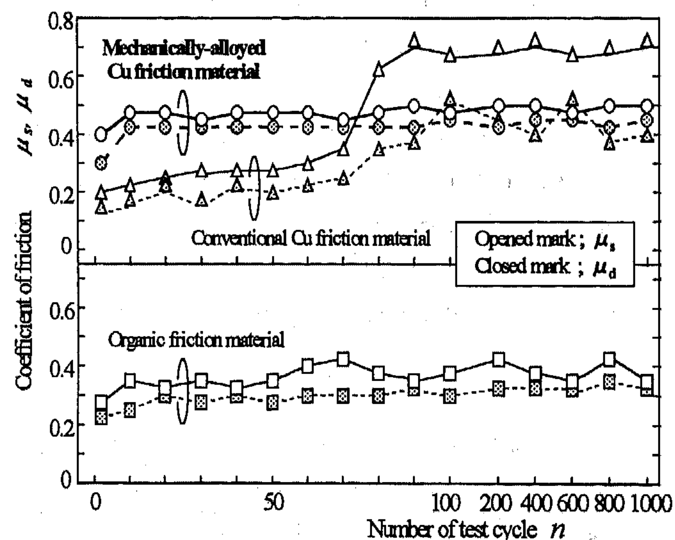

Figure 17. A change in the friction coefficient of each friction material evaluated by cyclic wear test simulating a magnetic clutch used in an automotive air-conditioner. (Chemical composition of both sintered materials ; Cu-9%Sn +15mass%FeMo)

In particular, μ_s corresponds to the maximum friction coefficient at the moment of starting or stopping, meaning the statistic one, and μ_d means the dynamic friction coefficient in this measurement. This mechanically-alloyed sintered friction material reveals a higher constant friction coefficient than both the conventional sintered friction material and the organic one, and no seizure or wear phenomenon at the contacting surface is observed. The difference particularly of μ_s and μ_d, which

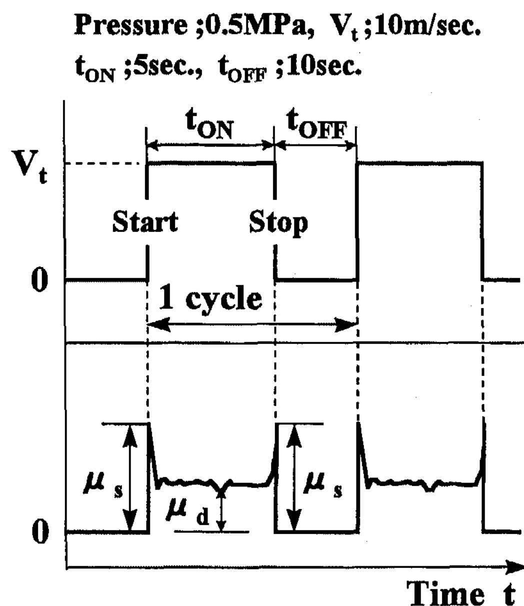

Figure 18. Ring-on-disc cyclic wear test conditions used in this work.

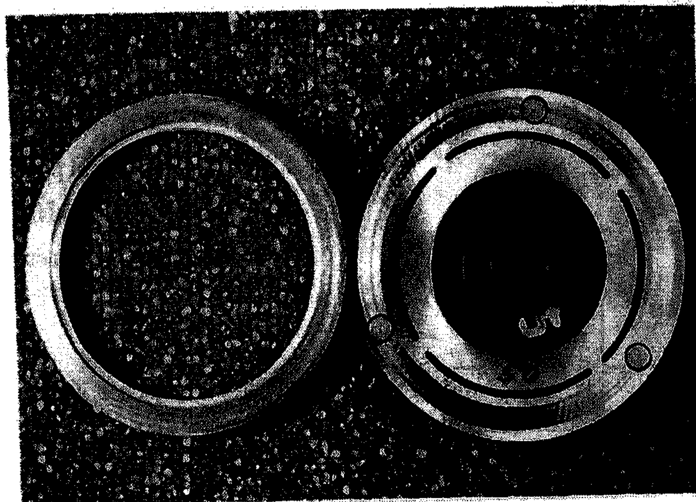
is relative to the vibration at the moment of stopping and starting the magnetic clutch, is smaller than that of the conventional sintered material with the same composition. Therefore, this friction material makes very little noise during the cyclic wear test as does the organic one, particularly at the moment of stopping and starting the magnetic clutch.

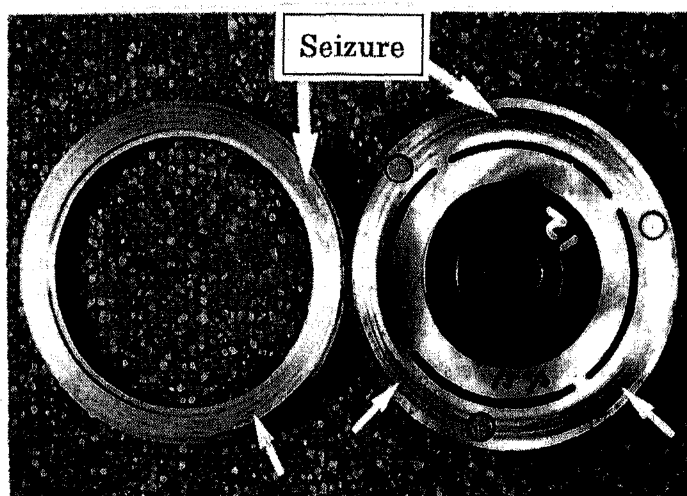
Figure 19 shows the contacting surfaces of each friction material and that of the surface (S15C low carbon steel) after a wear test in which the surface underwent 1000 cycles. No seizure or wear phenomenon is observed at the contacting surface of not only the friction material but also the surface material using the mechanically-alloyed sintered friction material. On the other hand, the conventional sintered friction material does have seizures and damaged areas at the contacting surface, and the thermally damaged areas are observed at the surface of the organic friction material. The same results, of course, are fully recognized in various durability and reliability tests by our customers and it is found that this mechanically-alloyed sintered friction material has the ability to realize a more compact magnetic clutch system with high performance.

CONCLUSIONS



1.Wear and/or seizure phenomena of the conventional typical sintered friction material including some hard particles usually occur when contacting a surface material under severe friction conditions.

2. There are gaps at interfaces between the hard particles and the matrix, and such hard particles are poorly bonded to the matrix. The hard particles therefore, detach from the matrix and the seizure phenomena occur.



3. The integrated composite sintered material consists of the mechanically-alloyed copper-based powders which include the hard particles dispersed uniformly in the matrix. There is a diffusion layer at the interface between hard particles and the matrix in the mechanically-alloyed powders, so that finer hard particles with less 10 μ m in a diameter are securely bonded to the matrix.

4. This new sintered friction material shows superior anti-seizure properties, wear resistance and mechanical properties to the conventional sintered one, and it is also less abrasive to the surface material because no fine hard particle detach from the matrix when contacting the surface material. Furthermore, this new friction material shows a higher friction coefficient with a constant 0.4~0.45 than that of the conventional one.

5. In the application of this advanced sintered friction material to a magnetic clutch for automotive air-conditioners, it also shows a higher friction coefficient and excellent anti-seizure properties. It is, therefore, expected that this friction material will provide a more compact magnetic clutch system with high reliability.

Evaluation of the Corrosion Rate of Zn Coated Steel Sheets for Automotive Body Use

Shigeo Kurokawa, Morishige Uchida, Chiaki Kato, Kazuo Mochizuki, and Toshiyuki Kato
Kawasaki Steel Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The corrosion mechanism of zinc coated steel sheets in automotive bodies was studied in field vehicle tests and several types of accelerated tests. Perforation corrosion starts in unpainted areas of lapped parts, and proceeds in the following steps: i) galvanic protection by the Zn coating, ii) protection by corrosion products, and iii) corrosion of the steel substrate and perforation. Although the corrosion processes were the same in all the cases tested, the corrosion rate depended significantly on the environment, such as atmospheric exposure conditions and the part of the automotive body. In accelerated corrosion environments, Zn coating is largely ineffective against perforation corrosion because galvanic protection and protection by corrosion products cannot be maintained over the long term. Conversely, coating is highly effective under actual atmospheric conditions which produce slow corrosion rates because galvanic protection and protection by corrosion products continue to protect the steel substrate over an extended period. Accelerated tests may be an accurate predictor of corrosion in cold rolled steel, but may not be representative of corrosion in coated products. On the other hand, cold rolled steel can be used to extrapolate the rate of corrosion in coated products. Therefore to evaluate the effects of Zn coatings quantitatively, the authors suggested an index of for corrosion resistance relative to cold rolled steel sheets under each atmospheric conditions. It is considered possible to estimate actual perforation corrosion life by using this index.

INTRODUCTION

Corrosion of automotive bodies became a problem after the widespread use of de-icing salts on roads was adopted in North America and Europe. In the late 1970s, Zn coated steel sheets were introduced to protect automotive bodies from corrosion. However, corrosion can be divided into two significantly different types. One may be characterized as outside-in corrosion, caused by paint chipping damage to outer panel surfaces, resulting in under-the-film corrosion and / or scab corrosion. This type is generally called cosmetic corrosion. The second is inside-out corrosion caused by salty or muddy water penetration into places that do not dry readily, such as panel joints and the inner surfaces of closed structures (perforation corrosion).

Progress of cosmetic corrosion is often discussed in terms of pH changes of the under paint space (1,2). As for perforation corrosion, extensive analytical studies have been conducted in the lapped portions of dismantled field vehicles (3,4) to elucidate the corrosion mechanisms. Other studies have provided information about the effects of corrosive environments (5,6) and the effects of gap in the lapped parts (7), which was obtained from cyclic corrosion tests. These studies were usually qualitative, and information on the corrosion rate of Zn coated steel was not available in the literature.

In this work, corrosion rate measurements were conducted in various corrosive environments using Zn-Ni alloy coated steel and cold rolled steel. Based on the results, the authors suggested an index of the corrosion resistance of coated steel extrapolated from cold rolled steel sheets under various atmospheric conditions as a means of evaluating the effects of Zn coatings quantitatively. It is considered possible to estimate actual perforation corrosion life using this index.

EXPERIMENT

MATERIALS- Zn-Ni alloy electroplated steel sheets and cold rolled steel sheets were prepared for the tests. The alloy contained 11.2% Ni, and the coating weight was 21g/m². Front doors of a 4-door sedan type vehicle were manufactured from these two kinds of steel sheets. The door was chosen because the door hem flange is categorized as a part which is subjected to severe corrosive conditions and is also an exchangeable part. Based on a domestic Japanese specification, the door samples were phosphated, painted and sealed then exposed to the following corrosion tests.

FIELD VEHICLE TEST-In the field test vehicle, the doors were installed in a monitor vehicle of the four door sedan type which was driven for 8 years, from October, 1985 to November, 1993 in Naha-City, Okinawa Prefecture.

Okinawa Prefecture is classified as a subtropical marine environment, with high temperature and high humidity, and a large amount of dispersed sea salt particles. The mileage driven was approximately 80,000km. The vehicle was used for business purposes and was parked in a garage. The details of this test have been described in our previous paper (8).

SEA SHORE EXPOSURE TEST-Another set of doors was exposed to the atmosphere at a coastal exposure test site located 10m from the ocean for 5 years from May, 1985 to July, 1990. The site was located on the coast in southeast Okinawa.

MODIFIED VOLVO TEST-Another set of doors was exposed at Chiba Works of Kawasaki Steel Corp. The test site is located 10m from the ocean. In this test, sea water was sprayed for 10min. twice a week (Modified Volvo Test). The test was conducted from 1985 to 1988.

CYCLIC CORROSION TEST-For cyclic corrosion tests, bottom portions of the door (hem) were cut away and placed in a cyclic corrosion test chamber. The cut edge was mended with a seal. The following two cycles were used in the test.

CCT1: Salt spray (35 ℃, 5%NaCl, 5hrs.) / Dry (70 ℃, 7hrs.) / Wet (50℃, 95%RH, 12hrs.) 1cycle/day

CCT2: Salt spray (35 ℃,0.1%NaCl, 6hrs.) / Dry (50 ℃, 3hrs.) / Wet(50 ℃, 95%RH, 15hrs.) 1cycle/day

PERFORATION CORROSION EVALUATION-The inner and outer steel sheets were taken from the door hem. Paint remover (alkaline type) and ammonium citrate were used to remove the paint and corrosion products, respectively. Various area of the sheets were measured to determine the maximum thickness reduction by corrosion. From some areas of the door hem, cross sectional samples were cut and mounted in plastic holder to study the progress of corrosion.

CORROSION PRODUCT ANALYSIS-The corrosion products removed from the door hem flanges were analyzed by X-ray diffraction. The micro X-ray diffraction method was applied for the analysis of the inner and outer steel sheets taken from the door hem flange within the range of parts of 100μm in diameter.

EXPERIMENTAL RESULTS

CORROSION PROGRESS (sheet thickness reduction) AND CHANGES IN CORROSION PRODUCTS- It is generally believed that perforation corrosion starts from closed structures, such as lapped and hemmed portions, where little or no paint can be applied. Many automobile manufacturers employ sealers, adhesives and wax injection to reduce penetration by corrosive water. In this experiment, only the sealer was applied. This was done to simulate defects of the adhesive and imperfect wax injection. The sealer was necessary to avoid the corrosion at the cut edge. In the field vehicle test, obvious perforation corrosion (the sheet thickness was 0.8mm) was recognized after 2.5 years of the test on the cold rolled steel sheet. On the Zn-Ni steel sheet, the maximum thickness reduction was only 0.18mm after 8 years. Figure 1 shows a schematic diagram of the corrosion products identified by the micro X-ray diffraction technique. In the figure, Locations 1-4 correspond to the order of corrosion progress, which was suggested by the amount of thickness reduction (figure 2) and kinds of corrosion products. Figure 2 was a cross section of an outer panel facing the inside of the hem inside. The sample was prepared after taking the flange apart. The numbers correspond to the portions indicated in Figure 1. Location 1 showed only white Zn corrosion products ($ZnCl_2 \cdot 4(OH)_2$), suggesting the beginning of corrosion. Location 2 showed some Fe corrosion products with less amount of Zn corrosion product, although the thickness reduction was less than 0.01mm. Location 3 was covered with β- and γ-FeOOH, Fe_3O_4 and ZnO. By this time, the Zn-Ni coating had disappeared and the thickness reduction had become measurable. At Location 4, significant thickness reduction was measured, and no Zn corrosion products were found. It is reported that Fe corrosion products, such as β- and γ-FeOOH, and amorphous, tend to change to stable α-FeOOH (9), which was found at Location 4. From these results, it can be said that the corrosion started at Location 4, where corrosive water was obtained from inside the door. Corrosion then proceeded along with the gap between the inner and outer steels toward Locations 3, 2, and 1, in that order.

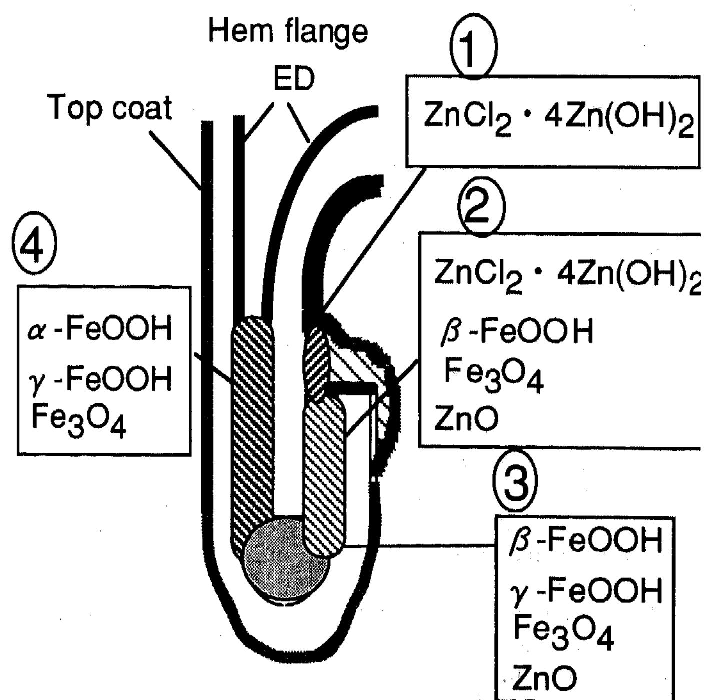

Figure 1 Schematic of corrosion products in door hem flange of Zn-Ni alloy coated steel after field test for 8 years

EFFECTS OF CORROSION TEST CONDITION ON THE CORROSION PRODUCTS-Similarly to the studies conducted in Figure 2, thickness reductions and the identification of corrosion products were conducted on the hem flanges tested in all environments. The corrosion products were the same as those found in the door hem of the field monitor vehicle. Moreover, the cross-sectional studies indicated similar corrosion behaviors to those shown in Figure 1. This suggests similar corrosion mechanisms under all the test conditions.

EFFECTS OF CORROSION TEST ENVIRONMENTS AND Zn COSTING ON CORROSION RATE-Figures 3 and 4 show the variation of thickness reduction with time in the various tests. The thickness reductions of the cold rolled steel are linear with time in the all tests, and the extrapolations of the linear line pass through the origin. The thickness reductions on the Zn-Ni alloy are also linear with time; however, the lines do not pass through the origin, indicating the existence of an incubation period. In the incubation period, the thickness was reduced within the Zn coating, and only Zn corrosion products were identified by X-ray diffraction analysis. After the incubation period, the thickness reduction rate was rather low up to a 0.02mm thickness reduction. In this period, the corrosion products consisted of both the Zn and Fe types. Above 0.02mm, the reduction rate became high and only Fe corrosion products were detected. This corrosion behavior of the Zn-Ni alloy is summarized in Figure 4 for the case of the field vehicle test. These findings indicate that perforation corrosion proceeds in the following steps:

1) The steel is completely protected by the galvanic reaction of the Zn coating and by Zn corrosion products.
2) The steel thickness reduces at a low rate. The steel surface is covered with fewer protective Zn and Fe corrosion products.
3) The steel thickness reduces at a high rate. Only Fe corrosion products are present on the steel surface.

Table 1 shows the corrosion rate in each step. It is obvious that the corrosion rate increases and the effect of the Zn coating decreases with an acceleration of the corrosive environment. Table 2 shows the corrosion acceleration ratios when the corrosion rate of the Zn-Ni alloy in the field vehicle test is considered to be 1. The ratio is obtained for each step of the corrosion process, although the cold rolled steel has only one step. These data indicate that corrosion acceleration is more effective in increasing the corrosion rate with the Zn-Ni alloy than with the cold rolled steel. For instance, CCT 1 accelerates the corrosion rate of the Zn-Ni

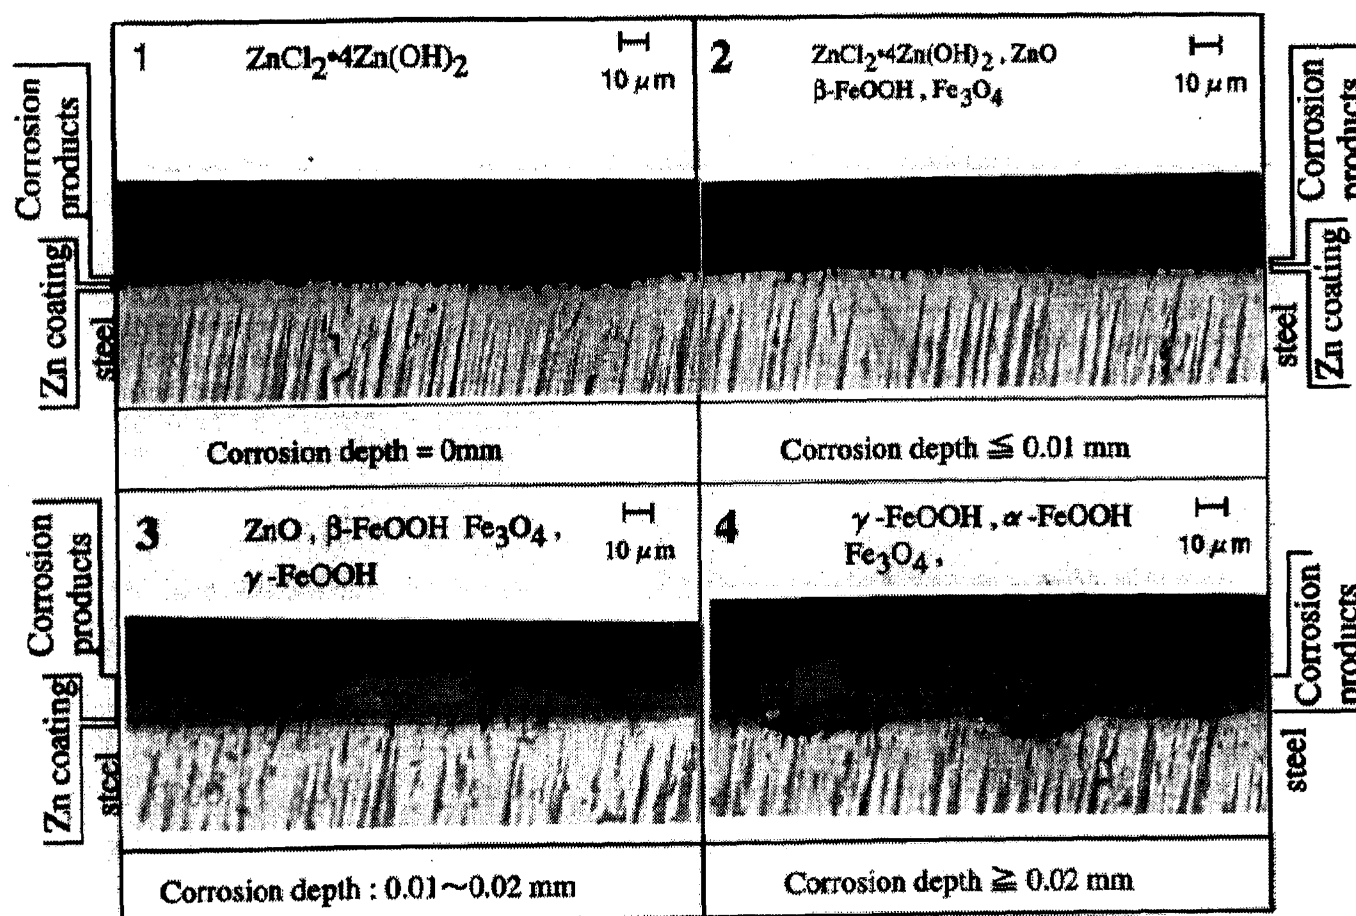

Figure 2 Correlation between corrosion products and corrosion depth at several stages of corrosion on Zn-Ni alloy coated steel.

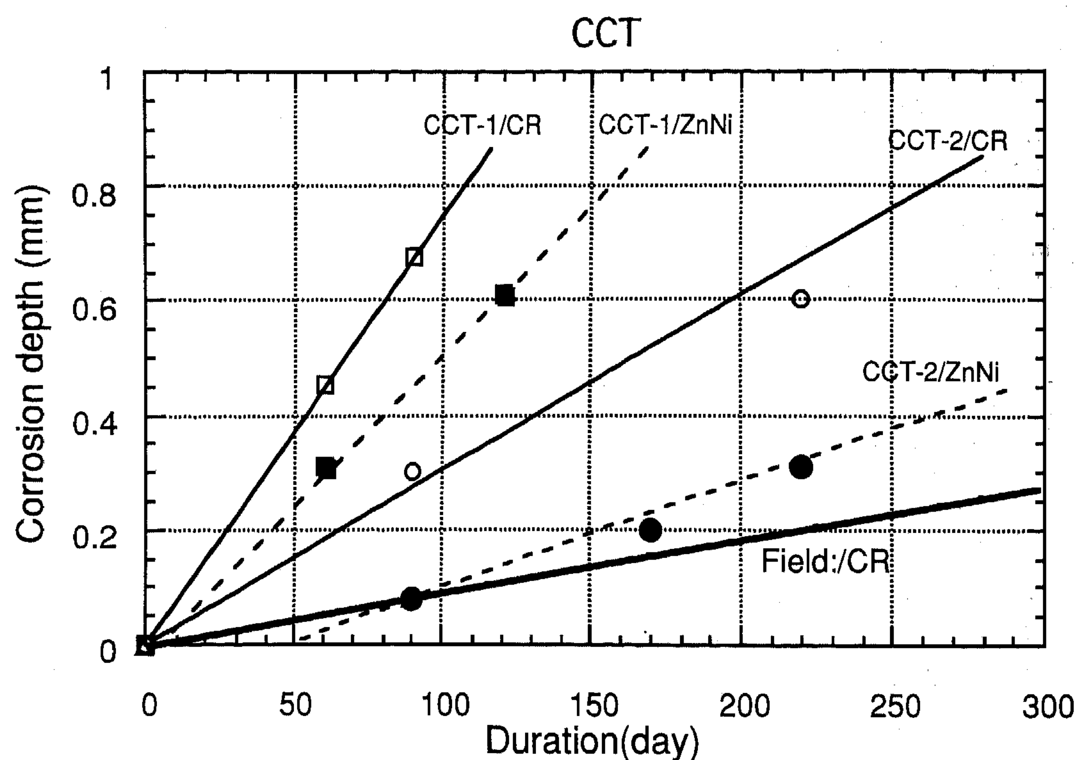

Fig.3 Comparison of corrosion behavior of Zn-Ni alloy coated steels (Zn-Ni) and cold rolled steels (CR) in cyclic corrosion tests

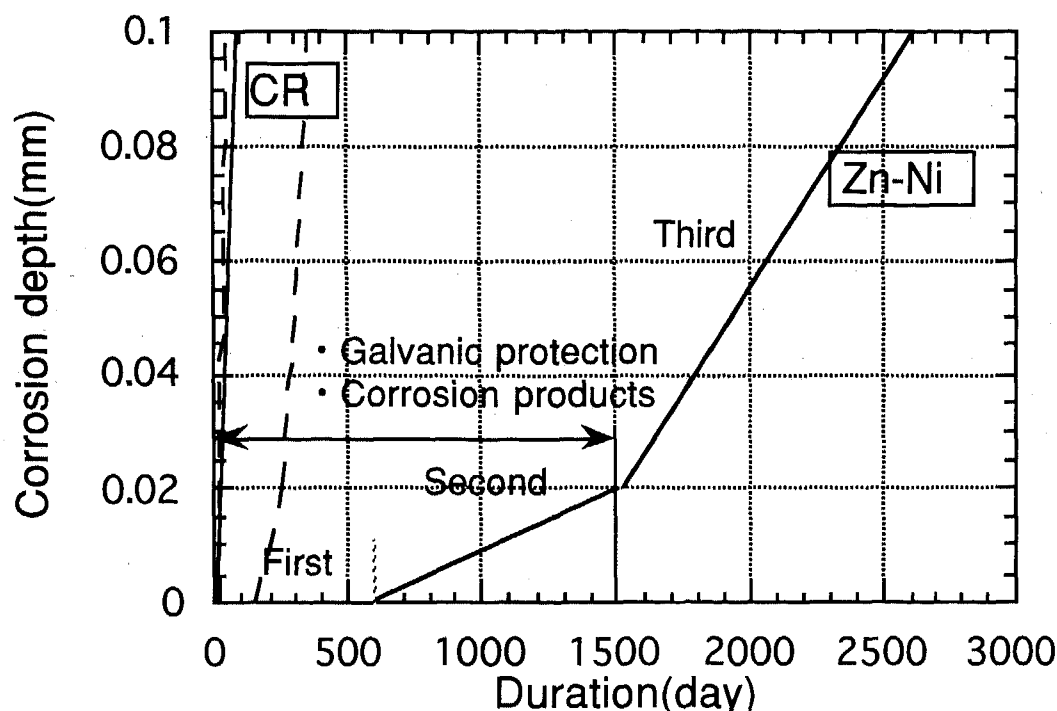

Fig.4. Estimated corrosion behavior of Zn-Ni alloy coated steel applied to door hem

alloy in the field vehicle test 60 to 110 times, where as the acceleration is only 8 times with the cold rolled steel. Table 3 shows the corrosion rate of the Zn-Ni alloy when the rate on the cold rolled is 1. This clearly shows the effect of the Zn coating, which is most obvious in the first corrosion step with the field vehicle test.

DISCUSSION

PERFORATION CORROSION MECHANISMS OF Zn COATING-As shown in Figure 4, the significance of the corrosion mechanism of the Zn coated steel is the existence of an incubation period (first step) and initial slow corrosion (second step) due to the presence of protective Zn corrosion products. In these steps, the corrosion rate is influenced by the Zn coating weight and alloying element. In the third step, corrosion is governed by only the differential aeration cell, and the effect of the Zn coating is minimal. In this step, the Zn coated and uncoated steel were expected to show the same corrosion rates. However, the rate was slower with the Zn coated steel. This may be explained by the existence of a small amount of Zn in the corrosion products, which would lower the corrosion reaction rate or retard the movement of corrosion products (10).

INFLUENCE OF CORROSION TEST CONDITIONS OF THE CORROSION RATE-In order to discuss perforation corrosion more quantitatively, the corrosion rate, in Section 3.3 was converted to a corrosion rate ratio, which is defined as follows:
Corrosion resistance ratio
={Time to reach a given corrosion depth in coated steel sheet}/{Time to reach the same corrosion depth in cold rolled sheet}

The calculations were conducted at the corrosion depths of 0.02mm (effect of Zn coating) and of 0.8mm (perforation depth). The results are shown in Table 4. The values are small in the accelerated test. The effect of the Zn coating was evaluated to be 72 in the field vehicle, but it was only 2.2 in the CCT 1. Since the corrosion products, and thus the corrosion mechanism, are the same in both tests, the difference may be attributed to the time duration of the effective corrosion current (i.e. wet time period) and/or by the intensity of the corrosion current, influenced by the resistance of corrosion current flow through the corrosion products. Moreover, the high NaCl concentration used in the accelerated test increases ionic conductivity, and thus the corrosion rate.

The corrosion resistance ratios evaluated at perforation were 9.2 in the field vehicle test and 1.5 in the CCT-1, and were smaller than those at the depth of 0.02mm. The small values are caused by the fast perforation corrosion rate of the steel substrate, which reduces the effect of the Zn coating evaluated at 0.02mm. The effect of acceleration was also seen in the ratios evaluated at perforation.

In general, cosmetic corrosion is evaluated under relatively dry condition (6). In such dry environments, slight variations in the test conditions do not influence the corrosion rate. Thus, the corrosion rate in the field condition

can be predicted easily by exposure tests and cyclic corrosion tests. However, the predictions are not as easy for the perforation corrosion rate, because the corrosion rate is significantly influenced by the corrosion condition. The results obtained in this study provide some information for the prediction of the perforation corrosion resistance.

An approximate time to reach the perforation corrosion depth can be calculated from the time required for perforation of cold rolled steel and the corrosion resistance ratio of the specific Zn coated steel sheet. In other words, the perforation corrosion rate of the cold rolled steel obtained under the specific corrosion conditions (the rate varying with the location and shape of the installed part, amount of corrosive water, amount of paint available, and others) is compared with the rate shown in Table 2 to estimate the severity of the corrosion condition. The door hem used in

$$= \frac{\text{[Time to reach a given corrosion depth in coated steel sheet]}}{\text{[Time to reach the same corrosion depth in cold rolled sheet]}}$$

this test is classified as a rather mild corrosion condition (4). The quarter rear and hood outer may be severer than the hem tested in this work and may be of the same severity as the Okinawa exposure condition. If the Zn-Ni alloy is applied at a coating weight of 20 g/m^2 in a specific part, one can easily predict the corrosion depth by using the corrosion resistance ratio shown in Table 4. Other Zn coatings and coating weights are applied in these and other parts, and information on these effects must be obtained. In the future, such information can be utilized for the selection of suitable Zn coatings and coating weights to obtain sufficient corrosion protection.

SUMMARY

Perforation corrosion starts from closed structures, such as lapped and hemmed portions where paint is difficult to apply. Thus, the perforation corrosion rate is strongly influenced by the degree of corrosion severity, which is difficult to characterize or define. In this work, corrosion tests were conducted under various conditions with Zn-Ni alloy coated steel and cold rolled steel. Based on the results, a corrosion rate prediction method was suggested.

Through the course of these studies, it was found that the significance of Zn coating was to provide an incubation period and reduce the corrosion rate at the beginning of corrosion. This Zn coating effect is minimized under accelerated (severe) corrosion. The corrosion rate of the Zn coating can be estimated from the above relation and the corrosion rate of the cold rolled steel in the same corrosion condition.

Stabilization Requirements for T409 (UNS S40900) Ferritic Stainless Steel

Ivan A. Franson and J. D. Fritz
Allegheny Ludlum Corp.

Copyright 1997 Societv of Automotive Engineers, Inc.

ABSTRACT

Type 409 (UNS S40900) ferritic stainless steel was developed more than 30 years ago specifically for automotive exhaust systems where it has subsequently found extensive use. Performance of this 11 Cr- Ti alloy for the most part has been good. However, recent failures of exhaust system components demonstrate that the T409 alloy can become sensitized in weld heat-affected zones and suffer intergranular corrosion. Results of a broad study of commercial heats illustrate that weld heat-affected zones of T409 are stabilized when titanium plus columbium or titanium alone meets the criterion:

$$Ti + Cb \geq 0.08 + 8(C + N)$$

Experimental procedures used to establish this criterion are described, including development of a test to detect sensitization. Also the benefits of stabilizing with titanium in combination with columbium are discussed.

INTRODUCTION

The T409 alloy (UNS S40900) is a low chromium ferritic stainless steel which is used quite extensively in automotive exhaust systems. The ASTM compositional requirements[1] for this alloy are presented in Table 1.

Recently, it has been demonstrated that applications which expose welded T409 alloy to aggressive environments can result in intergranular corrosion (IGC) of the weld heat-affected zones. This form of corrosion which involves a rapid attack of the grain boundaries, can be initiated by exhaust system condensate. Figure 1 shows the cross section of an automobile muffler weldment which joins the muffler's cap, nipple, and tube. As shown, this cross section suffered IGC in the weld heat-affected zone (HAZ) of the tube, which resulted in the muffler prematurely falling off the automobile.

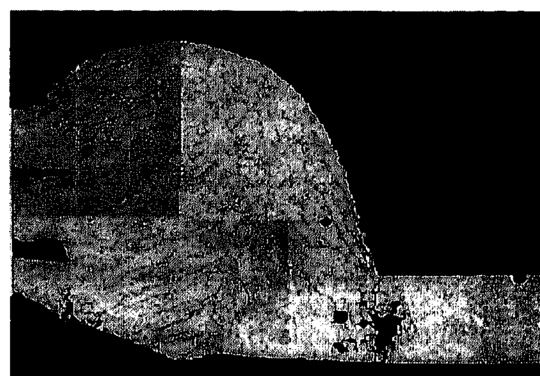

Figure 1. Weldment from failed muffler (8 X Magnification)

The mechanism which is responsible for producing a susceptibility to IGC in ferritic stainless steels is very similar to that which is operative in the austenitic alloys[2]. The precipitation of chromium

carbides (and chromium nitrides in the case of the ferritic alloys) at the grain boundaries of the alloy results in the depletion of chromium from adjacent regions. Because of this loss of chromium, the depleted grain boundaries become sites for rapid preferential attack when exposed to certain acidic environments. This process of producing chromium-depleted regions due to the precipitation of chromium-rich second phases is termed "sensitization".

For the ferritic stainless steels sensitization will typically occur after being heated to temperatures of 925°C or higher. At these higher temperatures there is a substantial increase in the solubility of carbon and nitrogen in the ferrite crystal structure. Upon cooling the solubility is strongly reduced resulting in the precipitation of chromium carbides ($M_{23}C_6$) and/or chromium nitrides (Cr_2N). In the temperature range of 925 to 700°C the rate of Cr diffusion is quite rapid which tends to replenish any Cr depleted regions. However, in the temperature range of 700 to 400°C the precipitation of carbides and nitrides will produce chromium depletion at grain boundaries. Hence any thermal treatment , such as welding, which takes the alloy to temperatures of 925°C or higher followed by cooling through the sensitization temperature range of 700 to 400°C could potentially produce sensitization.

In order to avoid the loss of corrosion resistance due to sensitization, commercial ferritic stainless steels are usually stabilized with additions of Ti, Cb, or Ti + Cb and alloy producers strive to keep the C and N levels to a minimum. The amounts of stabilizing elements required to prevent the sensitization phenomenon depends on how much C and N are present in the alloy. The more C and N which are present the more Ti, Cb, or Ti + Cb is required to prevent susceptibility to IGC.

As shown in Table 1, the ASTM stabilization requirement for T409 mandates the Ti% to be equal to (6 x C%) with a maximum Ti content of 0.75 wt%. The obvious shortcoming of this stabilization requirement is that it ignores the detrimental contribution of N which in a ferritic alloy is isomorphous with C. This results in the undesirable situation of being able to meet the ASTM compositional requirements and still be susceptible to IGC. This is demonstrated in Figure 1 where the muffler tube suffered IGC in the weld HAZ during routine automotive service even though the Ti%/C% ratio of 10 for this tube substantially exceeds the ASTM minimum of 6.

Because of this potential problem with the existing alloy specification, Allegheny Ludlum decided to undertake a study to determine what amount of stabilization is required to prevent IGC of welded T409 sheet material. In order to do this it was necessary to have a test method which would detect the susceptibility to IGC in the T409 alloy. Currently, no standard test methods are defined for low Cr ferritic stainless alloys. The ASTM A763-93 Standard Practices for Detecting Susceptibility to Intergranular Attack in Ferritic Stainless Steels does specify various test methods for evaluating higher Cr-bearing (>16%) ferritic stainless steels but these test methods are too aggressive for use with lower Cr alloys.

Although no standard test method exists for detecting sensitization of T409 material, various methods applicable to low Cr ferritic stainless steels have been reported in the literature[3,4,5]. These test methods are summarized in Table 2. The current investigation evaluated methods I and IV in Table 2 for use with commercial T409 alloys. Method IV was then used to determine the stabilization requirements of welded T409 sheet material.

EXPERIMENTAL PROCEDURES

Two of the reported test methods (I & IV) outlined in Table 2 were chosen for further investigation

Table 2. Test Methods Used For Detecting IGC Susceptibility of Low Chromium Ferritic Stainless Steels

to determine if they are appropriate methods for testing T409 production heats. Since the mechanism of IGC involves preferential attack of the Cr-depleted regions at grain boundaries, any test solution which will detect IGC must show a general corrosion rate which is a strong function of the Cr content of the alloy. A series of experimental Fe-Cr alloys was prepared in order to look at how the corrosion rate varies with Cr content using test methods I and IV. The Cr contents of the experimental heats and three production heats used in this experiment are summarized in Table 3. Samples of these compositions in the solution annealed (nonsensitized) condition were exposed to test methods I and IV.

** Production T409 Heats

The results of this testing, summarized in Figure 2, show that the Cu/ $CuSO_4$/H_2SO_4 test (method IV) produces a much larger increase in the corrosion rate with decreasing Cr content than the HNO_3 test. Because of this finding all subsequent work was done using method IV.

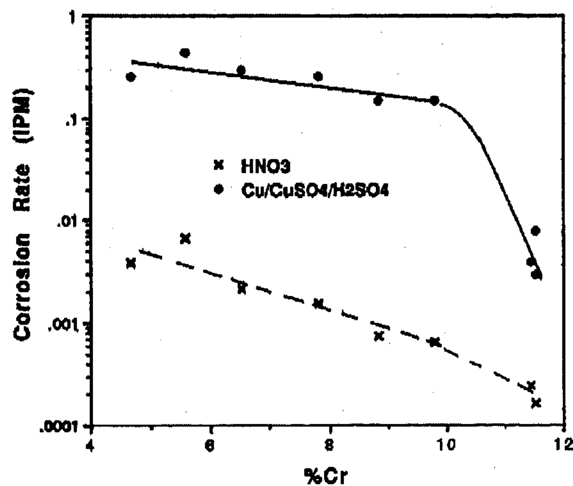

Figure 2. Plot of the General Corrosion Rate vs % Cr.

In order to verify that method IV does detect sensitization of commercial T409 alloys an experiment was conducted using three additional production heats which were stabilized to different levels based on the ratio, Ti/ (C + N). Samples from these three heats were first heat treated to 1200°C to put all C and N into solution and then aged for various times at 600°C. After a specified aging time each sample was tested using method IV. Samples were weighed before and after the test and the corrosion rates determined in inches per month (IPM). The results of this testing are summarized in Table 4. A graph of the corrosion rate versus aging time for heats A and B is presented in Figure 3.

C	10.0 hrs	3.8	0.0300

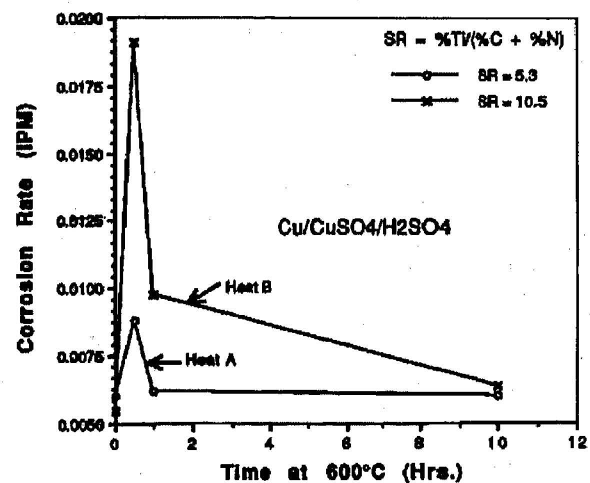

Figure 3. T409 samples held at 1200°C/1hr./WQ and aged at 600°C for various times.

In order to determine if the observed increase in corrosion rate for the short aging times was in fact the result of intergranular attack, the cross sections of the exposed samples were examined. The cross sections from Heat B are shown in Figure 4. These cross sections demonstrate that intergranular attack does occur after the 30 minute aging cycle and the resistance to intergranular attack is restored by the 10 hour aging cycle. As discussed below these observations indicate

that the test method IV does indeed detect susceptibility to IGC with T409 production heats.

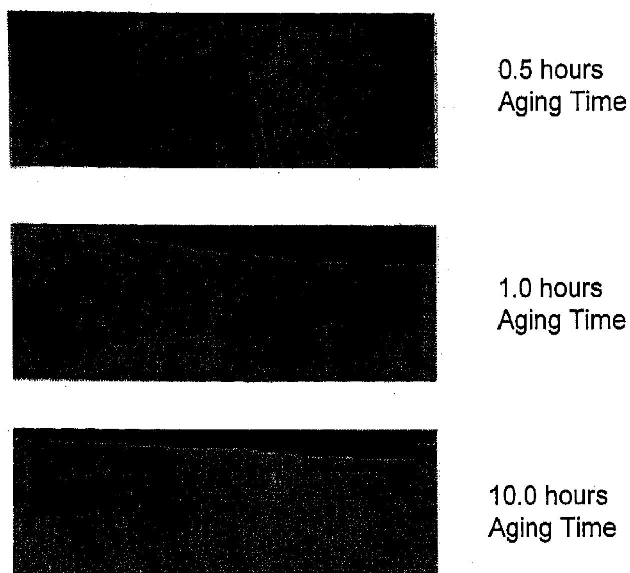

Figure 4. Cross Sections of Heat B after exposure to the $Cu/CuSO_4/H_2SO_4$ test solution. (95X mag)

A sample of the same kind of weldment as that shown in Figure 1 was cut from a muffler which was never put into service. This muffler was chosen because the degree of stabilization of the material used to fabricate the muffler was rather low with a Ti/(C + N) ratio of 5.3, 6.6, and 5.7 for the cap nipple and tube respectively. This sample was tested using method IV to see if the test could detect IGC. The cross section of this muffler weldment after the test exposure is shown in Figure 5.

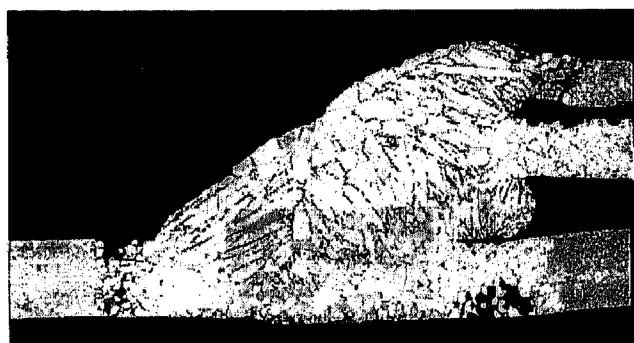

Figure 5. Muffler Weldment with no service. Microstructure Following Exposure to $Cu/CuSO_4/H_2SO_4$ (8X Magnification)

After having qualified a test method for determining susceptibility to IGC, a program was initiated to use this test method on various production heats in order to define the stabilization requirements for the T409 alloy. Samples from thirty-six different production heats of T409 sheet material were welded using an autogenous gas tungsten arc welding process. This group of heats included material which was only stabilized with Ti as well as material stabilized with additions of both Ti and Cb (dual stabilized). Care was taken to avoid any full penetration during welding. After welding the samples were pickled in a 10% HNO_3/2% HF solution at 60°C for 2 minutes and were then tested using method IV.

After testing the samples were mounted and polished to expose the cross section of the weld area and microscopic examination was used to determine if the specimen suffered IGC at the weld or HAZ. The cross sections were classified as "no attack" if no evidence of IGC could be found. Samples which suffered obvious intergranular attack were classified as "IG attack" and samples which showed shallow grain boundary grooving were designated "grooved GB". Typical examples of these three designation are shown in Figures 6-8. The results of this investigation are summarized in Table 5. It should be noted that all the heats which were tested in this investigation meet the current ASTM A240 stabilization requirements of Ti=(6xC).

RESULTS AND DISCUSSION

The results summarized in Table 4 and Figure 3 show that the corrosion rates of the test heats increase substantially following the 0.5 hour treatment at 600°C. Also, the corrosion rate after this aging period depends on the stabilization ratio, Ti/(C + N). For example, the heat with the 3.8 stabilization ratio completely disintegrated while the heats stabilized to 5.3 and 10.5 had corrosion rates of 0.0191 and 0.0088 IPM respectively. The high corrosion rates measured after short aging times are restored by longer aging periods. As shown in Figure 4 these high corrosion rates are the result of IGC. All these observations are consistent with the formation of Cr depleted regions during the short aging times which then heal by the back diffusion of Cr during the longer aging times. These results demonstrate that the IV test method does detect Cr depleted regions with commercial T409 alloys and can be used to detect susceptibility to IGC.

Figure 5 demonstrates that the IV test method does detect susceptibility to IGC in HAZ of actual muffler weldments. Note that the attack in Figure 5 is very similar in severity to the attack which occurred during service (see Figure 1). These observations suggest that the test results measured with method IV do parallel service performance.

The data which are summarized in Table 5 were plotted as (%Ti + %Cb) versus (%C + %N) to determine if a relationship could be found which would separate the samples which suffered IGC form those that pass the test. The plot of these data, which is presented in Figure 9, reveals that there is a well defined separation between the samples which passed the test and those which suffered IGC and/or grain boundary grooving. The dual stabilized heats (circled data points in Figure 9) also show a well defined separation between the heats which suffered IGC and those which pass the test. The boundary between the "pass" and "IG attack" heats is independent of whether the heats are dual stabilized with Ti + Cb (circled data points in Fig. 9) or just stabilized with Ti. Based on the straight line which separates the "passes" from the "IG attack", the stabilization requirement for T409 Ferritic stainless steel can be given as;

$$\%Ti = 0.08 + 8(\%C + \%N) \quad (1)$$

(for Ti stabilized heats)

$$(\%Ti + \%Cb) = 0.08 + 8(\%C + \%N) \quad (2)$$

(for dual stabilized heats)

Recent work by Sunomiya et al [6] gives close confirmation to this stabilization requirement for T409 alloy.

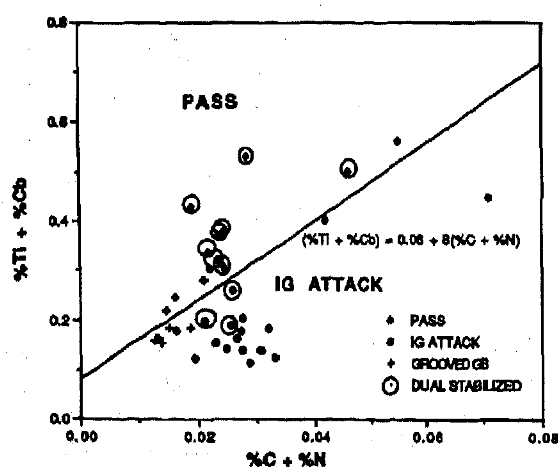

Figure 9. Welded Production Heats

Within the range of chemistries which were tested in this investigation, use of Ti + Cb provides an alternate means of achieving stabilization. Dual stabilization is currently employed for several ferritic stainless steels included in ASTM A240[1]. Dual stabilization provides the alloy producer with an alternative means of achieving a high degree of stabilization without having to increase the Ti content of the alloy. This can be a big advantage to the user because minimizing the Ti concentration of the alloy will reduce the level of Ti precipitates which can degrade surface quality and add to the processing costs. It has also been shown[7] that the dual stabilized T409 product offers improved formability over product which has been stabilized solely with Ti.

CONCLUSION

Based on this work the following conclusions can be drawn about IGC of the T409 alloy and test methods for evaluating susceptibility to IGC.

1. The existing stabilization requirement given in the ASTM A240 specification for T409 alloy does not consider the detrimental effects of N.

2. Muffler weldments fabricated from T409 sheet material which meets the existing ASTM specifications can be susceptible to IGC if the degree of stabilization is inadequate and a corrosive environment is present.

3. Although no standard test method currently exists for low chromium ferritic stainless steels, the boiling Cu/0.5% H_2SO_4/6% $CuSO_4$ test conducted for 20 hours does detect sensitized grain boundaries with T409 production heats.

4. Based on the results from the Cu/0.5% H_2SO_4/6% $CuSO_4$ test, the minimum stabilization requirements for Ti or (Ti + Cb) to prevent susceptibility to IGC in T409 alloys is:

$$\%Ti = 0.08 + 8(\%C + \%N) \quad (1)$$

(for Ti stabilized heats)

$$(\%Ti + \%Cb) = 0.08 + 8(\%C + \%N) \quad (2)$$

(for dual stabilized heats)

5. The use of dual stabilization provides an alternate and highly effective means for attaining a proper degree of stabilization without the detrimental effects of increased Ti levels.

Ventilated Brake Rotor Air Flow Investigation

Michael D. Hudson and Roland L. Ruhl
University of Illinois at Urbana-Champaign

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Air flow through the passages of a Chrysler LH platform ventilated brake rotor is measured. Modifications to the production rotor's vent inlet geometry are prototyped and measured in addition to the production rotor. Vent passage air flow is compared to existing correlations. The inlet modifications show significantly improved vent air flow, over the production rotor. The result improvement in heat transfer and rotor cooling is reported. These benefits in performance should be attainable at very low increases in production cost.

1.0 INTRODUCTION

One of the basic functions of a brake system is to slow a vehicle. In doing so, vehicle kinetic energy is transferred to thermal energy via the friction between brake pad and brake disc (or drum). Brake discs absorb such a large amount of thermal energy in a short period of time (braking) that they effectively serve as energy storage devices. While this large heat input must be dissipated quickly to allow for additional braking when necessary, the effective time constants for each process are far from equal. Thus, brake discs are designed with two major factors in mind:

(1) Thermal Capacitance: Energy Storage
(2) Heat Transfer: Dissipation of heat primarily by forced convection.

In addition, modern cars are designed to minimize weight, including brake rotor weight. Although smaller rotors weight less and typically cost less to manufacture, their thermal capacity is reduced. Furthermore, vehicle down sizing and front wheel drive components can compromise available air flow to the brake discs. Thus, the cooling characteristics of brake systems are increasingly important, and should be maximized with minimal cost and weight penalties.

For years, ventilated brake rotors have been used for their weight savings and additional convective heat transfer from the air passages between the rotor rub cheeks (passages lacking in solid rotors). However, the amount of additional cooling due to this internal air flow is not well defined and depends on the particular brake rotor's geometry and the cooling air flow conditions around the brake assembly.

2.0 PROBLEM STATEMENT

With the aid of Chrysler Corporation, investigation of ventilated brake rotor vane air flow is undertaken herein. The goal of this investigation is to measure the current vane air flow for the given test rotor at various speeds (simulating 30, 45, 60 mph), and to improve this vane air flow to increase brake disc cooling.

Test Rotor

Brake rotor vane air flow is examined for the Chrysler LH-series front brake disc (see Figures 2.1 and 2.2). At the inlet, air flow into the vane is drawn only from the inboard side of the rotor. In addition, the air must flow by the knuckle and turn approximately 90 degrees into the entrance of the rotor intake. Since the bearing hub and knuckle are not axisymmetric, the inlet clearance between the inner rub cheek and the bearing to knuckle mounting varies around the circumference. This inlet restriction due to the mounting/suspension components is accepted as a given, unalterable geometric constraint.

Figure 2.1: Test Rotor - Basic Geometry

Also, the approximate 90 degree inlet turn is believed to cause loss and possibly flow separation at the inlet, thus reducing the effective inlet area and resultant vane flow.

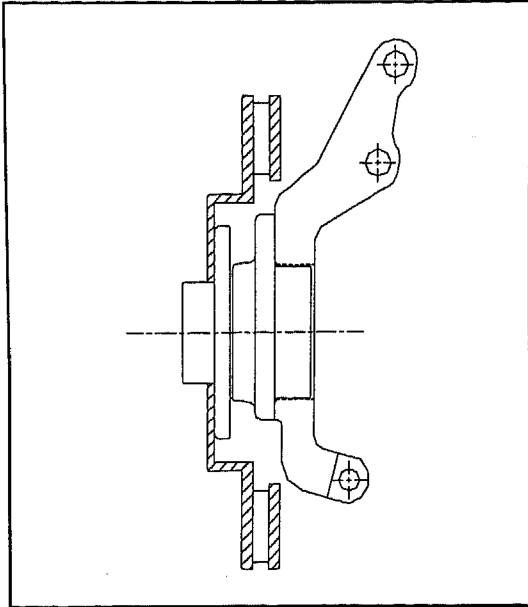

Fig 2.2: Test Rotor - Basic Mounting Geometry

Focus

Improving the flow of air through the brake rotor vanes centers on two primary factors:

(1) The centrifugal pumping aspects of vane orientation (i.e., straight, radial vs. curved, involute or angled vanes)
(2) Flow conditions at the inlet, including inlet geometry

First, the straight radial vanes of the current LH front brake rotors do not yield the best pump from the vane velocity/cooling standpoint [3,4]. However, involute or angled vanes are more difficult to manufacture and the loss of symmetry for such vanes results in left and right hand versions of the brake rotor. The associated production cost increase has effectively ruled out any non-symmetrical rotor designs. For these reasons, little consideration is given to vane orientation.

Focus is placed on the inlet flow conditions and inlet design. All modifications are chosen to result in symmetric brake rotor geometry. To avoid production cost increases, modifications should allow rotors to be horizontally sand cast, just as current production rotors.

3.0 BACKGROUND

Brake rotor vane flow correlations to estimate heat transfer coefficient have long been used in brake system thermal modeling. Unfortunately, these models can be only as accurate as estimates of heat transfer coefficients and boundary conditions allow. In general, these conditions require empirical adjustment to make the model fit actual brake temperature data. From a theoretical standpoint, estimating the air flow velocity (to predict heat transfer coefficient) over the "exposed" brake surfaces is almost impossible.

The literature to date suggests that one directly measure rotor air flow (as best possible) or turn to an empirical relation based on prior published investigations. Currently, there are two primary empirical relations for ventilated brake disc air flow. Both have been accepted as probative over the years, in one form or another. Both are (loosely) based on Reynolds Analogy.

The first relation for average vent velocity is from Sisson [2] and quoted later in Sheridan et al.[1].

$$V_{ave} = \xi\,\omega\,\frac{D_o}{2}\,, \quad \xi = \sqrt{-0.020 + 0.908D_i - 0.202D_i^2}$$

where ξ = correlation factor; ω = rotational rate; D's = the diameters at inlet & outlet. Inlet diameter must be in meters. Sisson's correlation is valid over the range of rotors tested, from 23 to 41 cm outer diameter, 10 to 18 cm inner diameter, and 0.6 to 2.5 cm vane widths. The number of vanes varied from 20 to 40. All models had straight radial vanes.

In addition, Sisson measured the vent heat transfer coefficient, by insulating all but the interior passages of the rotor. [Heat transfer coefficient, h_{air} is the ratio of heat transfer at the surface to the temperature difference; Nusselt number, Nu is a nondimensionalized form of h_{air};]. Sisson's heat transfer relation is

$$Nu = 0.045Re^{0.8}(D_o/2)^{0.2}\left[1 + 6.6(D_o/2)^{0.8}\right]$$

where Nusselt number, Nu is based on a characteristic length equal to rotor outer radius ($D_o/2$) and Reynolds number, Re is based on that same radius and average vent velocity from the first equation (above). However, some of Sisson's graphical data might suggest somewhat higher values for vent heat transfer than predicted by the above equations.

The other prominent vent air flow correlation comes from Limpert [3].

$$V_{ave} = \frac{V_{in}}{2}\left(1 + \frac{A_{in}}{A_{out}}\right), \quad V_{in} = 0.001655\sqrt{D_{out}^2 - D_{in}^2}$$

where V is mean air velocity; D is diameter in meters; A is vent area, all at inlet and outlet.

Limpert's average velocity values are roughly one-third lower than Sisson's. Limpert also splits two cases to estimate vane heat transfer coefficient, one for turbulent flow and one for laminar flow. For laminar flow ($Re < 10000$),

$$Nu = 1.65Re^{0.33}(d_h/l)^{0.33}$$

For turbulent vent flow ($Re > 10000$),

$$Nu = 0.0204\left[1 + (d_h/l)^{0.67}\right]Re^{0.8}$$

where d_h is hydraulic diameter of a vent passage; l is the length of a passage. Nusselt number is based on hydraulic diameter. Reynolds number is based on hydraulic diameter and Limpert's average vent velocity correlation. (Prandtl number appears in the original equation for laminar flow but has been given the standard 0.7 constant for air and combined in the proportionality constant).

Limpert's turbulent vane flow heat transfer correlation mirrors Sisson's in basic form but represents a more rigorously non-dimensionalized Reynolds' Analogy relation as opposed to a more empirical correlation. Either relation is viable, especially since vent inlet flow conditions are so complex and the influence of these complex geometric factors cannot be correlated in any simple way [10].

Both Sisson's and Limpert's relations for vent heat transfer coefficient have been widely used and agree within five percent at 600 rpm. (Limpert's coefficient is less sensitive to rotational rate than Sisson's). Though neither air flow estimate accounts for splash shields, suspension mounts, or other possible inlet restrictions, both provide an excellent reference for relating vent flow to vent heat transfer.

4.0 TURBOMACHINE ANALYSIS

Flow in the Rotor Vanes

The general theory and solution for the average air flow in the rotor vanes centers on these standard assumptions for turbomachine analysis:

(1) Air is an ideal, incompressible, inviscid fluid where gravitational potential energy is negligible.
(2) All shaft work is transferred to the fluid, i.e. no loss.
(3) Mean air flow is 2-D, axisymmetric flow for an ideal impeller with an "infinite number of infinitely thin blades", i.e. along a "mean flow surface" (streamline).

In this case, the mean flow surface is a path outlined by the rotating, straight radial rotor vane, i.e. the relative motion of the air is in the same direction as the rotor vane surfaces.

Based on the First Law of Thermodynamics, an ideal rotor's air pumping equation is represented as follows [see also ref. 14,15,17].

$$g\,(h_2^o - h_1^o) = \frac{c_2^2 - c_1^2}{2} + \frac{u_2^2 - u_1^2}{2} + \frac{w_1^2 - w_2^2}{2}$$

where c is the absolute air velocity; component velocities w and u are relative vane velocity and peripheral (tip) velocity, respectively; h^0 is enthalpy and g is the gravitational constant.

The first term on the RHS of the equation is the kinetic energy change due to the work input. The combination of terms containing peripheral and relative velocities is the static pressure change from the vane inlet to outlet. (Recall Bernoulli's Equation along a streamline). The relative velocity term represents the diffusion or retardation of the fluid relative to the impeller. The peripheral velocity term represents the change in static pressure due to the centrifugal force acting on the fluid.

It can be seen from the above equation that increasing the inlet pre-rotation (u_1) and reducing the relative velocity at inlet (w_1) will decrease the "effective" opposing pressure gradient. Note the trade off: minimum inlet relative velocity makes for a more efficient pump, but higher relative velocity over the length of the passage between the rotor rub cheeks makes for better cooling.

Since pumping work is negligible compared to engine output, any work penalties for higher relative velocities are not of practical concern. Higher vane flow velocities for cooling outweigh rotor pumping efficiency. In addition, the next section will show that accelerating the inlet stream may also help reduce flow separation at the inlet. Flow separation at the inlet can dramatically effect impeller performance by greatly reducing the effective inlet area.

Inlet Flow

Inlet flow geometry is highly case-specific. Complex inlet conditions (Figure 2.2) make modeling extremely difficult. Even the most extensive published analyses usually reduce inlet design to a few rules of thumb. Some general guidelines for turbomachine inlet design follow:

(1) *Smooth the transition* at the inlet to reduce loss or separation on the lip.

(2) *Accelerate the main stream* to combat separation (favorable pressure gradient tends to prevent excessive thickening of the boundary layer on the surface).

(3) *Impart fluid pre-rotation* and direct flow into the rotor vanes with minimum loss via the addition of guide vanes, inducer, or pre-impeller.

Loss associated with the flow around the inlet bend is small relative to loss from flow separation at the corner of this bend, which can result in partial or full blockage of the inlet.

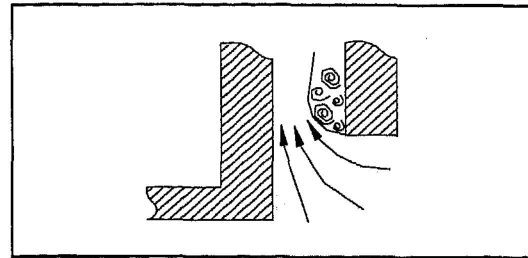

Figure 4.1: Flow Separation at Inlet

This accumulation of low-energy air can distort the effective air passage shape, thus reducing the total flow through the rotor (Figure 4.1). Thus, the inlet design should turn the air flow from the axial to the radial direction with minimum loss or separation [16].

5.0 DESIGNS

From the above turbomachine analysis, the following design modifications were selected to combat inlet separation by smoothing the intake, accelerating and directing the inlet air flow to the rotor vanes.

(1) Inlet lip chamfer/radius - Figure 5.2.

(2) Rounded inlet horn - Figure 5.3.

(3) Pre-impeller by means of extending the rotor ribs down into the inlet for greater active blade length - Figure 5.4.

All designs chosen to maintain rotor symmetry and manufacturability from a casting standpoint.

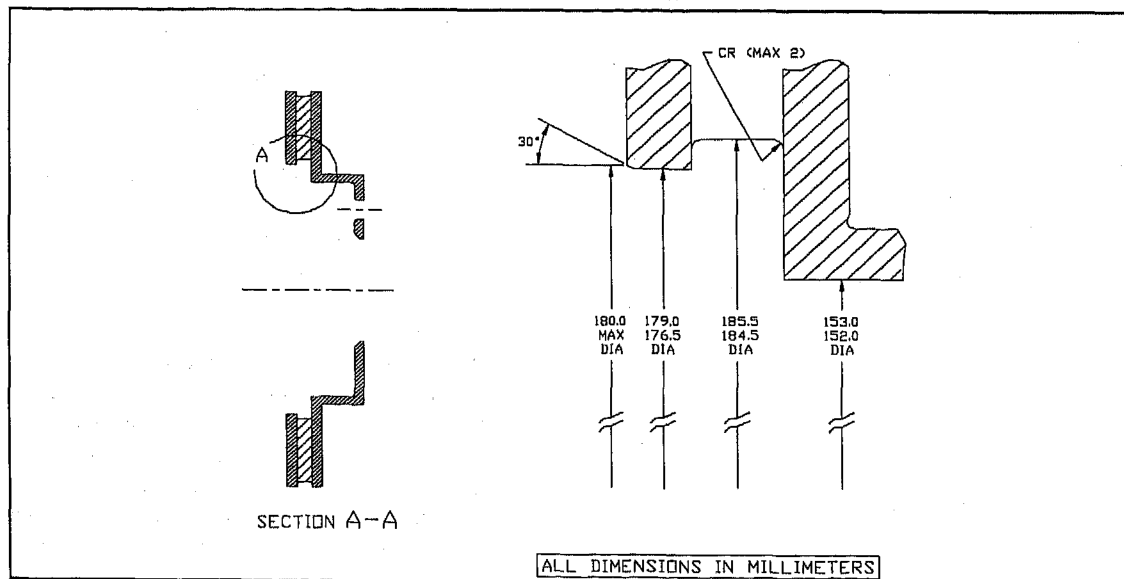

Figure 5.1: Original Rotor - Basic Inlet Geometry

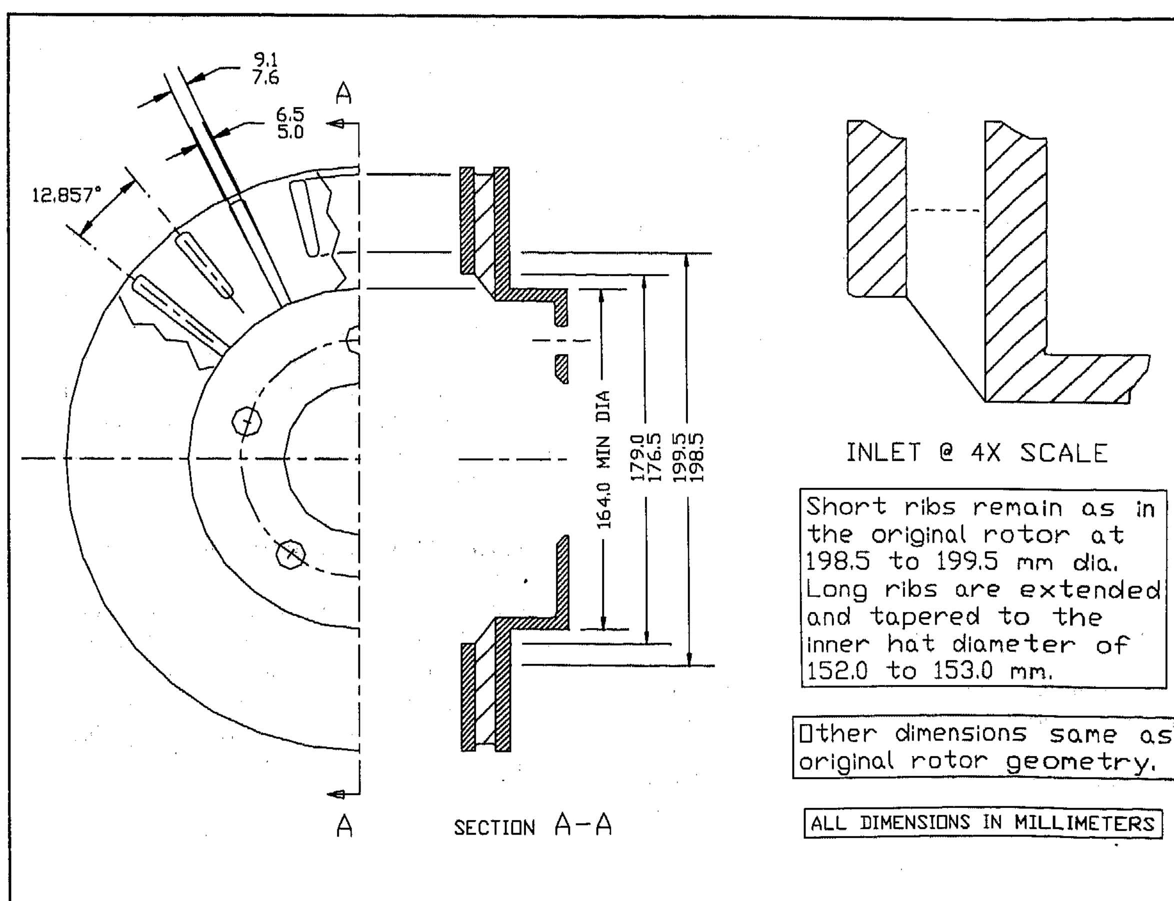

Figure 5.4: Rotor with Pre-Impeller Ribs

6.0 EXPERIMENTAL STUDIES

At rotational rates equivalent to 45 and 60 m.p.h., the production rotor outlet vane flow was measured for the current production rotor and all inlet modifications herein. Each rotor's outlet flow profile was measured at the various speeds with and without closed ventilation passages.

Direct measurement of interior vane flow was not accomplished due to the small vane cross-section and location of the associated measurement components in the rotating brake disc. Flow measurement at vane inlet is extremely difficult due to problems adequately defining the flow direction in the complex geometry (three-dimensional flow, high shear). Ventilated brake rotor vane air flow was measured at the outlet, where flow is two-dimensional (w/o wheel and tire blockage) - see Figure 6.1. Magnitude and direction of the outlet flow vector are measured using a three-holed wedge-shaped pitot-static pressure probe. Probe head design was adapted from a Bryer and Pankhurst [21] small wedge design, originally designed specifically for turbomachine research [21,22,23].

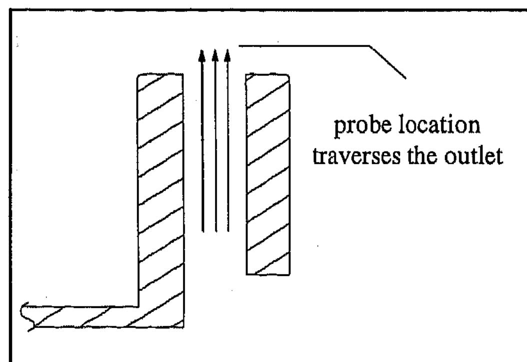

Figure 6.1: Two Dimensional Outlet Flow

Rigid steel framing served to mount the knuckle and modified bearing hub. The rotor was located on the wheel studs as on the actual automobile. And the bearing hub assembly was fit with a drive pulley and rotated by frequency controlled electric motor.

7.0 RESULTS

Flow separation at the inlet could not be conclusively shown (even when the rotor's outer diameter was machined down). The relative outlet vane velocity profiles do not show a backflow or zero flow region. Instead, the vane flow at the outlet appears to be very roughly parabolic. Figures 7.1 and 7.2 show typical measured vane flow velocity profiles. Table 7.1 summarizes the vent flow velocity measurement results.

Comparison with Vent Flow Correlations
Since the flow measurements were made at distance of one centimeter from the rotor vane outlet, the amount of fluid mixing that occurred (slowing the fluid) is not precisely known. Mixing of the outlet jet with stationary ambient air slows the fluid as it moves away from the rotor outlet. Thus, the reported average vent flow velocities tend to be slightly underestimated. (The mixing was minimized inasmuch as the outlet measurements were taken as close to the rotor as possible without the probe interfering with the outlet flow). It is clear that the relative velocity (in the rotor vane) is greater than that predicted by Limpert, and vent velocity may in fact be as large as that predicted by Sisson, since the measurements err on the small side. Clearly, the measured production rotor vane flow most closely matches the correlation of Sisson [2].

Predicted Heat Transfer for the Designs
Table 7.2 summarizes the heat transfer for the various designs as predicted by Sisson's and Limpert's correlations [2,3]. Using Limpert's research, the convective heat transfer coefficient associated with rotor vent flow improves by as much as 20%; upwards of 50%, using Sisson's model.

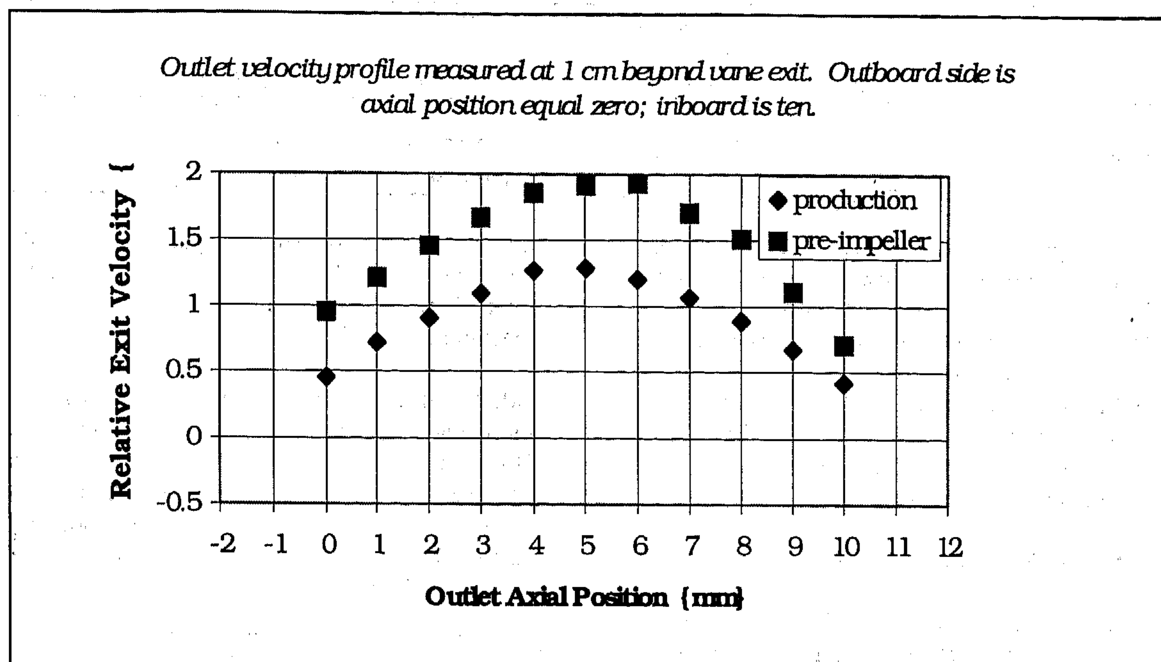

Figure 7.1: Pre-Impeller Rib Design's Outlet Velocity Profile - 600 rpm

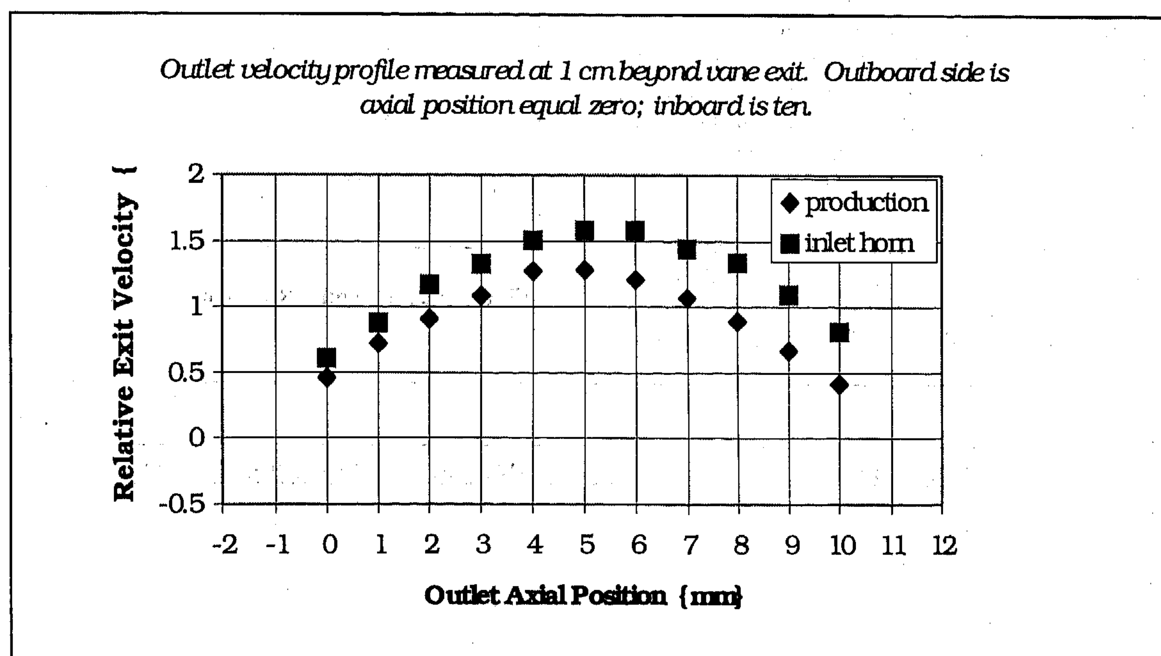

Figure 7.2: Inlet Horn Design's Outlet Velocity Profile - 600 rpm

Table 7.1: Average Vent Velocity as Measured at 1 cm Beyond the Vane Outlet

	Average Vent Flow Velocity {m/s}					
RPM	Limpert	Sisson	Prod.	Cham.	Horn	PreImp.
600	0.80	1.20	0.957	1.058	1.264	1.523
800	1.07	1.60	1.159	1.281	1.688	1.967

Table 7.2: Heat Transfer Coefficient Increase Based on Relative Velocity Increase

	Heat Transfer Coefficient {W/m^2K}			
	Prod.	Chamfer	Horn	PreImp.
RPM	600 / 800	600 / 800	600 / 800	600 / 800
Limpert	24.0 / 26.5	24.8 / 27.4	26.3 / 30.0	28.0 / 31.6+
Sisson	22.9 / 29.0	24.8 / 31.8	28.6 / 39.1	33.2 / 44.2

The improved heat transfer coefficient from increased cooling vent flow can be demonstrated by a simple fade test and lumped rotor model [1,7]. At the end of a ten stop (250 second) fade test the improved rotor's temperature above stabilization temperature is 3-6 % lower than the production rotor, depending on the chosen correlation. (Stabilization temperature is the rotor temperature at time infinity).

8.0 RECOMMENDATIONS

Measurements of current Chrysler LH series front brake rotors showed ventilation passage air flow corroborating Sisson's correlation [2]. Design modifications to improve the vane flow centered on the flow inlet conditions. The pre-impeller rib design yielded the most significant flow velocity improvement (greater than fifty percent) with negligible manufacturing cost increase, requiring only a slight change in casting shape and no machining operations.

If the pre-impeller concept is to be implemented, it is recommended that the modification of Figure 8.1 be examined in greater detail (i.e. optimized) to further reduce the inlet flow loss. A smooth inlet lip similar to that in Figure 5.1 with the combination of the pre-impeller and rounded inlet horn is desired within casting and machining limitations.

Additional possibilities include symmetric yet more egg-shaped rotor ribs similar to Figure 8.2. However, the curved flow path of the pressure rib-face is compromised by the restriction on the suction side (to maintain symmetry) and potential casting difficulty. Betz [15] and Lohmann [16] discuss the issues related to Figure 8.2.

Standard Test Procedure for Passenger Car Brake Components Using Operating Strength

H. J. Tumbrink
Lucas Varity, Light Vehicle Braking Systems

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Vehicle breakdown statistics show a clear trend: quality will be a major target for the future. This, taken together with the growing market demand for greater reliability, shows that the automobile industry needs to take action.
A way to achieve this is being sought, in some cases too frantically. All the concepts which have been formulated, as yet, have a common aim:

- **Price or cost reduction**
- **A more flexible response to market trends**
- **To boost the consumer's quality consciousness.**

The right response to these challenges leads directly to a reduction in development time.
The first answer is a standardization of test procedures according to operating strength.
The first idea and outlook was done in the SAE-Paper 790464 in 1979: "The ASSET-Technique". Now in 1996 it has become a standard in the German car industry.[1]

INTRODUCTION

Similar to other branches of industry, the modern brake manufacturer has had to research into more efficient manufacturing methods and the optimization of material content in order to satisfy the even higher standards demanded of its product.
To achieve this objective, the disciplines of **Finite-Element-Analysis** (FEA), **Photo Stress Analysis** and **Operating Strength** have been employed to optimize the damaging stress in passenger car brakes.
In particular and specifically for brake designs, the following basics have been introduced.

- statistically calculated failure modes for components to ensure product design (product liability),
- light weight design to save energy and cost,
- suitable and cost effective selection of materials and production methods,
- improved component form in the highly stressed zones,
- minimized installation space, particularly resulting from the introduction of negative steering offset,
- correlation of stress tests in the function stress loading.

USAGE IN BRAKE DESIGN

But what were the considerations which led us to research into operating strength ?
In our first few years of disc brake production we knew precisely why a component failed after a given number of brake operations. Figure 1 shows a typical brake of the Colette type (floating caliper).
We had however no idea why other components of the same design withstood similar loads. The development of Woehler curves for components gave us the first chance to evaluate the factors responsible.

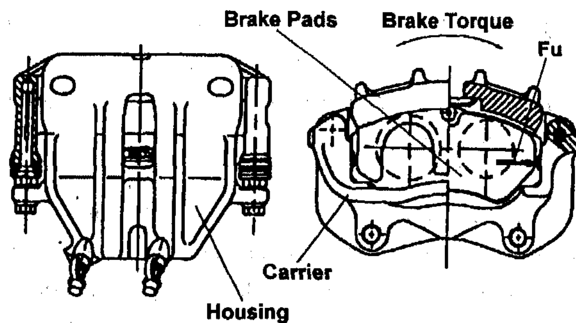

Figure 1: Fist Type Caliper Colette

Lightweight design was, is and will remain the "Leitmotiv" of the German Automotive Industry. We must however be in a position to create "tools" which will enable us to predict fatigue life fairly realistically and/or which we can modify using known correlation parameters.

Weight reduction with an ensured endurance life can only be achieved by using the method available through Operating Strength. [2]

Test specifications must be worked out with our customers so that there are not dozens of test procedures, differing for each customer, to be considered, for the self-same component. The tests should, in general, be as simple as possible and as rigorous as needed. [3]

In our case the required component strength must be established and the endurance life calculated. It is no longer possible to design on the drawing board optimal light weight components with an acceptable endurance life.

In short, it is now possible to load components not only to the limits of fatigue stress but in some cases up to and even over yield point always providing that the extreme loading does not occur too frequently in the normal working life of the component.

That brings us to the real problem in the fatigue life prediction theory:

"What is, in practice, too frequent ?" [4]

The solution is: Finite Element Analysis (FEA) and Operating Strength (FATIGUE) that means: "FATIGUE DESIGN" !

Since 1938 (and Gaßner's fundamental work) the logical opinion has been held that:

- There is no such thing as a service stress at constant amplitude and

- there are no un-notched components

This initiated the experimental determination of endurance life of components under realistic loading. [5]

We are now able to determine endurance life of components in advance (design stage) by using **Finite Element Analysis** and **Operating Strength,** and also with real components.

To answer the question the Woehler (S-N) - curve for the component must be considered in conjunction with the load histogram. The load histogram tells us the frequency at which a particular load occurs during the components normal life. This does not satisfy the customer, since he does not know, how frequently he may prudently allow overloads. In the case of fluctuating loads (brakes) the load cannot be defined numerically but rather by a characteristic function, i.e. the load collective.

Light-weight components cannot be laid out for to last forever but only for a defined life. Operating strength assessment and light-weight are therefore two sides of the same coin. It must be ensured that these collectives are realistic and apply to all components. The basic equation is an exponential function, derived from a discrete frequency function, illustrated in Figure 2. The scaled loading factor $\xi = 1.0$ represents 1.0 g deceleration.

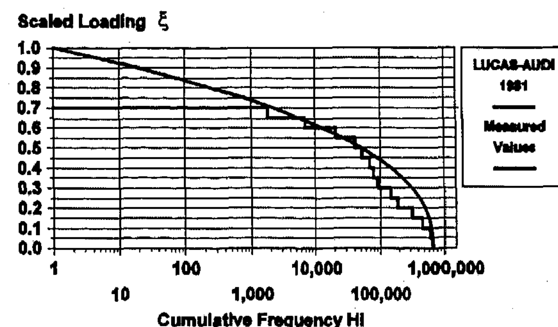

Figure 2: Cumulative Service Brake Load

A brake collective was collated between 1978 and 1981 in cooperation with AUDI (Dr. Anton Wimmer)[6] [2].

The collective was extrapolated to 300 000 km (186411 Miles) and therefore conserves a discrete frequency distribution which is also plotted in Figure 2.

The Fraunhofer Institute for Operating Strength (LBF) of Darmstadt has issued a technical report TM-81/77 which deals with the formal description of frequency distributions, by means of exponential functions. [7]

The collective can be described mathematically by using this well-known exponential procedure. The mathematically calculated collective is described in Figure 2.
The collective conforms to the equation:

$$H_i = 701269 * e^{(-13{,}4606 * \xi_i^{2{,}37338})} \tag{1}$$

$$\xi_i = \left(\frac{F_i}{F_1}\right) = \left(\frac{\sigma_i}{\sigma_1}\right) = \left(\frac{p_i}{p_1}\right) \tag{2}$$

The basic equation of this collective has the form:
H_0 = Zero passage for this function

$$H_i = H_0 * e^{[-\ln(H_0) * \xi_i^{n}]} \tag{3}$$

Safety related vehicle parts must last for at least **300000 km** at a failure probability of $\mathbf{10^{-5}}$.
The topic light-weight components and their loading has been a side issue till now.
Fundamentally:
Only when the service loading is accurately known or can be accurately estimated is it possible to dimension a component to suit the application.
Dubious loading assumptions lead to excessive safety margins and therefore impede the use of light parts [8].

TEST METHODS AND RELIABILITY

Teamwork between all specialist departments and all technologies is demanded for the development of a product. The part played by theoretical and experimental reliability assurance is very significant. Optimization takes place basically in the first design stages, so that the first prototype is 80-90% ready for production. The safe answer to the designer's frequent question to the stress engineer "Will it hold", can only be given by making sure that the component achieves the demanded endurance life under the specified **"Service loading collective"** conditions.

STANDARDIZED TEST METHODS - Taking a disc brake as an example, we show how generally applicable guidelines can be formulated, in cooperation with the German Automotive Industry and with the help of fatigue life analysis and modern statistical techniques. This has been worked out in a working circle of the Automotive Industry in concert with the two biggest brake suppliers. The aim is to carry out service load tests, based on a new collective, in the first stage of development. Until then a solution [9] has been worked out, which is based on a fixed collective and the Miner linear cumulative damage calculation.
First proposal of the "Brake Working Circle":
In the second meeting of the Brake Working Circle, an interim proposal of the German Auto-industry was agreed, as "lowest common denominator":
$N_{50\%}$ = 200 000 loading cycles and S_{log} = 0.2.
This implies testing against a mean life.
It is however clear from the literature [10] [11] that tests should not be based on the mean life. The reliability should always be determined for a minimum cycle count which represents a given endurance life or mileage.
Statistically it is reasonable to fix a minimum count (e.g. $P_{ü}$ = 99.9%, 99% or 90%). This led to a common proposal from the Brake suppliers [9] with an assumed collective and the test load cycle count N_{1k}.
The working circle initiated a comparison of all test stands at brake and car manufacturers with respect to damage and scatter.
In Figure 3 and Table 1 the test results are depicted.

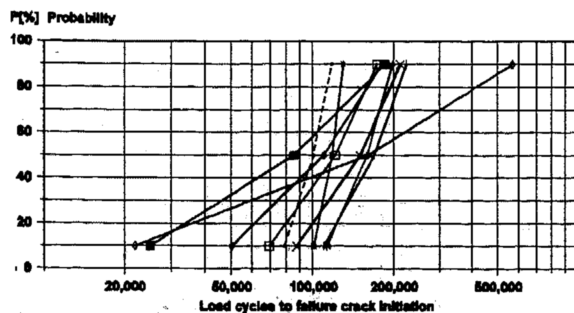

Figure 3: Test Rig Comparison Car Manufacturer and Brake Supplier

Lucas built a new test stand which closely simulates the vehicle setup.
The results showed very little test stand moment scatter (previously ± 5% and now ± 2%)
- Original stub axle and bearing
- Moment controlled directly at bearing.

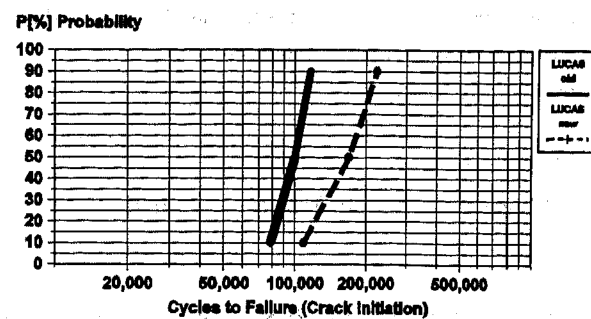

Figure 4: Test Rig Comparison Lucas old to Lucas new design

Figure 4 shows the difference between the results with the LUCAS rigid mounting (LUCAS old) and those from the new configuration using the original stub axle (LUCAS new). With the original stub axle "X" times as many cycles can be withstood. The mounting therefore plays an important part in running realistic tests. The results relating to 90% and 10% scatter, the log. Standard deviation and the b-value of the Weibull-Distribution are tabulated below.

Table 1: Test results of comparison tests

Tests:	T_N (90%/10%)	S_{log}	Weibull Slope b
Car Manufacturer (CM) 1 (all tests)	**7.45**	**0.340**	**1.54**
Car Manufacturer (CM) 1 (without min.)	**3.61**	**0.218**	**2.40**
Car Manufacturer (CM) 2	**1.75**	**0.094**	**5.57**
Car Manufacturer (CM) 3	**2.50**	**0.155**	**3.37**
Car Manufacturer (CM) 4	**25.98**	**0.552**	**0.95**
Brake Supplier 2	**1.29**	**0.043**	**12.30**
Lucas (old test stand)	**1.49**	**0.067**	**7.88**
Lucas (new test stand)	**2.04**	**0.121**	**4.33**
All (without 1 and 4 min. results)	**2.43**	**0.151**	**3.48**

It can also be seen from these results that the total evaluation exhibits a Gauss normal distribution. (b = 3.48; 3.2 - 3.6 = Gauss - normal distribution). [11]
The logarithmic standard deviation is 0.151, the max value 0.155 was chosen.
Recent Engineering Release Tests also confirm that the detected scatter is <2.5.

STATISTICAL BENCHMARKS - The results from table 1 lead to the following findings as regards statistical data. Statistical benchmarks must be determined from these tests and comparisons made over the past few years. The limiting quantities for minor single tests and the safety factor related to endurance life are to be chosen from the statistics. The risk from the fortuitousness of small sized random samples must taken care of, the confidence interval and P_a must be established.
It follows that:

$$J_{C,n}=S^{[\frac{U_C}{\sqrt{n}}]} \qquad (4)$$

S= 1.43 from S_{log} = 0.155, equivalent to a scatter T_s= 2.5, n=4, U_C = 1.282 for C = 90% (from TM68/78 (LBF) [12]) (1.282/2 = 0.641)
$J_{C,n}$ = $1.43^{0.641}$ = 1.26

and:

$$J_L=S^U \qquad (5)$$

S = 1.43 as equation (4) above
U = 3.10 for 99.9% survival probability. (P_a=99.9%)
J_L = $1.43^{3.10}$ = 3.03

This gives us a statistically based safety factor **S_F = 3.82**
(S_F= $J_{C,n}$ * J_L)

The factors are illustrated in Figure 5.

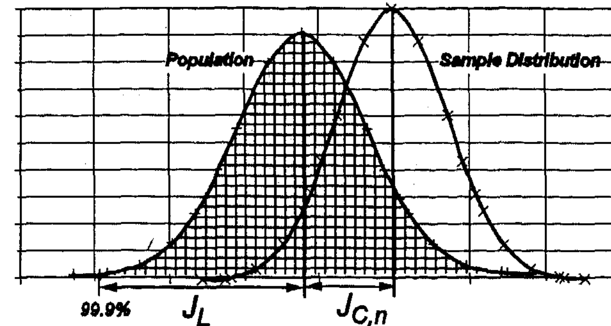

Figure 5: Statistical Factors $J_{C,n}$ and J_L

COLLECTIVE - The new brake load collective takes into account **20** non-negligible cases, from previous customer reports, where the tangential force exceeded the equivalent of more than 1.3 g (braking on extremely rough tracks, road edges etc.).
2130 stops at 1g are included in the scope of the collective. These could conceivably be harder stops, masked by ABS.
The remaining collective sections follow the so-called normal distribution, which applies for 1 to 1 200 000 cycles. The whole collective covers 4 braking operations per km = H_{ges} = 1.2 X 10^6 cycles, as recommended by LBF.
This collective can also be applied to light trucks as an initial approach.

The equation reads:

$$H_i=(H_0-2149)*e^{(-lnH_0+\xi_i^2)}+2149 \qquad (6)$$

Plus 20 cycles at 1.3 times 1.0 level.
H_0 = 1.2 * 10^6. In Figure 6 the new brake load collective is illustrated and is also valid for ABS applications.

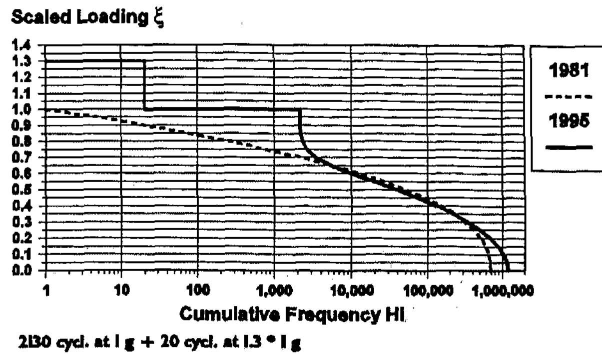

Figure 6: New Standard Brake Load Collective

WOEHLER (S-N) CURVES - A Woehler curve must be plotted for every brake or component to be released. This should be based on the brake assembly or its weakest part.

When testing components it must be ensured that the weakest part always fails first. 12 items (brake or component) minimum are to be tested, at two loading levels (6 items min. per load case) and the $P_{\ddot{u}}$= 50% curve drawn.

The failure criteria are either a 1 to 2 mm technical crack or a dynamic load drop of 5%. The $P_{\ddot{u}}$=99.9% survival probability curve is calculated using the factors $J_{C,n}$ and J_L.

Although the Woehler curve was calculated for 12 items, $J_{C,n}$ remains at the value 1.26, which affords us additional safety. With n=12: $J_{C,12} = 1.14$.

The equation for the 99.9% survival probability Woehler curve is:

$$N_{99.9\%}=\frac{N_{50\%}}{J_{C,n}*J_L} \tag{7}$$

$N_{99.9\%} \geq N_{1k(D=1)}$

REQUIREMENT

Using the new collective as described above and taking the slope (k-factor) of the Woehler curve and the individual frequencies n_i into account, we calculate the cycle count of the rectangular collective of equivalent consistent maximum load test.

THE N_{1k} - FACTOR - The minimum requirement for a brake is covered by the simple equation:

$$N_{1_{k(D=1)}}=[\Sigma(\frac{F_i}{F_1})^k*n_{i_k}] \tag{8}$$

$N_{1k(D=1)} \leq N_{99.9\%}$

However we know that we cannot always use D=1 (rel. Miner = 1) in our calculations. we must introduce a factor which leads to the specified cycle count.

THE $N_{1(spec)}$ - FACTOR - From the literature [13] [14] it is apparent that the rel. Miner-Count is dependent on the collective, the component and the material.

It follows that different brake designs:

- **Hammerhead (Brake Supplier 2)**
- **Colette (Lucas)**
- **Frame-type caliper**
- **Fixed (opp.piston) caliper**

are allocated a different D-value.

Service load testing at Brake Supplier 2 and at Darmstadt TH (university) showed a clear effect due to design differences.

Tests also showed a strong dependence on crack length and excess loading.

For 1.3 x max.load and 1g a rel. Miner count results from different crack lengths.

The max. collective load for the scaled loading factor ξ_i=1 during simulated service testing must not exceed 1g; plus the 20 cycles at 1.3 * 1g.

	1.3 X 1.0g	1.0g
0.3 mm:	D=0.2	D=0.6
0.6 mm:	D=0.7	D>1
2.0 mm:	D=1.2	D>1
Break:	D=2.6	D>1

Taking 1g as the highest loading figure resulted in a Miner-count of > 1.

The supplier gave for each brake type the D-factors to achieve $N_{1(spec)}$.

The equation therefore reads:

$$N_{1_{k(D=X)}} = N_{1_{k(D=1)}} * J_{C,n} * J_L * \frac{1}{D} \qquad (9)$$

FATIGUE LIFE AND TEST SPECIFICATION

All relevant parameters have now been developed or worked out. The following test specification is based on them. The collective has a more realistic loading profile. We are, nevertheless, still waiting for the test results of the working circle "Customer-Collective.

During the development stage the Engineering will carry out simulated service load tests based on the finalised collective in order to reduce the imponderables of the Miner-Factors and further inaccuracies to a minimum.

Single stage test on a complete caliper assembly on a pulsating disc, with pads of the lowest possible friction, connected to the disc via a three-way ball joint. Alternatively a test rig with original axle parts set up to drawing and including a rotating disc (friction grip) under controlled torque. Brake torque increase to lag pressure rise and torque decrease to synchronise with pressure fall.

Moment M_E and pressure p equivalent to a 1g stop, torque tolerance +5%; pressure tolerance +20%. M_E to be set by calculation equivalent to the ideal or installed brake force distribution for gross vehicle weight. The max. value has to be taken.

The required cycle count is $N_{1k(spec)}$.

If k-factors lie between given figures the next lower figure is to be chosen, in order to keep N_{1k} on the safe side, (e.g. 4.84 becomes 4.5).

The required cycle counts relating to the slope of the Woehler curve can be determined from the following table:

The required minimum cycle count is

$N_{1k(spec)} = N_{1k(D=1)} * J_{C,n} * J_L$ and shown in the Table 2 below.

The diagram in Figure 7 illustrate the influence of the slope factor of the S-N-Curve (Woehler-Curve).

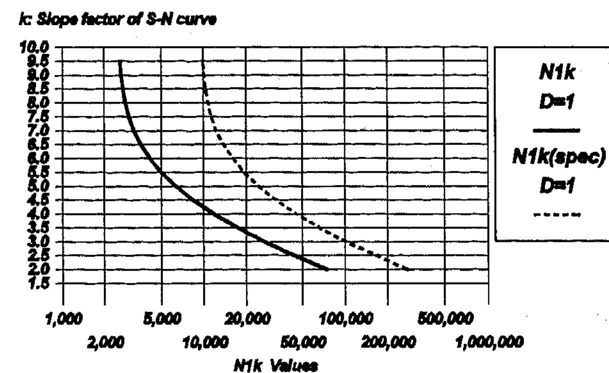

Figure 7: N_{1k} and $N_{1k(spec)} = f(k,n_i)$

Table 2: Test cycles versus slope factor k of the Woehler (S-N) curve

k-factor	Cycles $N_{1k(D=1)}$	Test cycles [*1] forward $N_{1k(spec)}=N_{1k}*J_{C,n}*J_L$ $J_{C,n}*J_L = 3.82$	Test cycles reverse 10% of forward application
2.0	**74546**	**275000**	**27500**
2.5	**43633**	**167000**	**16700**
3.0	**26832**	**102500**	**10250**
3.5	**17329**	**66500**	**6650**
4.0	**11766**	**45000**	**4500**
4.5	**8411**	**32500**	**3250**
5.0	**6334**	**24500**	**2450**
5.5	**5017**	**19500**	**1950**
6.0	**4167**	**16000**	**1600**
6.5	**3608**	**14000**	**1400**
7.0	**3237**	**12500**	**1250**
7.5	**2988**	**11500**	**1150**
8.0	**2822**	**11000**	**1100**
8.5	**2713**	**10500**	**1050**
9.0	**2644**	**10500**	**1050**
9.5	**2604**	**10000**	**1000**

[*1] *The test cycles are rounded to the next 500.*

The cycles for reverse applications have to be carried out at the beginning of the test
(i.e.: For k = 7: 1250 cycles reverse + 12500 cycles forward)
For brakes with an integrated handbrake (combined brake) the following additional test has to be carried out with the same brake parts:

15 000 cycles with 400 N hand brake lever load or 500 N foot lever load without tangential force to the brake carrier.

5 000 cycles with a hand brake lever load or a foot lever load with tangential force to the brake carrier corresponding 30% hill hold.

The procedure is now clearly defined, it follows the rules below:

Table 3: Test Procedure

Evidence:	Test Procedure:
1. First tests	Identify the weakest component by means of FEA analysis or test.
2. Woehler (S-N) curve	Determine the k-factor for the Woehler curve by testing $n \geq 12$ components or assemblies ($n \geq 6$ each load level). Find $N_{50\%}$ and $N_{99.9\%}$.
3. relative Miner-count	To be fixed for each brake type.
4. N_{1k} D=1	$$N_{1_{k(D-1)}}=[\Sigma(\frac{F_i}{F_1})^k * n_{i_k}] \quad (8)$$ = $f(k,n_i)$ elementary Miner
5. Minimum test cycle count $N_{1k(spec)}$ D=X	$$N_{1_{k(D-X)}}=N_{1_{k(D-1)}}*J_{C,n}*J_L*\frac{1}{D} \quad (9)$$ Test $n \geq 4$ up to $N_{1k(spec)}$ cycles without failure, then break off. Torque, pressure and cycles count given by suppliers.
6. Woehler curve for calculation. (The rel. Miner number will be use during life prediction.)	$$N_{99.9\%}=\frac{N_{50\%}}{J_{C,n}*J_L} \quad (7)$$ 99.9% Survival probability; determined using $J_{C,n} * J_L$; Assumption: log Normal-distribution.
7. Endurance life determination	Woehler curve from component or assy. test versus collective with Miner elementary. L*D > 300 000 km.

The final test procedure can also illustrated in a diagram and Figure 8 shows the theoretically S-N-Curves and the experimental S-N-Curves.

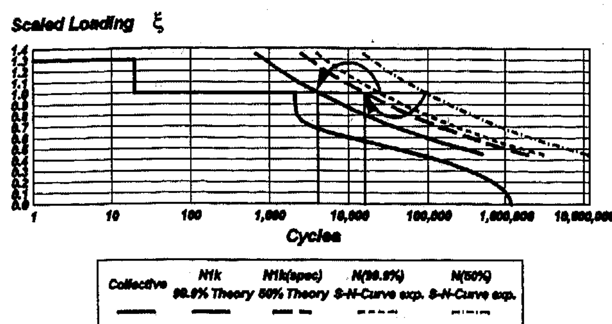

Figure 8: Theoretical and Experimental S-N-Curves

Now it is clearly seen that in the worse case the experimental curves will meet the theoretical curves calculated from the k-factors and the statistical factors J_L and $J_{C,n}$.

That means:

The 99.9% survival probability curve must fulfill 300 000 km and this is the N_{1k} curve (worse case) for a rel. Miner No. D=1 or as described in Point 7 in Table 3: L * D = 300 000 km min.

Additional to the Fatigue Life other tests has to be carried out.

SEAL TEST- Load to p = 100 bar (Pressure increase rate approx. 500 bar/s, piston stroke: 0.3 mm)

for 135 000 cycles at: RT; f=800-1200 [1/h]
45 000 cycles at: -40 ± 2°C; f=600- 800 [1/h]
70 000 cycles at: +150 ± 2°C; f=800-1200 [1/h]

After 250 000 cycles total:
the following conditions must be met:
- no hydraulic system leakage
Test pressure p = 150 bar; $\Delta p/\Delta t \leq 10$ bar within 2 minutes.
- no wear on piston or cylinder ID which impairs performance.
- Piston push-out pressure: 0.2 - 3.0 bar
- Piston push-in force: 50 - 700 N

Before measurements: Piston to move ± 5 mm 2 time; then the piston has to be moved back in position of new pad condition and 1 static pressure application with 100 bar.
Spot check quantity n ≥ 4.

Only one release is required for each housing diameter, providing that the expansion is in the same tolerance range and that the geometric results (e.g. roll-back) and the materials are identical.

SERVICE BRAKE - M_{ST} = 1.75 M_{req} + 5%; pressure and moment rise together.; M_E and p from 3.4; after M_{ST} has been applied there must be no hydraulic leakage and the following conditions must be fulfilled:

Housing sliding force:	10 - 150 N
Piston push-out pressure:	0.2 - 3.0 bar
Piston push-in force:	50 - 700 N

Before measurements: Piston to move ± 5 mm 2 time; then the piston has to be moved back in position of new pad condition and 1 static pressure application with 100 bar.
Spot check quantity ≥ 4.

SERVICE BRAKE WITH INTEGRATED PARKING BRAKE
- This test has to be carried out at a suitable test stand.
Installation corresponding to the required procedure.
One "reverse" brake application with a brake clamping force corresponding to a hand brake lever load of 800 N or a foot lever load of 1000 N. The lever ratios, the lever geometry of the appropriate cars and the efficiencies have to be taken into account.

No functional failure of parking brake.

Spot check quantity ≥ 4.

BURST PRESSURE - p > 350 bar
Spot check quantity ≥ 4.

SUMMARY

By developing the new, state of the art, test specification, we have been able to cut through much of the present tangle and clear the way for the future.
The same procedure is valid for other brake components (brake booster etc.).
Since 1981 we have used **Fatigue Life Prediction Procedures** in testing all our brake component prototypes and in their further development.
All brakes were analysed before release using the Palmgren-Miner Rule against the collective described.
We have built more than 200 million brakes of the Colette type for world-wide sale. To date not a single component has failed.

ACKNOWLEDGEMENT

I say thank you to all my colleagues at Lucas CAE department for the discussions during the preparation of the procedure and to my colleagues from ITT Automotive: K.Stoerzel and H.Rueckert and to the members of the working circle : A.Pradt, Chairman (Mercedes Benz), K.H.Boss (BMW), M.Luedeke (AUDI), R.Martin (PORSCHE) and Dr.L.Jung (VW) for the help during the discussions.
Thank you also to Prof. Dr.-Ing. V. Grubisic from the Fraunhofer Institute of Operating Strength in Darmstadt (Germany) and Prof. Dr.-Ing. Erwin Haibach for the help in the statistical determination of the load collective and safety factors.

NOMENCLATURE LIST

ξ_i	Scaled load factor of step i
σ_1	Max. stress
σ_i	Stress at step i
C	Confidence level
CAD	Computer Aided Design
CAE	Computer Aided Engineering
CAM	Computer Aided Manufacturing
D	Relative Miner
F_1	Max. load
FEA	Finite Element Analysis
F_i	Load at step i
H_0	Zero passage of the collective
H_i	Cumulative frequency at load step i
$J_{C,n}$	Risk factor for confidence level C at n test samples
J_L	Safety factor to be applied to fatigue life
k	Slope factor of Woehler (S-N) curve
n	1. Exponent of the collective 2. Number of test samples
$N_{1k(D=1)}$	Number of cycles for Miner No.: D=1
$N_{1k(spec)}$	Test cycles for a rel. Miner No.: D=1
$N_{1k(D=X)}$	Test cycles for a rel. Miner No.: D=X
$N_{50\%}$	Number of cycles for 50% survival prob. for Woehler curve
$N_{99.9\%}$	Number of cycles for 99.9% survival prob. for Woehler curve
p_1	Max. pressure
p_i	Pressure at step i
$P_ü$	Survival probability
S	Standard deviation
S_F	Statistic safety factor
S_{log}	log standard deviation
T_N	Scatter of 90% to 10% probability
U	Standardised normal distributed variate
U_C	Scaled variate for determination of C

Development and Improvement of Finite Element Side Impact Dummy (EUROSID) Model Based on Experimental Verifications

Nissan Research Center

ABSTRACT

In side-crash phenomena, finite element modeling is essential in investigating the occupant's post-impact dynamic behavior after contact with the door panels. A number of modifications have been made to the model described here based on combined simulation and experimental verifications of the dynamic and pseudo-static characteristics of different materials such as foam, damper and individual sub-assemblies. This report illustrates how the modified material and structural modeling of different components improve the accuracy of the overall dynamic behavior of the FEM model in simulating different HYGE experiments to speed up and optimize the vehicle design process. The rib-module drop test results with two different polypropylene pads clearly indicate the effect of the pad unloading characteristics on rib displacement. The verification of HYGE test results, showing the variation in response with two different speeds and relative timing of impact at the chest, abdomen and hip, clearly indicates that the present model can be effectively used in selecting the optimum deformation mode of door and B-pillar structures to control the input load on the occupant. The shoulder clavicle is found to be extremely important in controlling the arm movement which influences the load path to individual ribs. Proper modeling of the jacket is also found to be important in predicting the influence on lower rib deformation.

INTRODUCTION

More stringent safety regulations worldwide have made the development of a vehicle a difficult process. The automotive industry has been working hard over the last decade in searching for new methods and processes to develop new models to meet the market timing and safety standard requirements. Consequently, various computer-aided engineering tools have been integrated in the vehicle design process and have become key elements in reducing the development time and number of prototypes required for new vehicles. Two major side impact test procedures are used for verifying the ability of a vehicle to protect the occupants in a side impact. The proposed European Experimental Vehicles Committee (EEVC) procedure is based on the injury level of a driver measured with the EUROSID-I dummy, and in the National Highway Traffic Safety Administration (NHTSA) procedure, the injury level of the driver and that of the rear driver's side passenger are measured using two SID dummies. As full-scale side impact tests are expensive and time-consuming, they are supplemented with sled tests and extensive computer simulations. Numerical simulation techniques are commonly used to assess the crash performance of automobiles and guide their design during the development stage. Mathematical models of vehicle structures, restraint systems, and dummies are developed and verified under different conditions to ensure effective usage. Several analytical dummy models have been developed to simulate occupant responses in front and side impact phenomena. These models can be broadly classified into two groups: (i) rigid bodies of ellipsoids connected by springs i.e. mass spring models and (ii) elastic/plastic bodies of proper material strength and geometrical shapes connected together with or without springs and joints. Although rigid mass-spring dynamic models are widely used in frontal crash simulations because of their ease of modeling, they can only capture 2-D gross movements. Such ellipsoidal models fail to represent the actual 3-D contact mechanism which is extremely important in side impact phenomena. However, the recent versions of some of the numerical codes, such as MADYMO, based on mass-spring models, have included some extra features to simulate and visualize more realistic crash phenomena. On the other hand, the later approach based on finite element techniques is capable of predicting very complex and complicated responses such as deformation, contact force and so forth which can hardly be measured experimentally.

This paper describes the validation of the EUROSID FEM model. Some of the basic modifications that are incorporated to improve the degree of accuracy of the present model are described in later sections. The component level modifications are based on identifications of (i) static responses of hip-pelvis foam compression tests, (ii) dynamic responses of lumbar spine and neck bending tests and (iii) dynamic responses of rib module drop tests. The assembly level modification includes (i) identification of the effect of upper-lower connection on pubic symphysis force with the help of rigid impactor pelvis tests and (ii) identification of the effect of the pre -tension clavicle string on thorax rib displacements. With the help of a tentative HYGE impact configuration very close to an actual crash test, the overall dynamic behavior and different injury response criteria, such as, the rib displacement criteria (RDC), the abdominal peak force(APF) and the pubic symphysis peak force(PSPF), are initially verified at a speed of 35 km/hr. Further validation is made for different sets of configurations by changing the input force timing at the abdomen and hip in order to simulate a board spectrum of probable input patterns in real side crash tests. The explicit finite element code RADIOSS is used to obtain the numerical solutions. Finally, the data are also correlated with the results obtained at a lower impact speed of 25 km/hr.

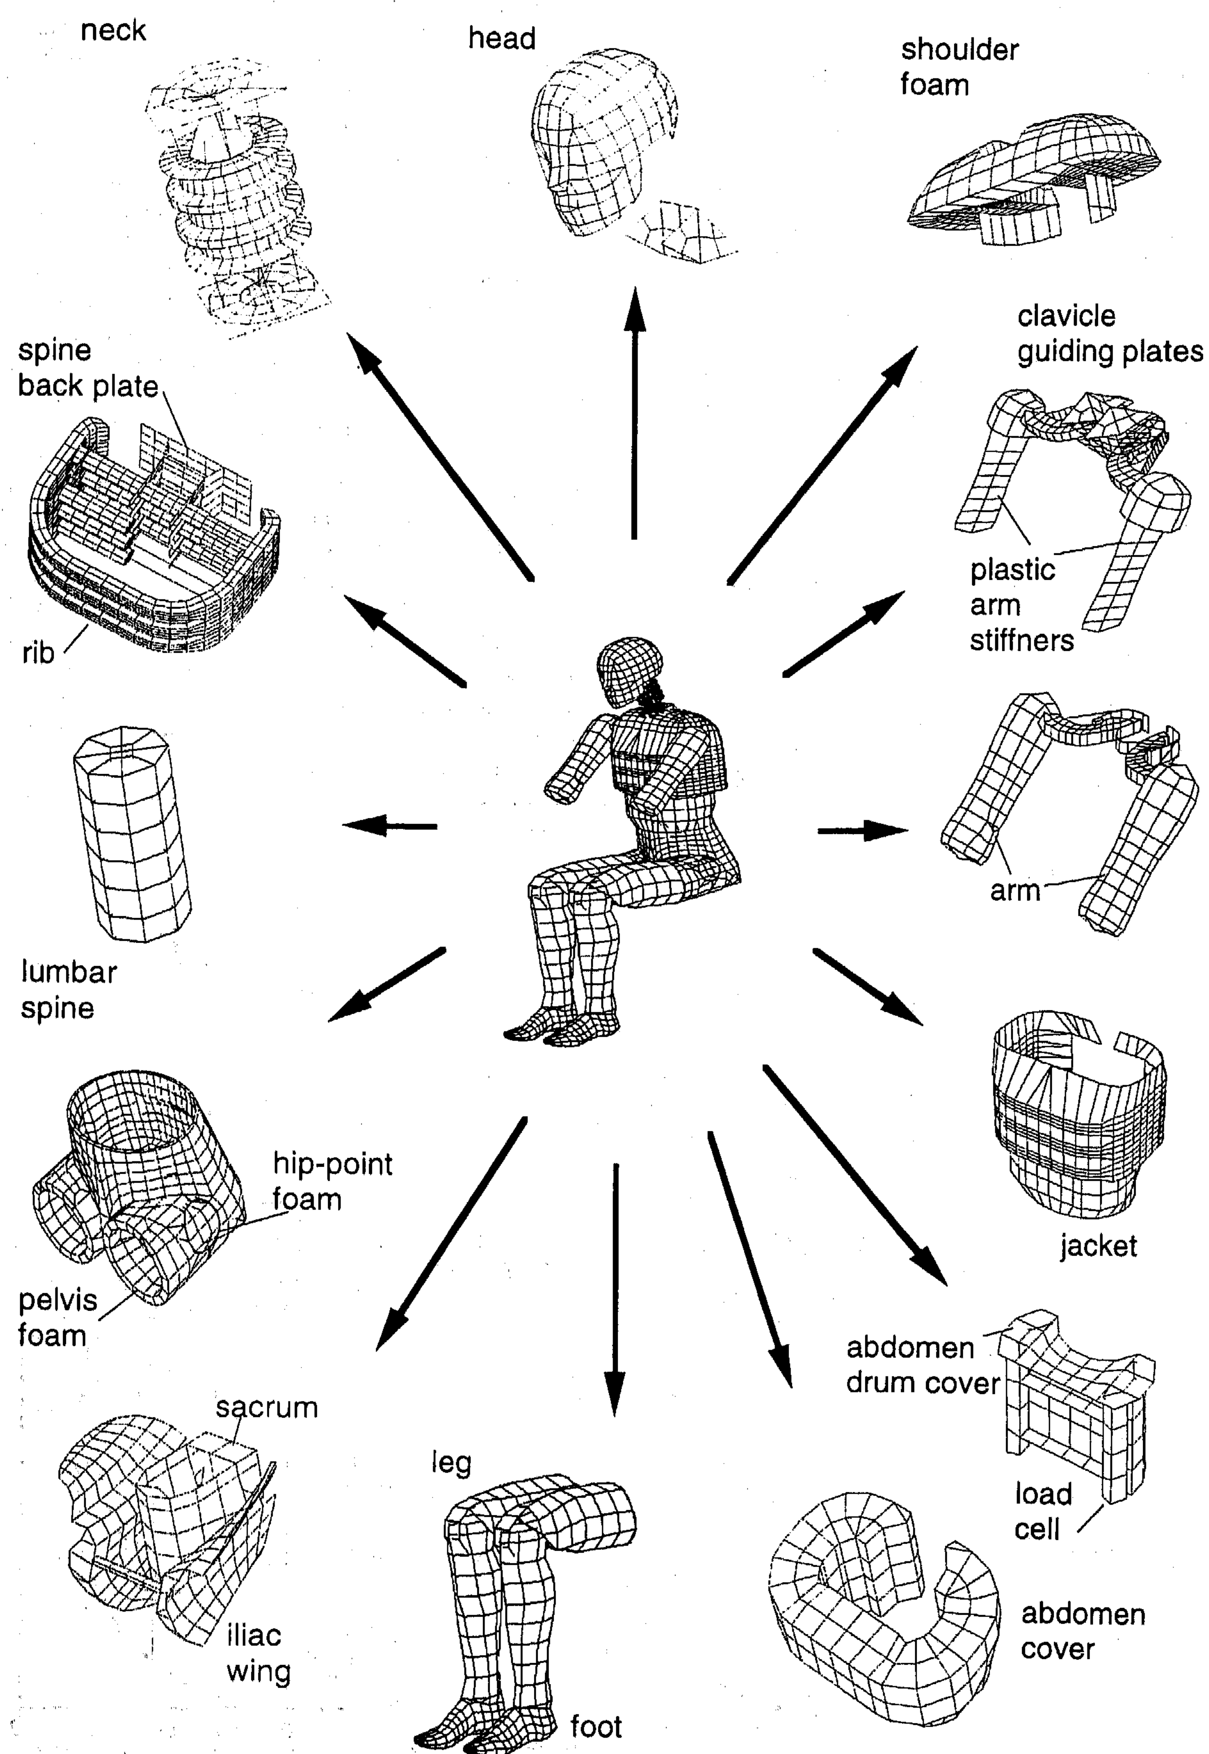

Figure 1. Different Parts of EUROSID Dummy FEM Model

FINITE ELEMENT MODEL

The overall geometry of the different parts of the present model are shown in Figure 1. It is originally based on the MECALOG model and consists of solid brick, thin shell and 6 degrees of freedom spring and beam elements. Different parts which undergo small deformation, such as the spine box, head and the legs below the hip are treated as rigid bodies to reduce the computational time by eliminating the extra degrees of freedom for unimportant parts. However, care has to be taken to represent the 3D shape of each of them for accurate estimation of contact forces. To improve the degree of accuracy of the present model, the following items have been checked and modified to obtain good correlation between the experimental and numerical results.

IDENTIFICATION OF INDIVIDUAL PARTS

(a) Nonlinear Characteristics of Hip and Pelvis Foam

The hip and abdomen part are modeled with sophisticated porous foam material. However, to set the parameters of the material requires accurate tests of samples of the same material. Further, it is to be noted that these parts are made airtight with a thin outer polyvinyl rubber completely covering the inside core foam (Figure 2a). Since the in-plane membrane stiffness of the outer rubber skin and the shape of the individual items greatly affect the overall equivalent compression characteristics of the item, a simple material test of the inner core material will not truly represent the actual compression behavior. Hence, as an alternative, direct compression tests of the relevant part, say the hip point flesh of the EUROSID dummy, were conducted to find the equivalent stress-strain relationship from the measured force-displacement characteristic under different compression conditions, the details of which are described below. The unknown material characteristics of the nonlinear foam material were determined by an iterative optimization procedure based on the concept of pseudo-static simulation performed by explicit nonlinear finite element codes. Figures 2b-2d show the process of evaluating the equivalent volumetric stress-strain characteristics. For example, the abdomen was initially tested in a frontal compression and the material characteristics were identified by the above-mentioned procedure. Using these material characteristics, it was then tested in a lateral compression to check the validity of the previous stress-strain characteristics. A comparison of the test and the final simulated results (Figure 2e) indicates fairly accurate identification of the nonlinear characteristics of the hip foam material. Similar results were obtained in a pseudo-static test of the pelvis foam.

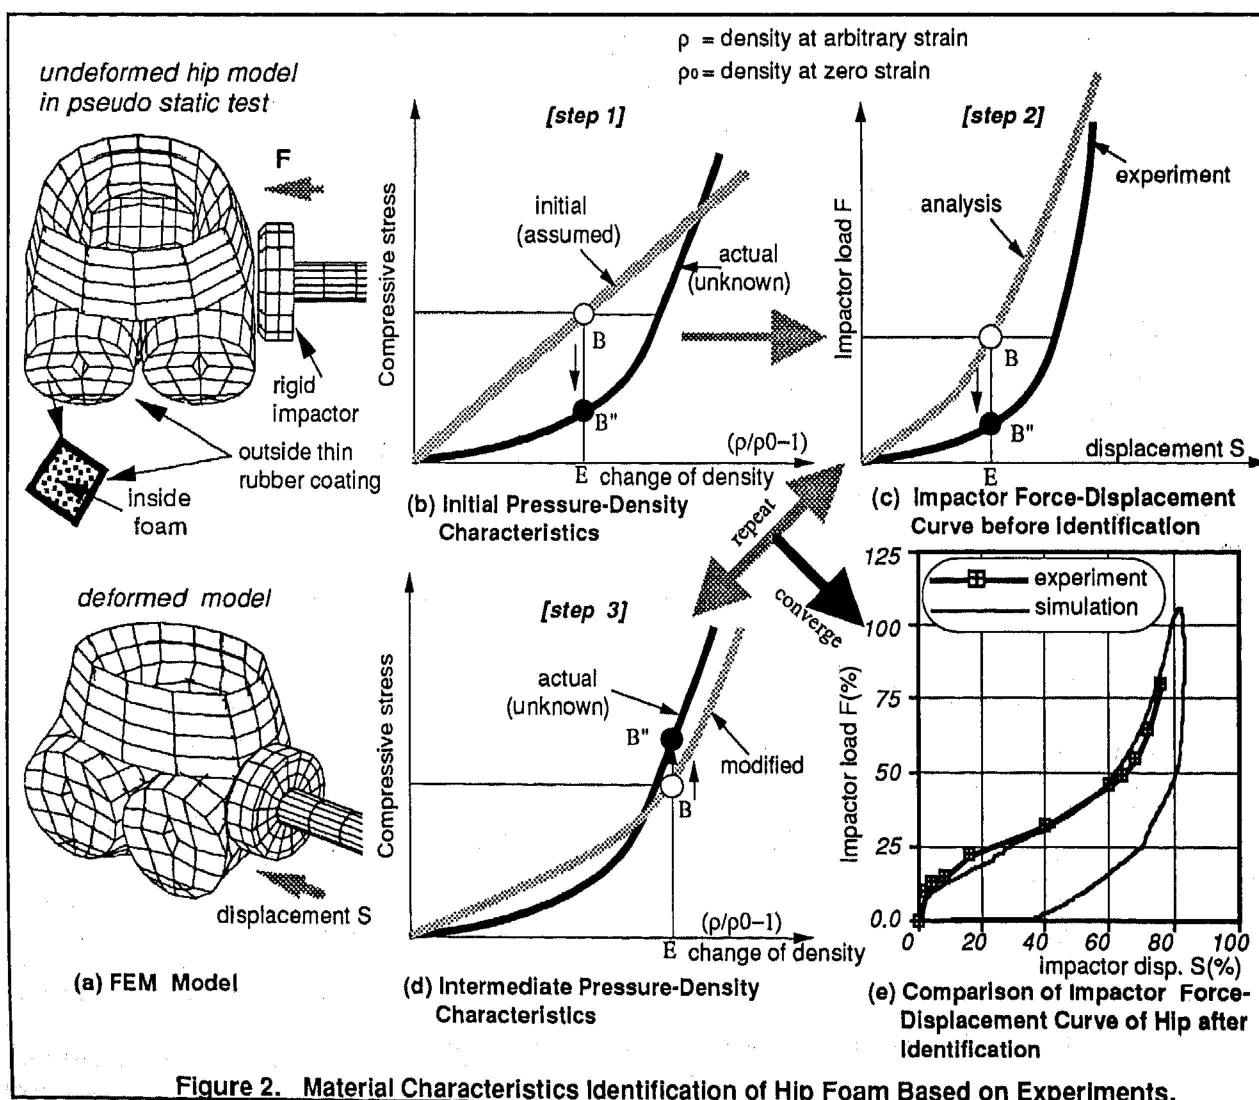

Figure 2. Material Characteristics Identification of Hip Foam Based on Experiments.

(b) Nonlinear Dynamic Characteristics of Lumber Spine and Neck

Since the lumber spine and the neck connect the hip and the head of the dummy with the spine box at the bottom and at the top of the spine, both of them behave as cantilever beams. Numerical simulation of a free fall pendulum (Figure 3a) as stipulated in the EUROSID manual [2] was performed for input pendulum acceleration (Figure 3b) having an impact velocity of 6.05 ± 0.1 m/sec in the direction of motion. A nonlinear solid material modeling (material 35 of RADIOSS) was chosen based on the Maxwell-Kelvin-Voight viscosity as shown in Figure 3c. Figure 3d indicates that the present nonlinear model has satisfactory accuracy. Typical deformation modes are shown in Figure 3e. Similar results were obtained in a pendulum test of the neck assembly.

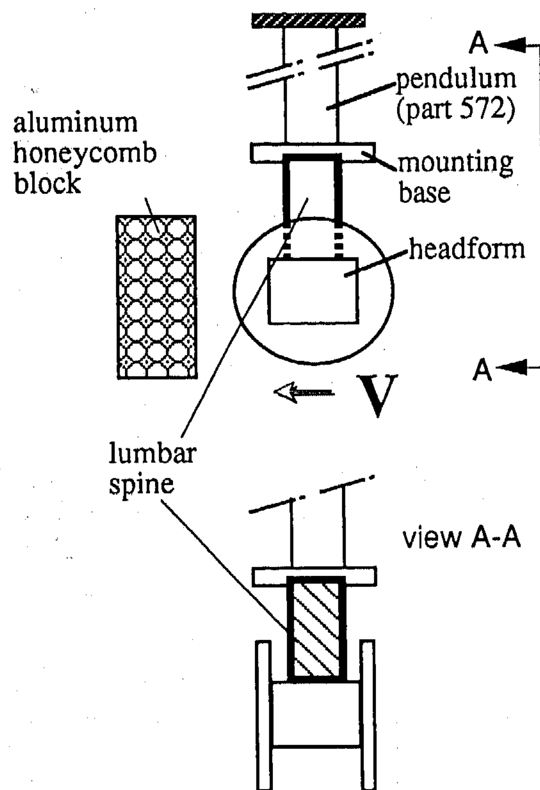

Figure 3a. Pendulum Test

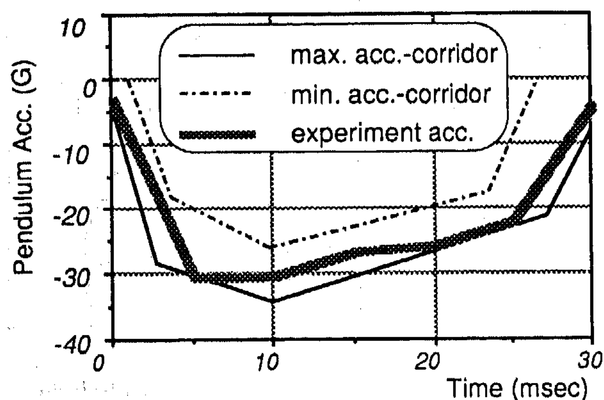

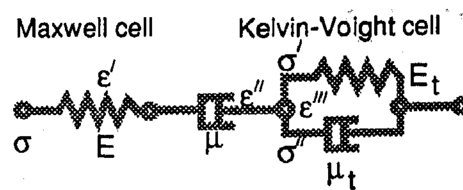

Figure 3b. Pendulum Input Acceleration of Lumbar Spine (V = 6.05 m/sec)

Basic relationship

$$\varepsilon = \varepsilon' + \varepsilon'' + \varepsilon''' \qquad \varepsilon' = \sigma / E$$

$$\sigma = \sigma' + \sigma'' \qquad \dot{\varepsilon}'' = \sigma / \mu$$

$$\dot{\varepsilon} = \dot{\sigma}/E + \sigma/\mu + \dot{\varepsilon}''' \qquad \varepsilon''' = \sigma' / E_t$$

$$\sigma = \mu_t \dot{\varepsilon}''' + E_t \varepsilon''' \qquad \dot{\varepsilon}''' = \sigma'' / \mu_t$$

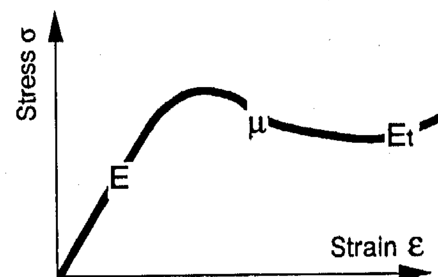

Figure 3c. Nonlinear Damping Material Model (Maxwell-Kelvin-Voight)

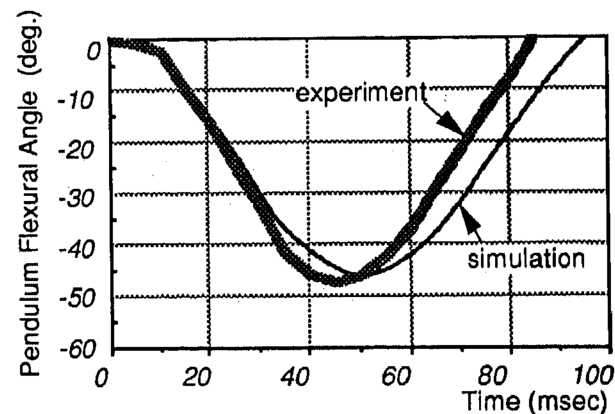

Figure 3d. Pendulum Angular Deflection of Lumbar Spine (V = 6.05 m/sec)

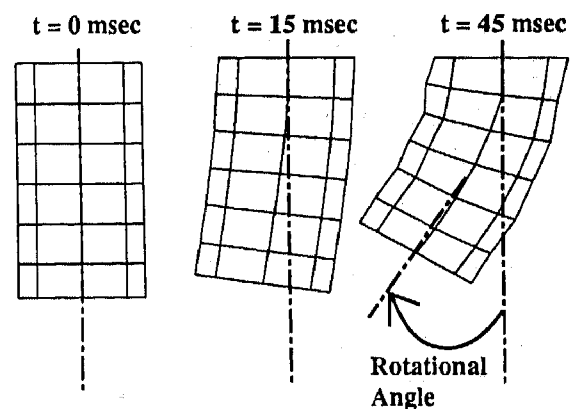

Figure 3e. Bending Mode of Lumbar Spine

(c) Effect of Nonlinear Dynamic Characteristics of Polypropylene on Rib Module in Drop Test

The rib module assembly was tested in a standard drop test (Figure 4a, 4b), as stipulated in the EUROSID manual, using (i) a rigid impactor and (ii) soft polypropylene pad 45PP. A comparison of the experimental results are shown in Figure 4e. The padded drop-test results are comparatively shorter in peak height, flatter at the top and longer in duration. The shortness is due to absorption of the input energy in the loading curve of the pad. The flatness of the peak is due to the high rebound effect of the pad during the unloading phase, and elongation of the time period is due to the small amount of energy loss to hysteresis. Accurate modeling of this part is extremely important in simulating the exact deformation characteristics such as the damper, return spring and tuning spring. Padded impacts were conducted to investigate the dynamic behavior of the thorax when impacted by the door trim. The pad was modeled with material 33 of RADIOSS [1] to incorporate the effect of hysteresis. Material law 33 is very similar to material law 35 as described in the previous section. A comparison of the simulation and padded impact test results, as shown in Figure 4f, indicates fairly accurate identification of dynamic response. The significance of this test from the hysteresis point of view will be more clear in later sections where full scale sled test results are compared.

IDENTIFICATION AT ASSEMBLY LEVEL

(a) Modeling of Lower Part of Leg and Its Effect on Pubic Symphysis Peak Force (PSPF)

The outer surfaces of the upper leg and the lower leg are modeled with shell elements. The inside rigid rod is modeled with beam elements and the joint between the upper and lower leg is modeled with general springs as shown in Figure 5a. Since the product of the mass of the legs and the distance of its center of gravity (G2) from that of the whole dummy (G1) is of a very high order, it greatly affects the total movement of the dummy as whole, especially for lower end impacts, say at the hip point. Hence, it is a key factor in designing the door and surrounding structures. The effect of legs on PSPF was studied by numerical simulation for two types of models: (i) one with beam elements to incorporate the inside steel rod and the links and (ii) the other without beams at an impact velocity of 32km/hr in the direction of motion. Figure 5(b-e) clearly illustrates the validity of the present model which satisfactorily predicts the impactor deceleration, PSPF and the overall lateral movement of the dummy as calculated from the response of the line joining the pelvis, lower spine and upper spine.

(b) Effect of Hysteresis of Impactor Pad and Thorax Module on Rib Displacement

Figure 6a shows the test configuration for multi-input padded sled impact tests for case 2 (refer to Figure 12 for other cases) with an offset in the hip pad. Typical deformation modes of the rib module for padded impactor drop tests are shown in Figure 6b. Figure 6c shows the effect of hysteresis on the chest deformation response. Without a hysteresis mechanism, as illustrated in Figure 6c, the predicted response of the upper rib displacement shows greater deviation from the experimental value due to a lack of pad restoration force in region B (refer to Figure 6b, d) where the relative velocity of the ribs and the spine box is very low. This mechanism can be properly explained by the force-displacement response characteristics of 45PP padded impactor drop tests for a single rib module as shown in Figure 6e. Similar results were obtained for all the other eight different cases of HYGE tests with various offsets at the abdomen and hip pad with respect to the chest pad.

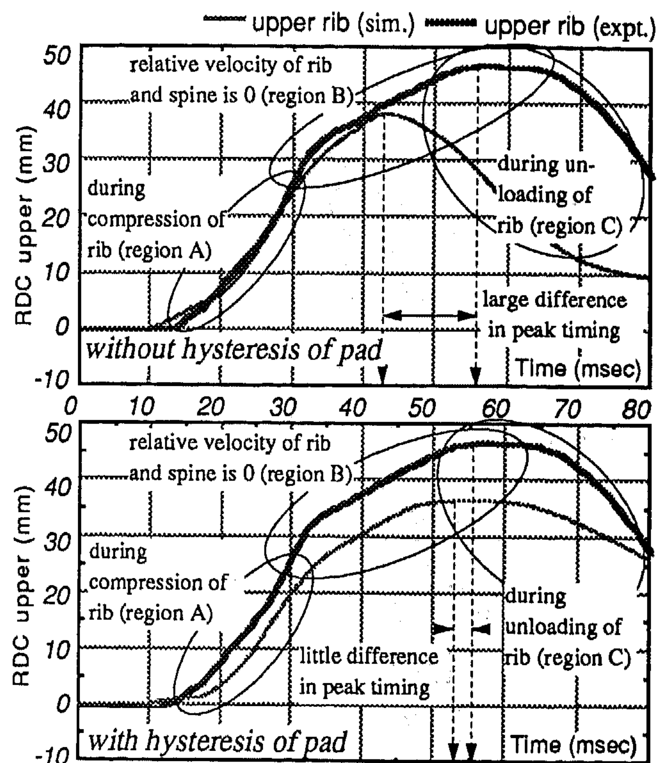

Figure 6c. Variation of RDC (case 2); V=25km/hr.

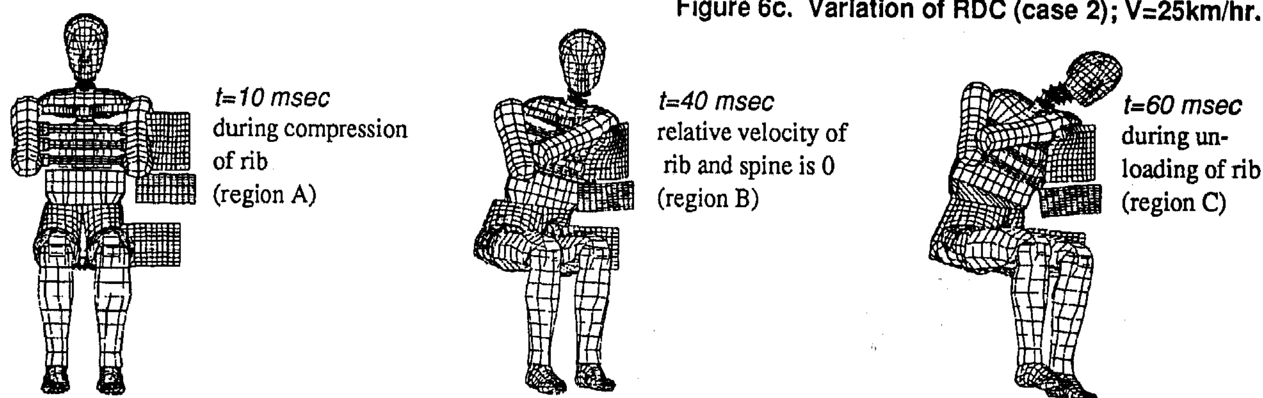

Figure 6d. Deformation Mode of Impactor Pad Corresponding to Regions A, B and C

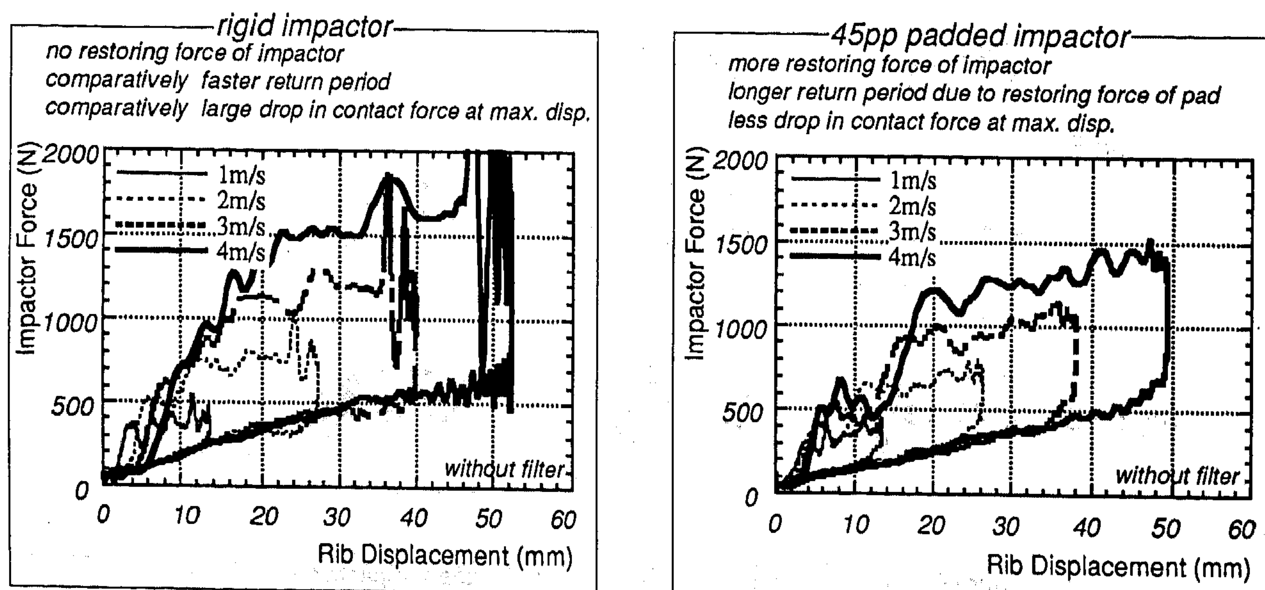

Figure 6e. Comparison of Rib Module Force Displacement Characteristics For Different Impact Speeds

(c) Effect of Hysteresis of Impactor Pad and Thorax Damper on Rib Displacement

The relative rotation of the arm is controlled by the movement of the clavicle within the top and bottom shoulder plates. The end of the clavicle is tied at the back of the shoulder block by a pre-tension elastic chord. This thin elastic string is modeled with 10 shell elements in order to simulate its contact with the sides of the shoulder block. The force displacement characteristics of the elastic chord is measured and modeled with 20 springs attached at the edges of the shell elements. Figure 7a shows the effect of the pre-tension of the elastic rod on rib displacements. Typical relative rotational deformation modes of the arm and shoulder and the consequent compression of the rib module for padded impactor tests are shown in Figure 7b. Without a pre-tension mechanism, the predicted response of lateral chest displacements shows greater deviation from the experimental values due to an improper distribution of contact force at the upper, middle and lower ribs. The distribution of contact forces at three different heights has a large influence on the relative compressive characteristics of these ribs[4]. Similar results were obtained for all the other eight different cases with various offsets at the abdomen and hip pad as shown in Figure 12. The experimental value of the lower is are not available.

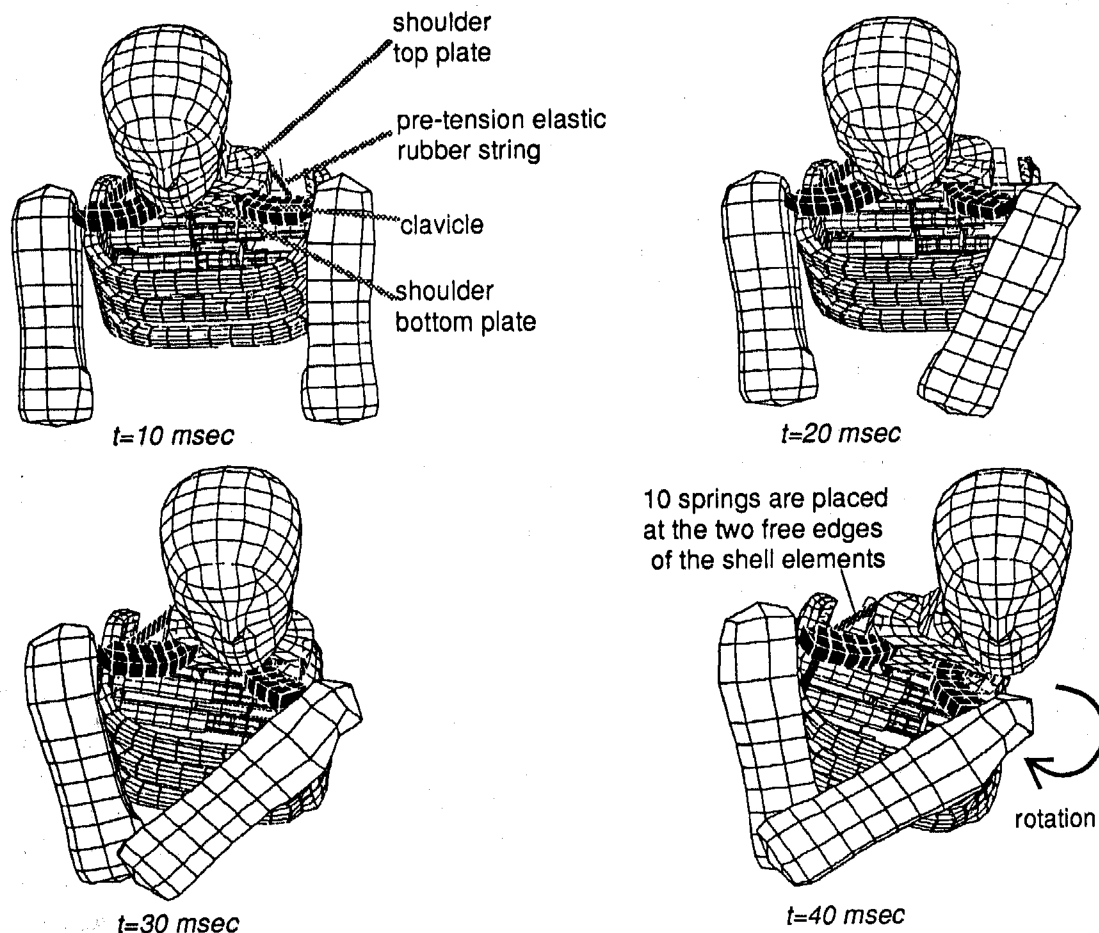

Figure 7b. Rotational Deformation Mode of Shoulder and Arm (case 2); V=35km/hr.

DETAILED VERIFICATION OF FEM MODEL IN DIFFERENT HYGE TEST SIMULATIONS

(a) Mechanism of Side Impact Simulation

An essential requirement for side impact applications is a validated database of the dummy and the barrier models for assessing whether the design meets safety regulations. Simulation results can provide a fundamental understanding of occupant behavior and an evaluation of design variations affecting the occupant responses in side impact crashes, rather than relying on expensive vehicle tests. The prediction of occupant responses in side impact events depends on how well the geometry, the material properties and the mechanism of the dummy can be represented and on how well the responses of the vehicle and the barrier can be predicted as individual items.

Figure 9b represents the typical velocity-time histories of the MDB, the struck vehicle, the impacted door and the dummy's spine in a FMVSS 214 test as illustrated in Figure 9a. The force input from the bumper of the MDB was transmitted via the door hinges to the A and B pillars. The MDB rapidly decelerate due to the reaction force of these pillars. A schematic diagram of the transmission of force from the arm-rest, B pillar and door to the dummy is illustrated in Figure 9c. The complex impact phenomenon can be analyzed with a simple HYGE test as shown in Figure 9d. The abdomen pad has a 50 mm offset with respect to the chest and hip pad to simulate an input pattern similar to that of real crash tests. The door impacts the dummy approximately at a speed of 35 km/hr.

(b) Verification of Dynamic Behavior and Different Injury Response Criteria at a Speed of 35km/hr.

The overall accuracy of the dynamic behavior of the present model is checked by comparing the acceleration of the upper spine (Figure 10a), lower spine (Figure 10b) and pelvis (Figure 10c). On the following page, the injury response criteria of the upper rib displacement, middle rib displacement, abdominal force(APF) and pubic symphysis force(PSPF) are plotted in Figure 10d, 10e, 10f and 10g, respectively. All of them show fairly good correlation which validates the present model. However, the following modifications are necessary to further improve the accuracy of the model.

(a) The shape of the upper rib displacement near the peak. Unlike the simulation results, the experimental result clearly shows two different slope before it reaches the peak.

(b) The shape of the pubic force(PSPF) near the second peak. Unlike the simulation results, the experimental result clearly shows a high peak around 40 msec.

(c) The shape of the experimental abdominal force(APF) is flatter at the top than that of the simulation result.

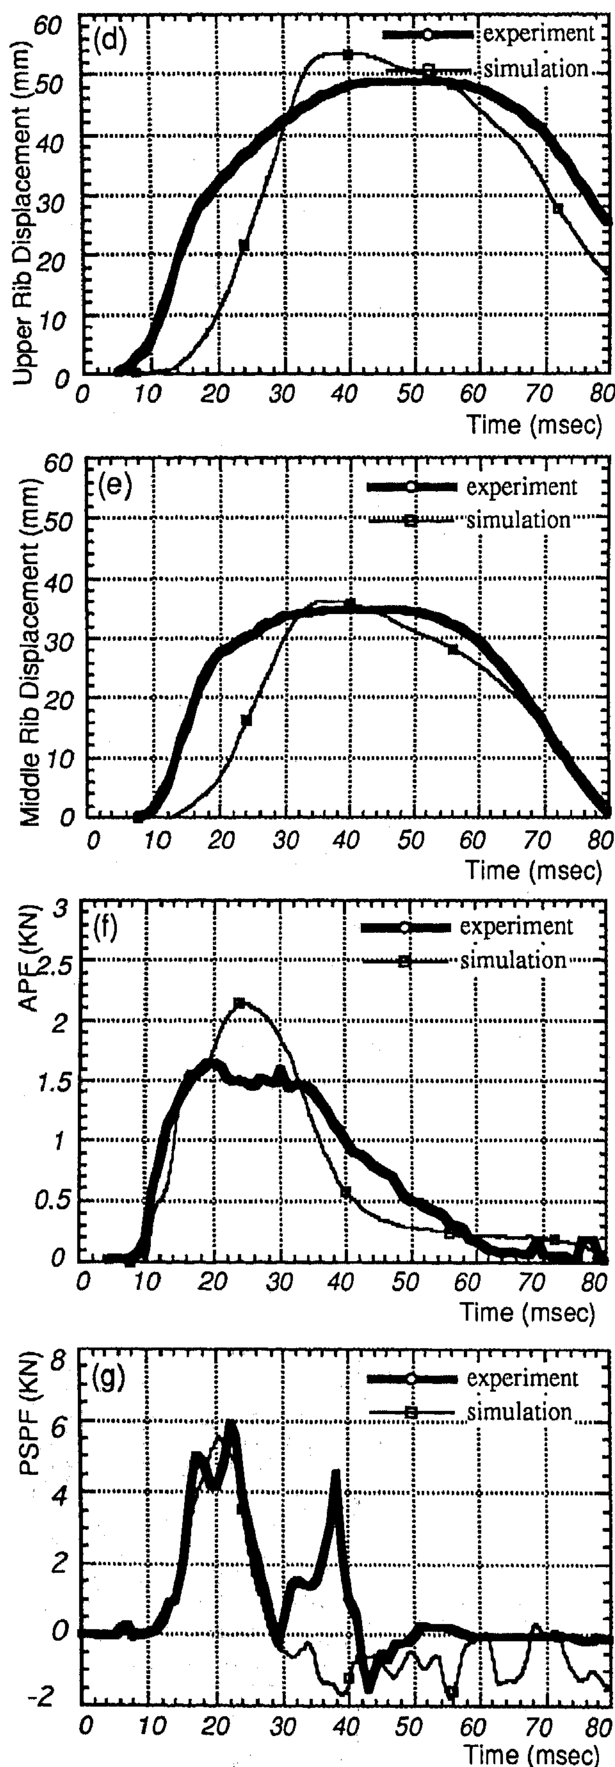

Figure 10. Comparison of (d) Upper Rib Displacement, (e) Middle Rib Displacement, (f) Abdominal Force (APF) and (g) Pubic Symphysis Peak Force(PSPF) (case 4, V=35 km/hr)

(c) Variation of Injury Criteria at a Speed of 35km/hr for Different Input Load Patterns

A series of nine different sled tests was performed by varying the input load pattern (Figure 12) at the abdomen and hip to investigate the variation of the injury criteria such as RDC, PSPF and APF, simulating a broad spectrum of possible input load patterns on the occupant in actual side crashes. The results are plotted in Figure 11.

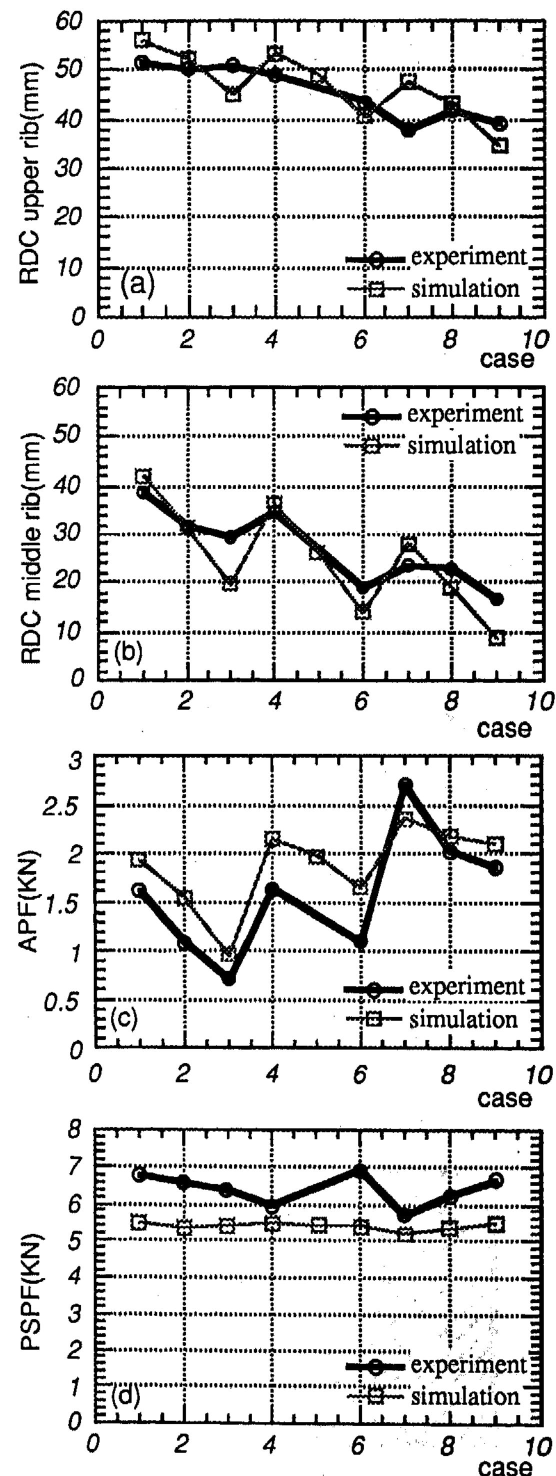

Figure 11. (a) Variation of Upper Rib Displacement, (b) Middle Rib Displacement, (c) Abdominal Force (APF) and (d) Pubic Symphysis Peak Force(PSPF) (V=35 km/hr)

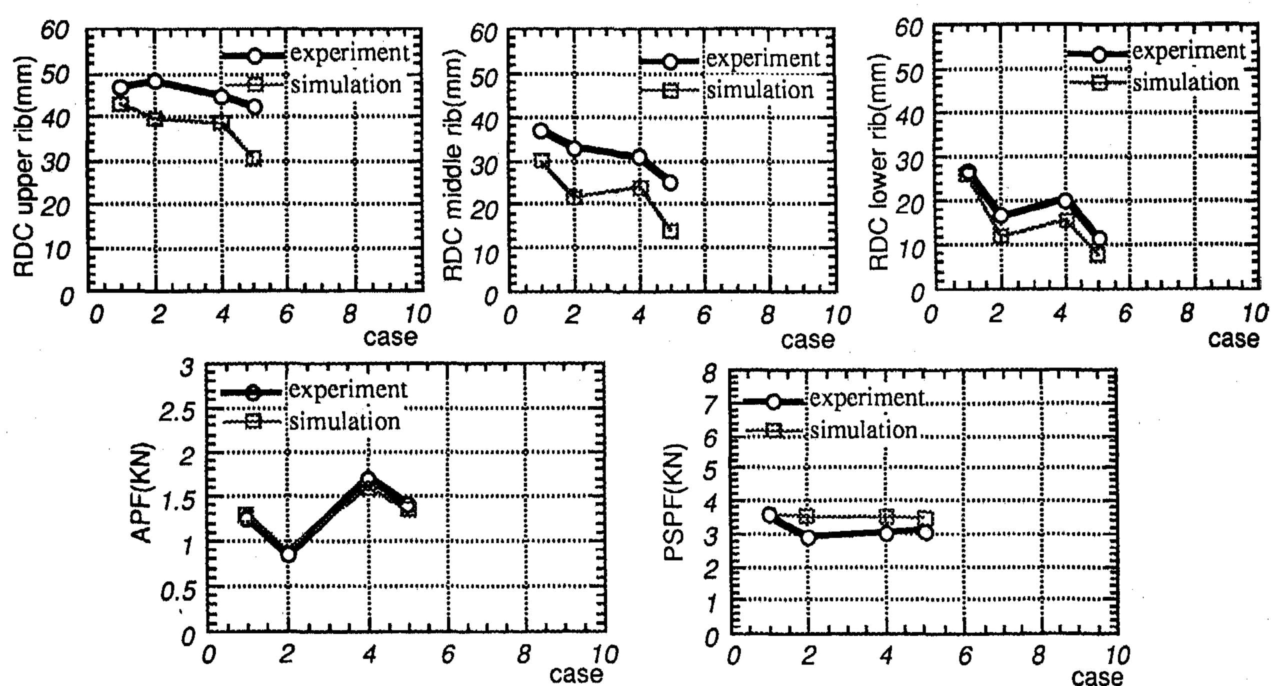

Figure13. (a) Variation of Upper Rib Displacement, (b) Middle Rib Displacement, (c) Abdominal Force(APF) and (d) Pubic Symphysis Peak Force(PSPF) (V=25 km/hr)

(d) Verification at a Lower Speed of 25km/hr

To further check the accuracy of the present model at a much lower speed (25 km/hr) than actual crash tests, four different cases (case 1, case 2 case 4 and case 5) were chosen. Case 2 has a 50 mm offset at the hip with respect to case 1 which has no offset. On the other hand, case 4 has an offset of 50 mm at the abdomen relative to case1 and case 5 is chosen as a combination of cases 2 and 4. Figure 12 shows a comparison of the tests and experimental results for the upper, middle and lower rib displacements, the abdominal force and the pubic symphysis pelvis force. The results are very similar to those at an impact speed of 35 km/hr.

CONCLUSION

Based on the results of the foregoing simulations and experimental verifications, the following conclusions can be drawn.

- Comparing the peak values of thorax damper displacement for different velocities and types of impact, a satisfactory level of correlation can be achieved with the present FEM model for studying the dynamic behavior of the EUROSID dummy.

- The above results indicate that proper modifications of material modeling lead to better representation of bottoming of the arm pad, rib deformation mechanism and lumber spine bending characteristics and so forth, all of which are very important in analyzing the distribution of the load path from the ribs to the spine.

- Single-input rigid hip impacts were studied to investigate the effect of the legs. The results clearly show the effect of leg inertia and the modeling of joints on pubic force PSPF.

- The sensitivity of the pubic force(PSPF) is comparatively low in comparison to the abdominal force(APF) with respect to the timing of the input load as discussed in the present analysis. However, rib displacements can be considerably reduced with a comparatively faster input at the hip. It can be well explained by analyzing the mechanism of rib displacement which is nothing but the area under the curve of the velocity profiles corresponding ribs and the spine as illustrated in Figure 9b. A faster input at the hip will accelerate the spine box with little rib displacement. This initial velocity will prevent a strong impact at the thorax.

- In spite of the reduction in rib displacement criteria(RDC)due to a faster input-load at the abdomen, the high sensitivity of the abdominal force with respect to the input-load timing at the abdomen negates the benefit of having a large offset at the abdomen.

- Good correlation with the experimental results at a speed of 35km/hr indicates that the present FEM model will allow the CAE engineers to evaluate doors, reinforcements, foam padding and B-pillar sections in side crash tests with sufficient accuracy.

- Further improvement is necessary in the pelvis model to predict the variation of PSPF values with higher accuracy. It may also be worthwhile to study the sensitivity of the location of the abdominal and pelvis input loads on different injury criteria.

DISCUSSION

This paper has focused on the basic dynamic behavior of the EUROSID dummy and the corresponding modifications incorporated in the FEM model. Only a small number of multi-input padded sled-impact dynamic responses were tested and verified. These were studied to investigate the effect of the timing of the door impact on the injury level of the occupant. Further study is needed to improve the cross-correlation of the hip-thorax input-output relation and vice-versa. A series of multiple sled tests with simultaneous impacts at the chest, abdomen and hip is also under way with the help of the present FEM model to determine the best feasible input load pattern for achieving the optimum dynamic response.

ABSTRACT

The paper describes the development process of a detailed finite element model database of the Hybrid III crash test dummy family using the manufacturer's product data and test facilities. Specific reference is made to the Hybrid III 50th dummy. The models are validated at material, component, assembly and sled test application levels, and the modeling methodology is described. Each component of the dummy model is discussed together with the specific component impact tests used to validate the model. The specially designed sled tests used to generate highly controlled validation data are detailed.

INTRODUCTION

Crash test simulation has rapidly evolved from the research and academic fields into an everyday design and development tool at automobile manufacturers worldwide. Rigid body models of the crash test dummies are generally accepted and widely used, but the rigid body technique is limited when modeling the vehicle and restraint systems. The rigid body codes are coupled with finite element codes so as to use the rigid body dummy model with a detailed finite element model of the vehicle and restraint system.

Various finite element models of the crash test dummies have been developed by industry and academia to different levels of validation and application and they have not yet been widely accepted. The model database described here is developed from the manufacturer's product data and uses many specially designed impact test conditions to validate the models at the material, component, sub-assembly and full assembly levels.

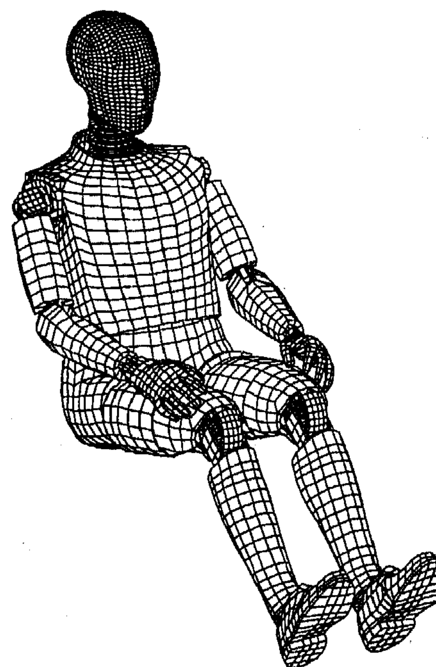

Fig. 1 Assembled Model

MODELING METHODOLOGY

The primary goal was to develop a model that will perform accurately and robustly in a variety of real application test conditions without the need to modify the model for each specific application. To achieve this objective, the models are developed and validated separately at the material, component, sub-assembly and full assembly levels.

Geometry for the models are taken from the manufacturer's engineering drawings for the machined parts. Three dimensional scans were made of the aluminum and brass castings, such as the skull, pelvis

bone and femur hip joints. The vinyl and foam parts were scanned from the manufacturer's production molds or master patterns. It was not assumed that each part was symmetrical, and left and right sides were scanned where there is asymmetry in the physical dummy. Model masses were checked against the production parts.

The component parts are all modeled exactly and without ambiguity. The non-deformable components, typically the dummy skeleton, are rigid bodies but are exact physical representations of the actual parts. The mass distribution is therefore also exact and avoids the need to rely on measured moments of inertia, which can be a source of considerable error.

The robustness of the model is also checked at the component and sub-assembly level. Several analytical test conditions were devised to check the interaction of the component models with special attention paid to the contact surfaces and hour glass energies.

TESTING METHODOLOGY

Individual components and sub-assemblies are validated to many specially designed impact tests as well as the standard calibration tests. Over 600 tests have already been performed for the Hybrid III adult family dummies to date. The full assembly dummy is then validated to pendulum calibration tests and to controlled sled tests.

The selection of the dummy components for the validation testing is carefully controlled. The dummies are certified to perform according to standard calibration corridors which are based on human impact response corridors. These corridors are essentially tolerance bands either side of a nominal performance curve. Manufacturing variations from dummy to dummy can cause individual dummies to perform either higher or lower then the nominal curve. All components selected for the validation tests are brand new and are taken from a dummy or dummy sub-assembly that meets the standard calibration specification as close to the nominal curve as possible.

Wherever practical, material properties are derived from material tests of samples made in special molds or sectioned from production parts. The manufacturer's production equipment was used to make the material samples. All component tests were conducted in the manufacturer's laboratories under controlled temperature and humidity conditions. Material tests were conducted at outside test laboratories.

HEAD

A highly accurate solid model of the head assembly was built using CAD data scanned from the production molds and finished parts. This model was used to calculate the moments of inertia which are within 2% of the nominal specifications for the skull assembly.

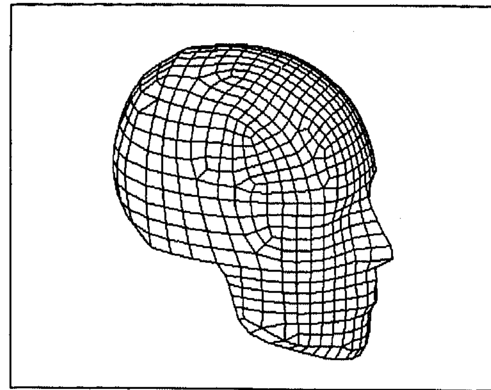

Fig. 1 Head Model

The regulation specification has a very wide tolerance band because of the inherent inaccuracy of physically measuring moments of inertia.

The actual head model has shell elements as part of a rigid body to represent the external surface of the skull. Additional nodal masses are distributed about the rigid body to accurately represent the correct inertia.

The deformable skin is modeled as visco-elastic solid elements. The material properties are derived from the basic vinyl material. Special molds were machined to produce flat vinyl samples at the same thickness as the head skin, and were tested statically and dynamically, and models of these tests built and correlated to the test.

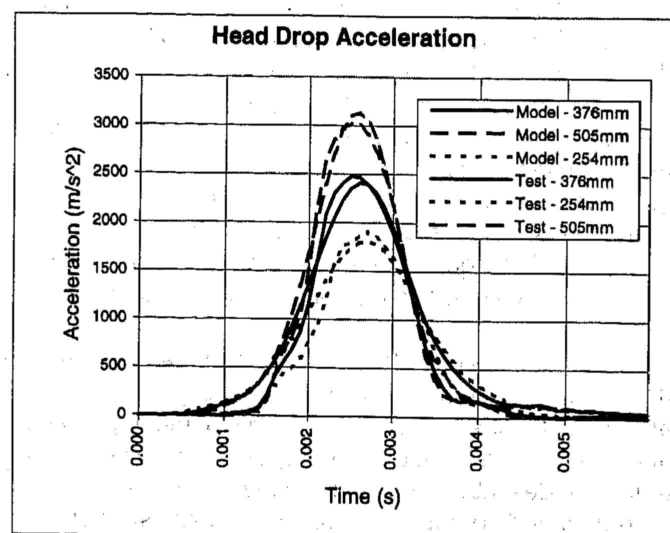

Fig. 2 Head Drop Correlation

Drop Height (mm)	HIC Test	HIC Analysis
254mm	**420**	**412**
376mm	**756**	**784**
505mm	**1282**	**1276**

Table 1 Head Drop Test HIC

The complete head assembly model is validated to three different head drop speeds, to drop impacts to irregular surfaces, to other pieces of vinyl and to a deformable sheet metal section. Peak accelerations and HIC values are within 5% of the test values, as shown in Table 1. The correlation to the three drop impacts is shown in Fig. 2.

NECK

The neck assembly is divided into two mechanisms. The occipital condyle is represented by a lateral pin pivot with anterior and posterior rubber stops controlling the nodding motion of the head. A component test was designed to isolate this joint and measure the moment/rotation stiffness at various rates. This joint was modeled in LS-Dyna as a revolute joint with a non-linear rotational spring and damper per the test measurements.

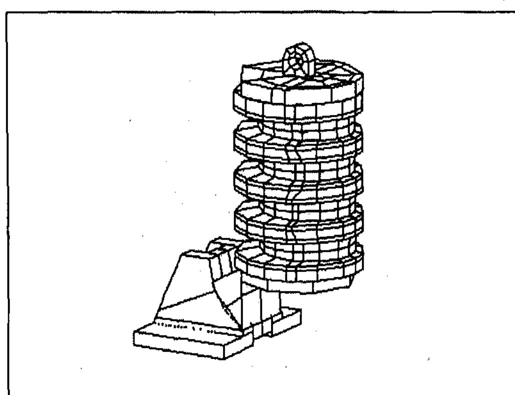

Fig. 3 Neck Model

The neck is composed of four butyl rubber segments sandwiched between five aluminum discs with a steel cable running through the center. The entire assembly is molded in one operation and the bonding between rubber and aluminum has to meet a specification. The rubber segments discs have a partial-depth horizontal slit on the anterior side. This results in a less stiff response in neck extension (head bent back) than in flexion (head bent forward) to match the human neck response. Each slit has a different depth to give a prescribed deformed shape.

A new certified neck assembly was rough sectioned and the samples of the rubber were milled in a fixture cooled by liquid nitrogen. The process made the rubber hard enough to produce precise, high finish samples for material testing. These samples were put through tension, compression and oscillatory shear tests to define the base material properties. The samples had to be cut from actual parts because the high temperature and pressure processing of rubber components determines the final material properties.

The geometry for the neck is taken from the manufacturer's drawings. The aluminum disks are modeled as rigid solid elements and the rubber segments are modeled as visco-elastic solid elements. Eight-point integration was necessary to avoid hour-glassing at the extreme deformations. The steel cable is represented by elastic truss elements with contact defined to the aluminum disks. A single surface contact surface was used for each neck slit. In order to increase the stiffness of these slit contact surfaces without causing time-step problems, the density of the neck rubber adjacent to the slits is increased and the densities of the remaining rubber and the aluminum disks reduced accordingly. The mass redistribution is not believed to affect the response.

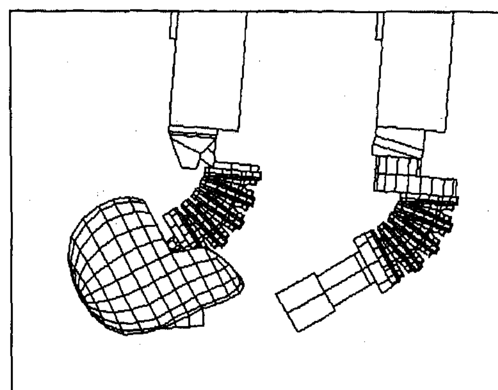

Fig. 4 Neck Pendulum Tests

To test the neck without the nodding blocks, a rigidly mounted steel dead weight was mounted to the neck to replace the head. This assembly was then tested at different speeds on the neck pendulum fixture. The test was exactly modeled (see Fig 4) and the test deceleration pulse used as input to the model. A six axis load cell measured moment and shear load, and rotary potentiometers recorded the angular deflection.

Final validation was completed with the complete head, nodding joint and neck assembly on the neck pendulum test fixture. The standard test calibration impact velocities are 7.06ms^{-1} for flexion and 6.07ms^{-1} for the extension test. Both tests were repeated at a lower velocity of 4.34ms^{-1}. The deformation of the neck during the standard extension test is shown in the left side of Fig. 4. Note the opening of the neck slits. The neck rotation vs. time correlation results are shown in Fig 5. "D-plane rotation" is defined as the rotation of the base of the head relative to the pendulum.

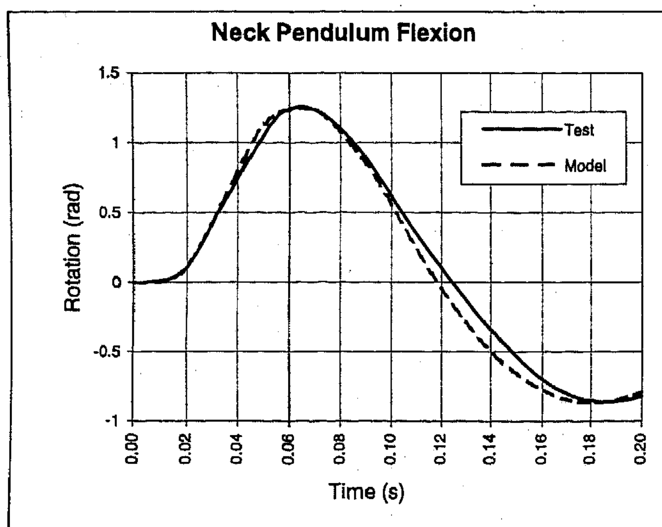

Fig 5 Neck Flexion Correlation

THORAX ASSEMBLY

The thorax is the most complicated of the Hybrid III components. A ballasted steel spine box acts as the backbone . Six spring steel ribs are attached by screws to its rear with additional leaf springs to prevent permanent deformation of the ribs. A high density damping material is bonded to the inside of each rib. The thickness of this material is modified to control the dynamic performance of the thorax assembly. The sternum assembly which joins the open end of the ribs, is a sandwich of Delrin (a brand name nylon), a hard polyurethane and aluminum.

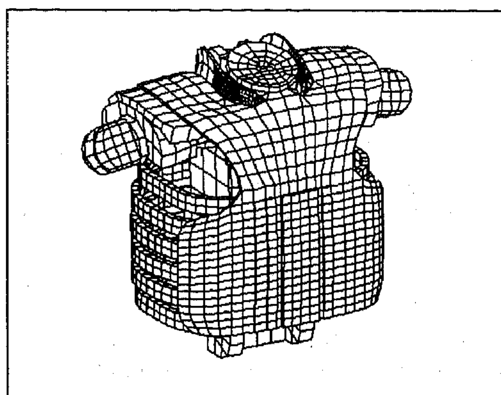

Fig. 6 Thorax Assembly

Each shoulder is represented by three aluminum castings, the clavicle link, clavicle and shoulder yoke, which are connected by joints that allow a few degrees of angular motion. These shoulder components have contoured upper surfaces for interaction with a vehicle's seat belts. Surrounding the thorax assembly is a jacket made from a vinyl-skinned polyurethane foam. An Ensolite pad is bonded to the inside of the front of the jacket. The hard polyurethane part of the sternum, called the bib, extends upwards and splits into three. The center of the bib is clamped between the spine box neck bracket and the neck's lowest aluminum disk. Ensolite pads are bonded to the side pieces of the bib and sit over the clavicles.

Chest deflection is the relative displacement between the sternum plate and the spine box as measured by an aluminum rod attached to a rotary potentiometer pinned to the base of the spine box. The other end of the aluminum rod slides in a groove in the aluminum sternum plate. As the rib set is compressed, the rod rotates and its outer end slides up the sternum. Chest deflection is calculated by applying a transfer function to the output of the rotary potentiometer.

THORAX MODELING

The spine box is modeled in detail as rigid solid elements including the internal lead ballast. The three accelerometers used to calculate the resultant chest acceleration are individually represented as the standard LS-Dyna accelerometer feature. Beams are added through the active axis of each accelerometer to aid visualization.

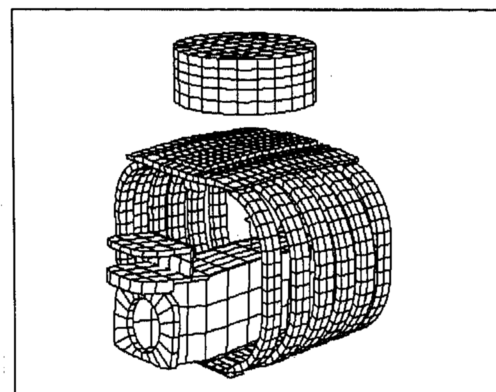

Fig. 7 Thorax Assembly Drop Test

The ribs are modeled as elastic shell elements, two rows deep, with a single layer of visco-elastic solid elements using single point integration for the damping material. The Delrin and aluminum plates of the sternum are represented by rigid solid elements and the bib as elastic thick shell elements. The jacket and ensolite pads are modeled as low density foam solid elements with 8-point integration. Fig. shows the thorax assembly model without the jacket.

The clavicle, clavicle link and shoulder yoke are modeled as separate solid rigid bodies. The clavicle link is pinned to the spine box, with resistance provided by a rubber shoulder bumper. The clavicle is pinned to the clavicle link, with resistance provided by a Delrin pad sitting between the two. The shoulder yoke is attached to the clavicle by a joint with Delrin bushings and cushioned

rubber bump stops. All these joints were modeled in LS-DYNA as generalized stiffness joints. Moment/rotation characteristics and stop angles were taken from test data.

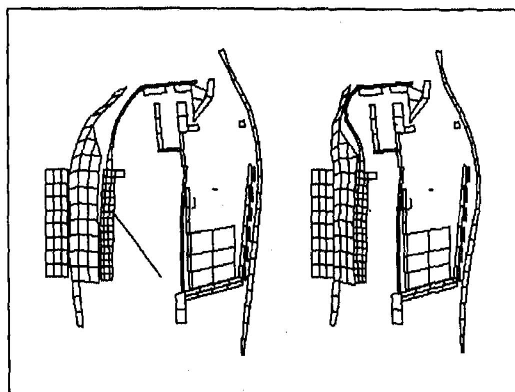

Fig. 8 Section Through Thorax Model

The chest displacement transducer is modeled rigorously. The aluminum rod is represented as a rigid beam with its lower end attached by a revolute joint to the adapter assembly which is similarly attached to the base of the spine box. Its upper end was connected to the sternum rigid body via a cylindrical/spherical joint combination that allows it to slide up and down the sternum. A zero-stiffness rotational spring at the base of the rod measures the rotation.

THORAX VALIDATION

Base material properties were measured from standard tension, compression and oscillatory shear tests of all the plastic materials. The rib steel is assumed to remain elastic.

A drop tower test was devised to perform individual rib and rib assembly impact tests. The ribs are clamped vertically on a bed plate with a load cell beneath it. A cable-guided drop head with accelerometer and velocity trap drops onto the ribs from varying heights generating impact velocities up to 10m/s. A vinyl pad was mounted on the drop head to avoid metal to metal impact. A linear potentiometer measures rib deflection.

Each rib of the six rib assembly was tested with and without the damping material. The ribs came from a new certified set of ribs. Models of each test condition were built to ensure the response of the damping material was correctly characterized at different velocities.

Drop tests were also performed on a rib-cage sub-assembly comprising the spine box, ribs and sternum. The model of this test is shown in Fig 7. An Ensolite pad was mounted on the drop head face to prevent metal to metal contact to the sternum screw heads. Correlation for this test is shown in Fig. 9. Note the accurate prediction of the residual chest compression.

To test the robustness of the material stack up between the chest jacket and rib assembly, an analysis of a drop test to the full thorax with jacket was performed to ensure that the many components in the thorax would interact properly. A section through this model is shown in Fig. 8. The left side shows the initial, undeformed geometry of the thorax and drop head. The right side shows the deformed geometry at the time of maximum chest compression.

The interaction with LS-DYNA one-dimensional seat-belt elements was also evaluated. The full thorax model with an initial velocity of 6ms^{-1} was decelerated by a shoulder belt with fixed end points. The maximum belt load during the analysis was 2000N.

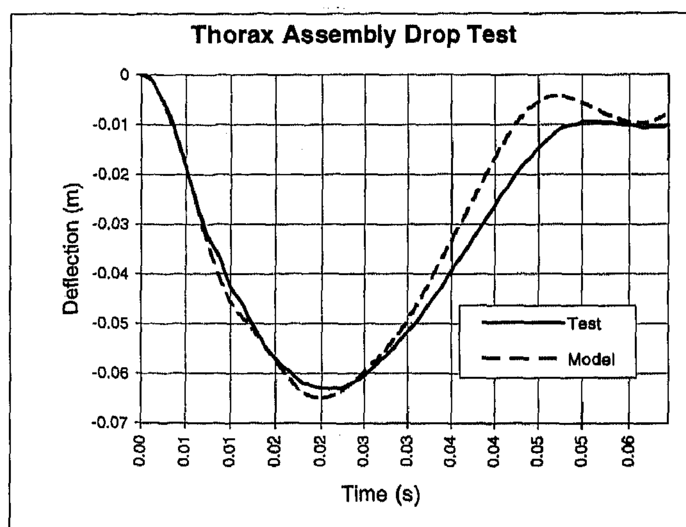

Fig. 9 Thorax Assembly Drop Test

ABDOMEN

The Hybrid III abdomen is a single C-shaped component molded as a one piece unit. The part is a polyurethane foam with a vinyl skin and locates in a cavity above the pelvis assembly.

The geometry for the abdomen model was scanned from the production mold and it is modeled with low density foam solid elements with single point integration (see Fig. 10). Drop tests at 4.50 ms^{-1} and 6.76 ms^{-1} were used to validate the model. Correlation for the 6.76 ms^{-1} test is shown in Fig. 11.

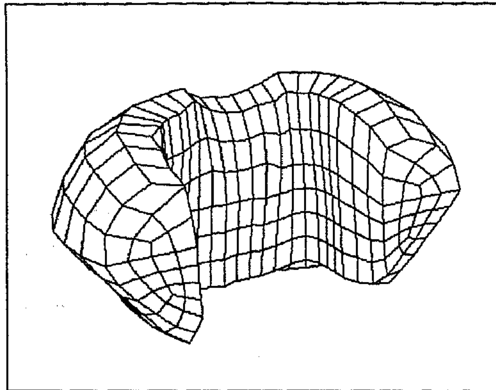

Fig. 10 Abdomen Model

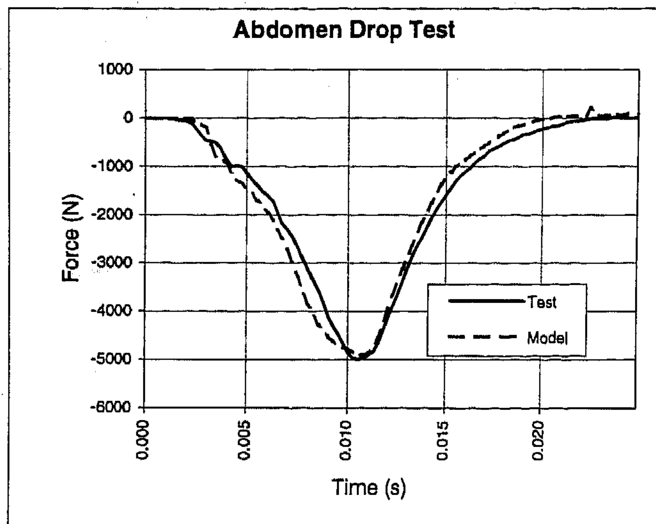

Fig. 11 Abdomen Drop Test Correlation

LUMBAR SPINE

The lumbar spine is a curved polyacrylate elastomer member, molded between steel end plates. Two internal steel wire-wound cables provide lateral stiffness and limit extension of the spine. The geometry for the lumbar spine model was taken from the manufacturer's drawings. The rubber is modeled as visco-elastic solid elements with single point integration. The fundamental material properties and short- and long-term shear moduli are derived from oscillatory shear tests performed on a sample of the polyacrylate elastomer material cut from a new lumbar spine. The steel cables are modeled as a series of elastic truss elements spaced from the rubber by rings of rigid shell element. Spherical contact entities were evaluated for these cables but the CPU costs were prohibitive.

The lumbar spine is a key load path between the upper and lower body in a vehicle impact, especially when the dummy is only restrained by an air bag and knee bolsters. If there is a time delay between the restraint of the upper and lower torsos, then a significant velocity difference can occur between these two bodies, until the lumbar spine corrects the difference. Shear loads in the lumbar spine can exceed 5000N which is a major component of the decelerative forces on the spine box and thus the measured chest accelerations.

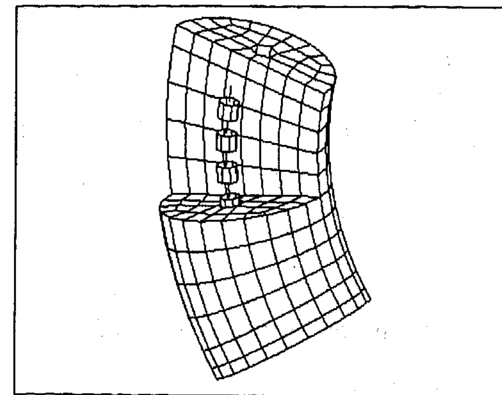

Fig. 12 Lumbar Spine

There is no specific calibration test for the lumbar spine as a component, but there is a static bending test on the fully assembled dummy. Because of the lumbar spine's important role in a crash test, this static test was ignored for the model and a dynamic component test was devised.

Special fixtures were built to attach the lumbar spine to the neck pendulum test fixture with a six axis load cell. A rigid steel mass was attached to the other end of the spine. Extension and flexion tests were performed at 4.34, 5.97 and 6.99m/s using an aluminum honeycomb block to provide the deceleration pulse. Fig. 13 shows the deformed and undeformed shapes of the lumbar spine undergoing the extension test, with the pendulum swinging from right to left. The correlation of the spine rotation with time is shown in Fig. 14 for the 5.97m/s flexion test.

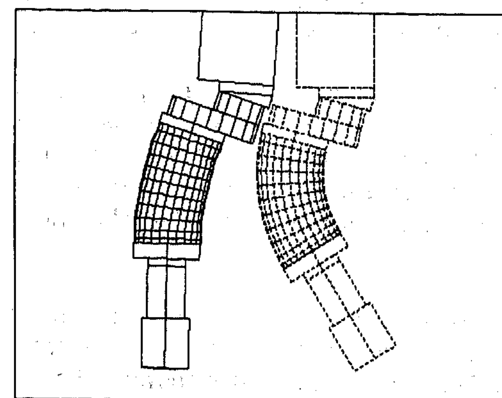

Fig. 13 Lumbar Spine Flexion Test

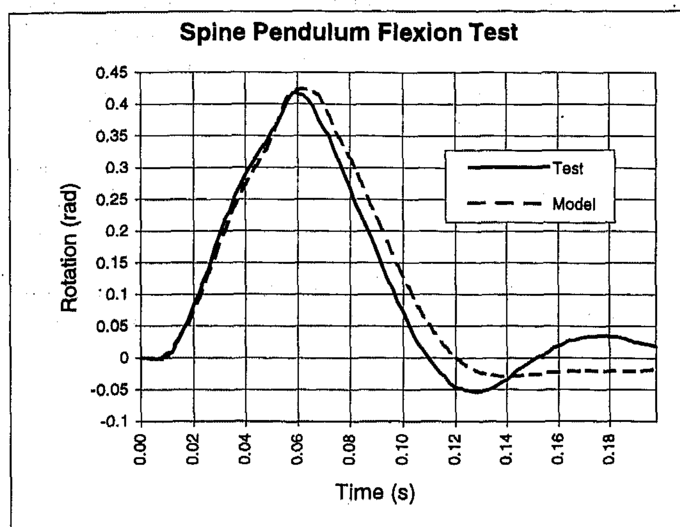

Fig. 14 Lumbar Spine Pendulum Flexion Test

PELVIS

The hip assembly of the Hybrid III is a vinyl-skinned polyurethane foam molded around a machined and ballasted aluminum casting representing the pelvic bone The pelvis is molded in a permanently seated position. The upper femur joints are brass castings with a ball joint that clamps into ball sockets machined into the pelvis bone casting. The pelvis casting is a regulated design and was originally cast from an actual human pelvis bone. Accordingly, the pelvis bone is not symmetrical.

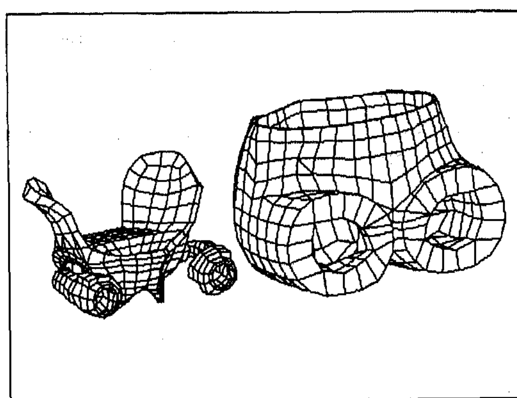

Fig. 15 Pelvis Model

In certain vehicle tests, the femur to hip joint can rotate up to the limits of its range of motion and the ball joint bottoms out, causing excessive loads in the lumbar spine and chest acceleration. To address this, NHTSA has recently proposed an additional calibration test that sets moment/rotation corridors for the hip to femur joint. This requires a design modification to the femur attachment and the addition of a reinforced polyurethane pad to achieve the necessary moment/rotation requirements. This new design has been incorporated into the model.

The pelvis model geometry was scanned from an actual pelvis casting with the asymmetry retained. The pelvic bone surface is modeled as rigid shells and the correct mass moments of inertia applied. The foam and vinyl skin is modeled with low density foam solid elements with eight point integration. The femur attachment member is made up of rigid solid elements, with the urethane pad modeled as elastic solid elements. Fig. 15 shows the pelvic bone and femur attachment members to the left and the pelvic skin to the right. The deformable pelvis elements are matched with the surface of the pelvis bone and the mating surface nodes are incorporated into the rigid body of the pelvis bone.

To assess the robustness of this model, a belt deceleration analysis was performed, similar to the analysis performed for the thorax. The maximum belt load during the analysis was 4000N and several modifications were made to the model to improve the robustness.

KNEE

The knee assembly is a machined steel part containing the knee pivot joint, with a steel clevis weldment attaching to the lower leg. On each side of the clevis pivot and the knee is a knee slider joint with a rubber block bonded to both sides of the slide. A vinyl-skinned urethane foam molding fits over the knee assembly with an additional rubber pad between the knee cap portion and the vinyl skin.

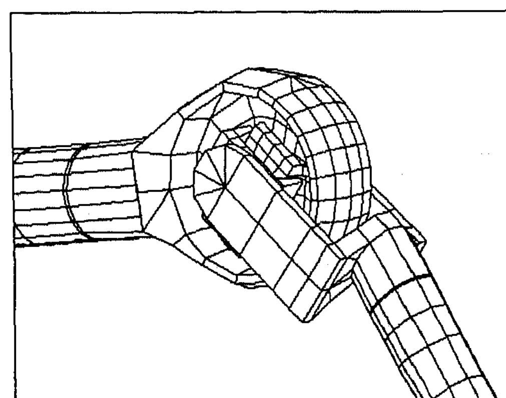

Fig. 16 Knee Model

The knee flesh geometry was obtained by scanning production molds. The remaining geometry was taken from engineering drawings. The LS-Dyna model of the knee is shown in Fig. 16. To the left is the femur (upper leg) skeleton and to the right is the tibia (lower leg) skeleton. The knee cap, friction block and slider are modeled using rigid solid elements and the knee pad is a single layer of visco-elastic solid elements

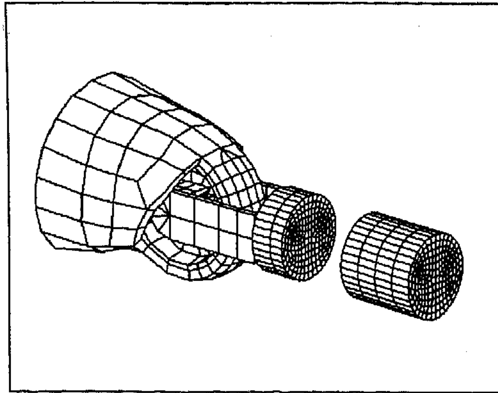

Fig. 17 Knee Slider Test

with eight point integration. The knee slider is modeled using a non-linear spring and a linear damper in parallel.

The two knee calibration tests are used to validate the knee model. The upper leg is rigidly mounted to a load cell and struck with a pendulum to the knee cap. The pendulum deceleration must fall within set performance corridors. Fig. 18 shows the analysis correlation for this test. The knee slider calibration test measures the response of the sliding joint inside the knee to a pendulum impact to a modified clevis bracket. See Fig. 17.

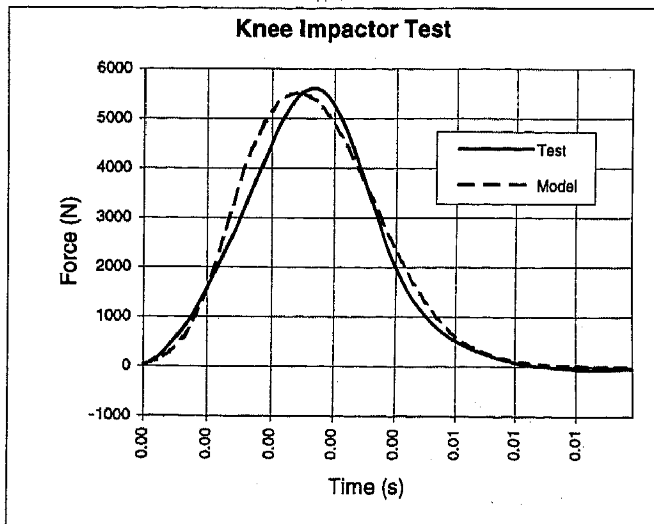

Fig. 18 Knee Impact Correlation

LIMBS

Geometry for the limb skeletons was taken from engineering drawings. The geometry of the external "flesh" was scanned from the master patterns and/or the production molds of the components. The skeletal structures are modeled as solid elements as part of rigid bodies. The deformable vinyl-skinned foam on the arms and legs are modeled as low density foam solid elements. Fig. 19 shows the legs, one with flesh removed to show the underlying skeletal structure.

The elbow, wrist, knee and ankle all include one or more joints to allow twist, rotation or flexion. All these were modeled as generalized stiffness joints. Many of these joints are adjustable in the physical dummy, and are set at "1g" friction - meaning that they should barely support a horizontally extended limb. The correct friction torque or moment was calculated for each joint from moment equilibrium equations based on the mass and center of gravity of the extended limbs. Each joint also has rubber stops to limit the rotation. Quasi-static range of motion tests produced the data for the generalized stiffness joints.

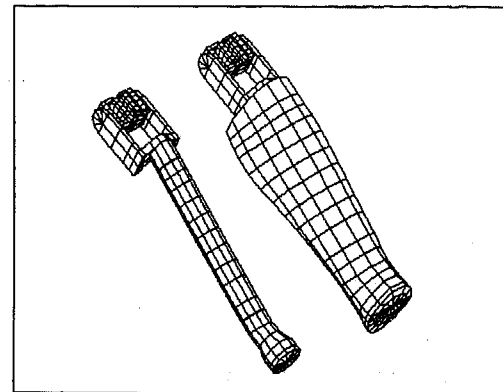

Fig. 19 Lower Leg Model

HANDS

The hands are molded in one piece with solid vinyl and have no skeletal structure except at the joint to the forearm and they play a significant role in a vehicle test. The hands are placed on the steering wheel for test set-up but are typically forced off the wheel as the arms are pushed outwards by the airbag. Also the hands often impact other portions of the vehicle and can cause peak load transfer though the arms to the spine box.

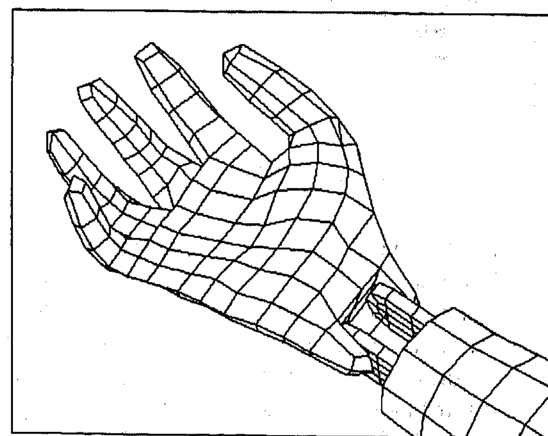

Fig. 20 Hand Model

For these reasons specific detail was put into the hand models which are modeled as visco-elastic solid elements with eight-point integration. There was initial concern that an accurate geometric model of the fingers could lead to such high deformation of the finger elements that the model could not be guaranteed to be robust. The hand model was analytically drop tested onto a rigid surface at 10m/s with added masses to represent the arms. The model. proved to be very robust at several different impact orientations.

ANKLES AND FEET

The model uses a generalized stiffness joint to represent the ankle and allows up to 30 degrees of rotation from the perpendicular position before it hits a hard stop. There is also a 45 degree ankle option with the Hybrid III dummy, and a new NHTSA proposal puts a rubber soft stop into the ankle joint. These will be parts of future model upgrades.

The Hybrid III dummy is always tested with regulation shoes, and these are included by default in the model. The specified regulation size 11EE shoe was scanned and modeled as an integral part of the foot model. The feet are currently modeled as rigid bodies, but a new proposed NHTSA regulation puts a vertical force/defection requirement on the foot which will be part of a model upgrade.

MODEL ASSEMBLY

After the development and validation of the component models, the full dummy model was assembled and subjected to further validation against pendulum and sled tests. Model robustness was a particular focus here - the ability of the model to interact with seat belts, airbags and other vehicle interior components is important.

Most of the components could be assembled easily as they fit together unambiguously. In some instances, however, the physical components undergo deformation during manual assembly, and this deformation needed to be represented in the model. The rear of the pelvis flesh, for example, needs to be stretched rearward by 30mm in order for the lumbar spine to be inserted. Dynamic relaxation analyses were performed for this and other instances (e.g. abdomen insertion). The assembled geometry represents the output from these dynamic relaxation analyses (but note that the model is not pre-stressed).

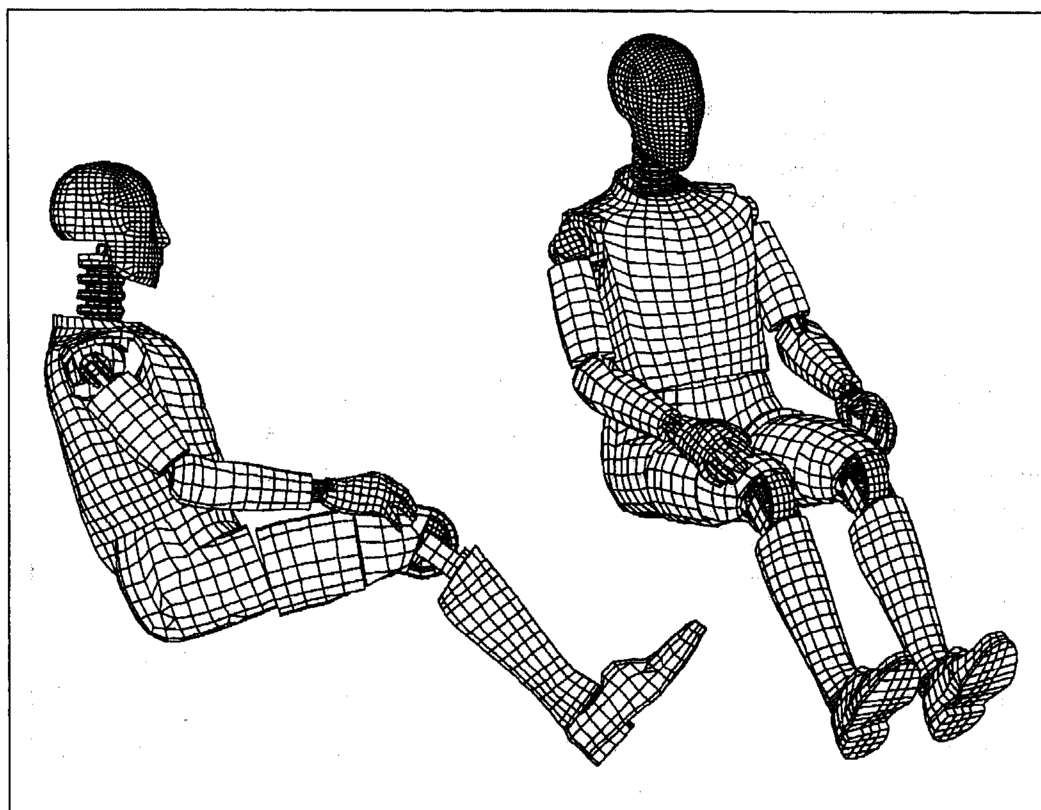

Fig. 21 Full Model Assembly

INSTRUMENTATION

The Hybrid III dummies are available with several instrumentation options in addition to those mandated in FMVSS208. All the optional instrumentation is modeled - See Table 2.

Load cells are modeled in LS-Dyna as stiff springs between nodes on two rigid bodies. Each load cell comprises three translational elastic springs of stiffness $10^5 Nmm^{-1}$ and three rotational elastic springs of stiffness $10^7 Nmm.rad^{-1}$ with orthogonal orientation vectors to allow the extraction of forces in the load cell local axis systems.

Component	Instrumentation	LS-DYNA Feature
Head	Tri-axial accelerometer set	Accelerometer
Neck	Upper - six-axis load cell	6 stiff springs
Neck	Lower - six-axis load cell	6 stiff springs
Thorax	3 accelerometers	3 accelerometers
Thorax	Thoracic spine 5-axis load cell	6 stiff springs
Thorax	Rotary potentiometer	Zero-stiffness rotational spring
Lumbar Spine	3-axis load cell	6 stiff springs
Pelvis	3 accelerometers	3 accelerometers
Upper Leg	Upper femur 6-axis load cell	6 stiff springs
Upper Leg	Femur 6-axis load cell	6 stiff springs
Lower Leg	Instrumented lower leg	12 stiff springs

Table 2 Model Instrumentation

ELEMENT SUMMARY

Table 3 lists the numbers of parts, nodes and elements in each component. Of the parts, 61 are rigid beams whose purpose is to allow the visualization of accelerometers and joint coordinate systems. Null elements are used for some contact definitions and are not included in the totals.

Component	Number of parts	Number of nodes	Number of deformable elements	Number of rigid elements
Head	5	1686	824	830
Neck	13	1749	710	361
Thorax	57	7475	2736	1194
Lumbar Spine	21	1059	464	224
Abdomen	1	825	576	0
Pelvis	15	2013	446	956
Knees & Limbs	85	6708	2206	2048
Total	**197**	**21515**	**7962**	**5613**

Table 3 Element Summary

MASSES

The masses of the individual components are summarized in Table 4. Note that the total is not the sum of each column of figures as each dummy has two sets of limbs. The model masses are within the allowable tolerances.

Each LS-Dyna generalized stiffness joint definition requires two coordinate systems, one for each connected part. To aid visualization during pre- and post-processing, beams were added to the model to show the coordinate system locations and orientations.

Component	**Mass (kg) Actual**	**Mass (kg) Model**
Head	4.5	4.5
Neck	1.5	1.4
Upper Torso	17.2	16.8
Lower Torso	23.0	22.4
Upper Arm	2.0	2.0
Lower Arm	1.7	1.7
Hand	0.6	0.6
Upper Leg	6.0	6.0
Lower Leg	4.3	4.3
Foot	1.4 (no shoe)	1.7 (inc. shoe)
Total	**78.2**	**77.7**

Table 4 Masses

TIME STEP

The component requiring the smallest time step is the thorax at 1.54μs, controlled by a shell element in the steel rib.

FULL DUMMY VALIDATION

The first validation test for the assembled dummy was the standard thorax pendulum test. A rigid pendulum of mass 23.4kg and velocity 6.7ms^{-1} impacts the dummy in the thorax, as shown in Fig. 22. The correlation results for the head, chest and pelvis accelerations and chest deflections are shown in Fig. 23 to Fig. 26. The three acceleration graphs are plotted to the same scale. In the physical pendulum test, the vertical and lateral components of acceleration were not measured, and so the accelerations compared here are for the longitudinal component only. The accuracy of the head and pelvis accelerations is encouraging. It demonstrates the correct load transfer between the dummy components.

BELTED SLED TEST VALIDATION

To prove the validation of the model, the sled testing was specifically designed to be highly controlled with as few unknowns as possible, so that the pure response of the dummy model could be measured and validated and not the restraint system.

A rigid seat structure was fabricated with seat belt anchorage locations taken from an average mid-size vehicle. There was no knee bolster or instrument panel.

The restraint system comprised a lap belt and a separate shoulder belt made from low strain webbing and bolted directly to the rigid seat. No slip-rings or retractors were used.

A sled acceleration pulse was developed representing a typical 30mph front impact and standard Hybrid III instrumentation was used. Seat belt load cells were used to measure seat belt forces.

SLED TEST SIMULATION

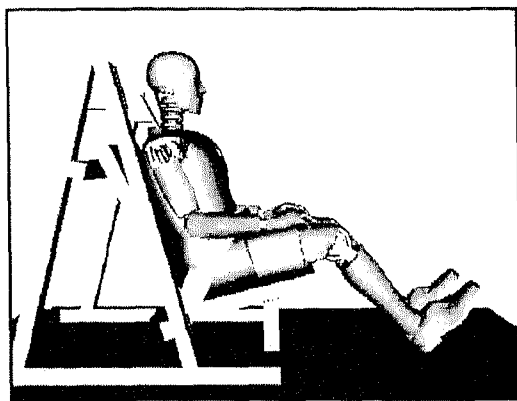

Fig. 28 Model Time 0ms

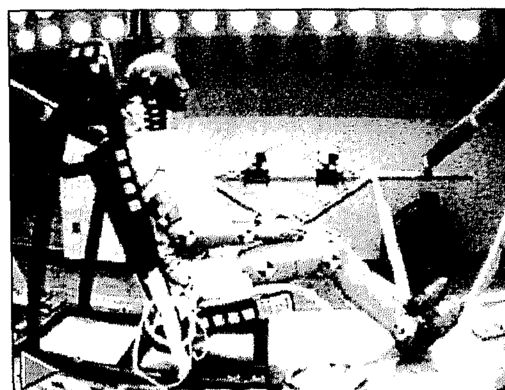

Fig. 30 Test Time 0ms

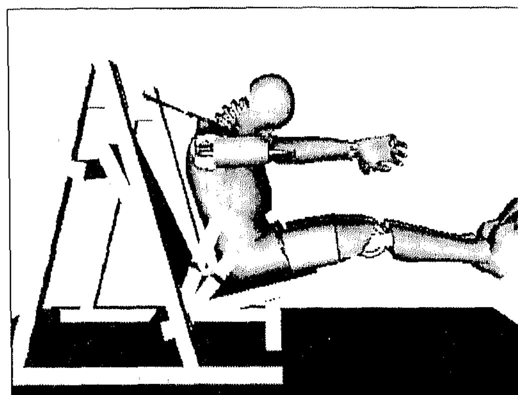

Fig. 29 Model Time 100ms

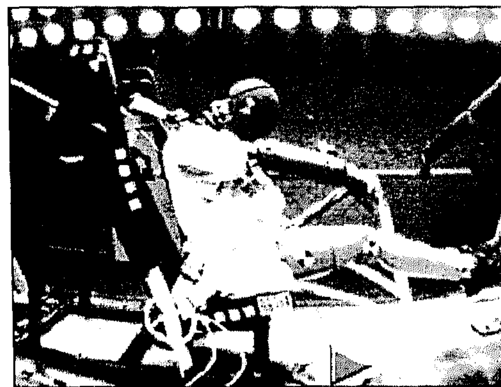

Fig. 31 Test Time 100ms

BELTED SLED TEST RESULTS

Despite the controls put on the sled test specifications, the initial belt slack proved difficult to measure. The seat belt load cell mass caused significant belt sag under static conditions. Parametric studies were used to achieve an accurate representation of the belt shape in the model and the shape of the belt was varied until the timing of the initial increase in belt loads matched the test data.

High speed cameras recorded the test. Fig. 28 to Fig. 31 compare the kinematic response of the model and the physical test. Correlation is generally good, except that at 100ms the hand motion is different. Parametric studies have shown that the limb motion is extremely sensitive to the exact torque settings of the friction joints, and there may be significant variation in this joint stiffness on the physical dummies depending on test set-up.

Two nominally identical sled tests were performed with the same physical dummy and there was very good repeatability between the tests. The correlation for key dummy injury criteria is shown in:

Fig. 32 Head Resultant Acceleration.

Fig. 33 Chest Resultant Acceleration.

Fig. 34 Pelvis Resultant Acceleration

Fig. 35 Chest Compression.

Femur loads are not discussed here since there was no knee bolster used in the test, and the loads would be inertial only.

When run on a HP J210XC workstation, this sled test model required 17.1 hours of CPU to reach 150ms, using a time step of 1.54μs.

This sled test is just the first of a series of tests designed to provide a comprehensive database for the validation of the Hybrid III dummy models. An unbelted sled test with a driver's side airbag is currently being designed and will be the next validation condition for the dummy model.

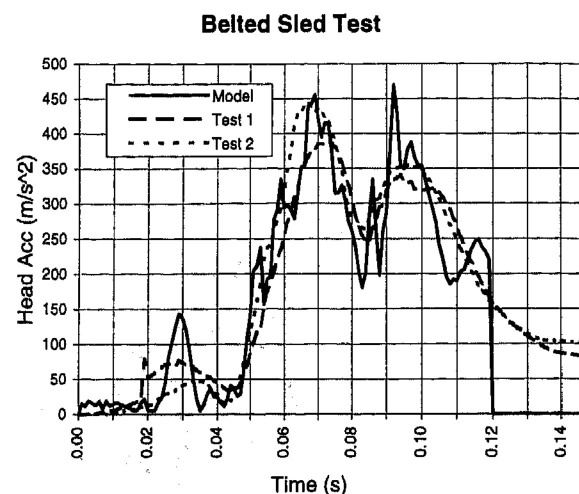

Fig. 32 Head Resultant Acceleration.

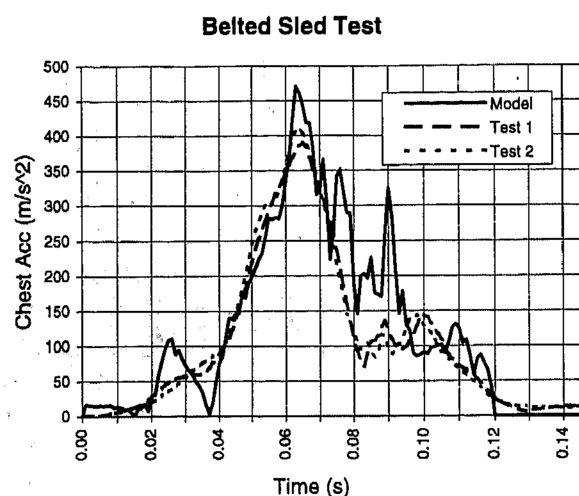

Fig. 33 Chest Resultant Acceleration.

BELTED SLED TEST RESULTS

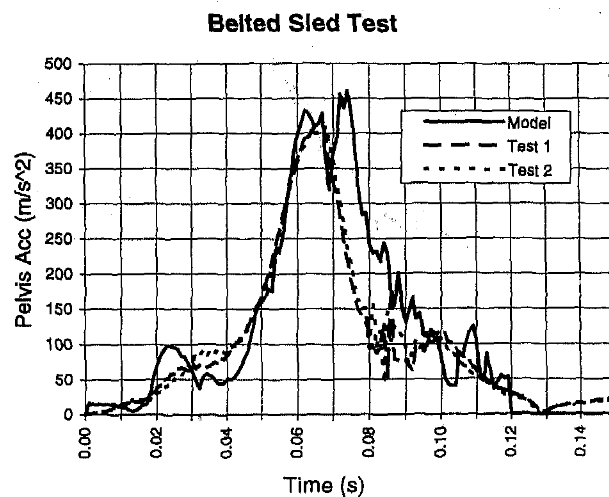

Fig. 34 Pelvis Resultant Acceleration

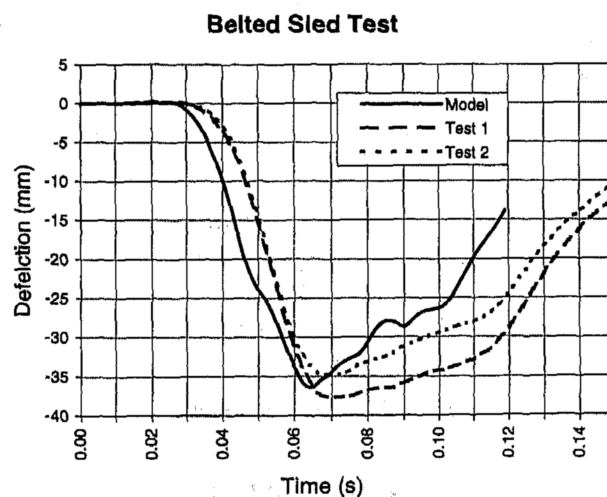

Fig. 35 Chest Compression.

AIRBAG SLED TEST

A second series of sled tests was performed to replicate an unbelted driver side occupant restrained by an airbag and knee bolster at a 30mph impact. As per the belted sled test, the philosophy was to design a test that would remove as many of the variables of the restraint system as possible to focus on the validation of the dummy model.

The seat was the same rigid fixture as used in the belted sled test. The steering wheel was represented by a rigid aluminum disk mounted to a rigid steering column. A six-axis load cell was mounted in the steering column behind the wheel. A rubber block was mounted to the face of the steering wheel disk to provide some compliance to the wheel should the dummy be inadequately restrained by the airbag. Recesses were cut into this block to accept the thumbs of the dummy hands.

The airbag was an existing production airbag, and was unfolded prior to test to avoid the need to have to model the unfolding of the airbag. A pressure tap was placed in the bag in front of the inflator to provide pressure curve data for the airbag model.

The knee bolster was represented by rectangular blocks of polystyrene foam attached to a rigid back plate. The properties for these foam blocks were derived from static compression tests and drop tower tests using spherical and cylindrical drop heads. The toe pan was represented by an inclined rigid plate.

The Hybrid 3 50th dummy had the regular MVSS208 required instrumentation plus upper and lower neck load cells, a six-axis lumbar spine load cell, pelvis accelerometers and upper and lower tibia load cells on one leg. The ankle was the 45 deg hard stop design.

The airbag sled test was repeated twice for the Hybrid 3 50th dummy with good repeatability as indicated in the attached test results.

AIRBAG SLED TEST RESULTS

All analysis and test data is filtered to the SAE classes specified by the Code of Federal Regulations.

The dummy exhibited acceptable kinematics and lifted slightly off the seat at the peak restraint of 90ms. The ankle stops did not bottom out.

The correlation is generally very good for all the measured channels. The lumbar spine shear load and neck moments were also well simulated.

CONCLUSIONS

An LS-Dyna model of the 50th percentile Hybrid III dummy has been developed. The development was a close collaborative effort between the dummy manufacturer, First Technology Safety Systems and Ove Arup & Partners International. Primary model development and validation was performed at the component level which has allowed a rigorous approach to model development. The assembled dummy model was also validated against results from pendulum and sled tests.

Limitations of ATB/CVS as an Accident Reconstruction Tool

Michael B. James, Ronald P. Nordhagen, Charles Y. Warner, Douglas "L" Allsop, and Thomas R. Perl
Collision Safety Engineering, Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Occupant simulation models have been used to study trends or specific design changes in "typical" accident modes such as frontal, side, rear, and rollover. This paper explores the usage of the Articulated Total Body Program (ATB) as an accident reconstruction tool. The importance of model validation is discussed. Specific areas of concern such as the contact model, force-deflection data, occupant parameters, restraint system models, head/neck loadings, padding, and intrusion are discussed in the context of accident reconstruction.

INTRODUCTION

The Articulated Total Body (ATB) program is also known as Crash Victim Simulator (CVS); it is the forerunner of another program called DYNAMAN. CVS was originally developed in the early 1970's at Calspan under NHTSA sponsorship. During the 1980's it was enhanced for use by the Air Force, and was re-named Articulated Total Body. Additional improvements and enhancements have continued to be made over the years. In 1989, GESAC, Inc. adapted ATB version IV.2 to run on personal computers. They also developed a user-friendly pre-processor and post-processor. This package is called DYNAMAN and is commercially available. In this paper, ATB refers also to CVS and DYNAMAN.

ATB is a general purpose lumped mass program. It can be used as a three-dimensional occupant simulation program by 1) creating "occupant" body parts of lumped mass ellipsoids connected together by joints, 2) building a "vehicle" by defining contact surfaces and ellipses, and then 3) specifying motion for the "vehicle." Each occupant body part consists of a lumped mass at a given location and a skin of elliptical shape. This is used to define contact between other ellipses and contact planes. The occupant body parts are interconnected by joints with defined properties which restrict the motion of the joint. The program calculates when and where contacts occur between the various ellipsoids & planes and applies forces as a result of those contacts. The occupant is displaced inertially and by the application of these contact forces.

ATB is an initial value simulation program. The input parameters are used to describe the initial occupant kinematics and contact parameters. The output of the first time step becomes the input for the second time step. This process continues through many iterations. As with all initial value programs, small errors in the input values can propagate or grow as the program goes through a large number of iterations.

The ATB program has undergone, and continues to undergo, changes and improvements [Fleck, 1991]. Some of these modifications are proprietary and are not publicly available [Deng, 1990, Prasad, 1993, Grew, 1985]. Most modifications were made in order to achieve reasonable simulations for specific applications. When reviewing the literature it is important to note that not all studies are using the same version of the program. In 1996, and ATB users group was officially formed to help users learn more about ATB, make them aware of new innovative modeling techniques, new applications, peripheral programs, problems and remedies.

The program is relatively complex to use. A typical input file contains 3000 to 7000 parameters. The appropriate values for many of these input parameters are not readily available. There are no recognized "default" or "typical" values. In practice, an existing input file is usually modified to fit the new application rather than creating a new input file from scratch. The input values in the existing files are often used when specific data for the new application are not available, even though the source of the existing data is often not known. Most of these data are not physically measured values, but are values which "seemed to work" in a prior simulation. Reliable input data are very sparse.

DESIGN PROCESS

Occupant simulation programs, such as ATB, can be very powerful tools when integrated into the design process. Once validated, they can be used to evaluate the effects of

parameter changes on the system response and substantially reduce the number of sled tests or full scale crash tests in a design or research project. They can be versatile and economical engineering tools.

For example, British Leyland used a modified version of ATB as a design tool for optimizing the three-point restraint system in a pre-production vehicle [Grew, 1985]. Sled and component tests were run and the appropriate input and output parameters for the model were measured. The input parameters were then adjusted within a reasonable range until the sled test was simulated. Modifications to the restraint system were then made in the model and the corresponding effects were evaluated. Based on the modified simulations, a second sled test was run with a modified restraint system. The inputs were then adjusted to get the best simulation for both sled tests. Further optimization of the model led to additional modifications of the restraint system. Additional sled tests were run to verify the effects of these modifications. Eventually, a well validated computer simulation was developed allowing the design parameters to be better understood. As the researchers pointed out, the tests established and validated the model, while the model helped to interpret the test results and insure that unnecessary testing was avoided [Grew, 1985].

In another research project, the dangers of invalidated modelling were pointed out. There, researchers attempted to develop an occupant simulation model of an unrestrained occupant in a frontal impact (using MVMA 2-D). Difficulties with determining appropriate input parameters led to the conclusion that "it is dangerous to draw conclusions from the model without having convinced oneself that the model matches up well with test results in a situation which is not too much different from the one under consideration" [Forrest, 1984]. In other words, validation is an important part of the application of occupant simulations in the design process.

VALIDATION

The crux of every mathematical modeling endeavor is validation. Validation is the process of establishing how well the predictions of a simulation agree with reality. The usefulness of a computer simulation depends on the extent to which it has been validated. Validation can be a difficult and time-consuming task for a complex simulation program such as ATB. A computer simulation cannot completely model every aspect and detail of a real event because of the innumerable complex physical events taking place. Simplifying assumptions must be made. Therefore, model validation is not a black and white issue; there are levels of confidence associated with each validation effort.

In reviewing the ATB literature, one finds different usages of the term "validation". It has been used to describe the program code as "working," i.e., that the code does not have any programming bugs and produces output that is not random. The more proper use of the term "validation" is demonstrating a specific application of the program properly simulates real physical events such as crash tests or sled tests. Fleck and Segal made this distinction by using the terms verification and validation. They verified that the ATB program ran without crashing and produced output that was reasonably related to the input. However they were unable to accurately model a real event using the ATB program [Fleck, 1982, Segal, 1984].

Since ATB has not been validated in general, it must be uniquely validated for each specific application in order for the results to have scientific meaning. Validation requires well documented crash test or sled test data to (1) establish the ATB input parameters, and (2) provide a basis for judging the reasonableness of ATB program output values. There are difficulties in obtaining appropriate test data for validation because many of the ATB input and output parameters are not routinely measured in crash tests or sled tests. In fact, some of the parameters cannot be directly measured and must be inferred from other measured data.

A true validation protocol requires that the input values be measured independently from the test that is being simulated. For example, input parameters measured from a series of bench or component tests might be compiled to create an input file that represents the actual test to be simulated. This is difficult with complex programs such as ATB, because some inputs cannot be directly measured in component tests. Therefore, such programs are often validated using a pair of full scale tests which are very similar. The first test is used to "calibrate" the model by adjusting the input values within reasonable limits until the measured loads and occupant kinematics from the first test are accurately simulated. The validation simulation is then made by changing only those inputs which represent the differences between the two tests (such as the crash pulse). The second simulation is then compared to the second actual test to determine whether validation has been achieved.

If only trends in "typical" impact modes are to be evaluated, a less stringent validation protocol may be sufficient. For example, a protocol of accurately simulating just one test has been used in some research applications. This procedure can be criticized as being merely a curve fitting project, i.e., showing that the program can generate curves to match the experimental data. There are likely multiple combinations of reasonable input data that could be used with the program to match the experimental curves. Before relying on the results of a study validated in this manner, additional full scale testing ought to be done.

Validation is difficult when reconstructing real world accidents because there is rarely a well documented full scale test with which to compare the simulation output. Sometimes claims of "validation" have been made by matching the injuries in a real world accident to injury threshold values in the simulation. This approach has several problems. First, the program is generally not able to accurately predict injury measures in actual tests. Its predictive power is limited to gross occupant motion. Second, the relationship between dummy injury measures and actual human injuries is not well established for individual exposures. Third, the simulation often requires unreasonable or arbitrary input values in order to predict the injury exposure seen in the accident. Tweaking

variables beyond acceptable ranges so the program matches a known injury is not a scientific endeavor and can result in conclusions that are erroneous and misleading.

Robbins [1989] presented a useful method of quantifying levels of validations in the form of the "Proposed Validation Index" developed by the Human Biomechanics and Simulation Standards Committee of SAE (see Table 1). He noted that for a simulation to be useful as a design parameter trend indicator, a validation level 5 is generally considered sufficient. This level of validation has not been achieved in published efforts using the ATB program [Kaleps, 1982, Smith, 1993, Ma, 1995].

Validation of ATB simulations has traditionally been difficult because of limitations of the program. More sophisticated occupant motion simulation programs, such as MADYMO and finite element impact models, have had much greater success. [MADYMO, 1990 Barbat 1995, Chang, 1994]. As occupant motion simulation programs continue to develop and achieve validation in the research arena, their use will naturally spread to accident reconstruction. However, strict validation will always be a problem when simulating real world accidents without test data for comparison.

In the absence of proper validation, a few keys can be used to evaluate how well a simulation matches an actual accident. First, there should be no obvious errors in the input file, such as improper vehicle geometry, missing contact parameters, occupant motions beyond the capability of the human body, etc. Second, the output must reasonably match the known facts of the accident. Third, the output must not violate the laws of physics. (There are no internal checks within the ATB program to verify consistency with laws of motion or physics.) Fourth, the simulation must actually be modeling what the user intends it to model. When the user focuses on certain output values and adjusts the inputs until those desired outputs are achieved, the simulation oftentimes will be doing things inconsistent with the initial modeling goal. Fifth, one must consider all of the outputs of the simulation: focusing on certain output parameters while ignoring others is bad science.

While it is difficult to create an ATB simulation of a real world accident using reasonable input values that match the physical evidence and comply with the laws of physics, simulations that achieve these criteria may add insights in evaluating real-world accidents, even without formal validation.

VALIDATION ATTEMPTS

Some of the problems experienced while using the ATB program can be illustrated by examining two independent attempts to validate a new data set developed to represent the Hybrid III crash test dummy. One attempt was by Obergefell, et al. [1988], the other was by Khatua, et al. [1988]. Both used frontal sled test data from a series of three tests run by Prasad [Prasad, 90]. Each sled test used two dummies; one Hybrid II (H2) dummy and one Hybrid III (H3) dummy. The sled buck consisted of a plywood seat, toe-board and floorboard, and a 3-point restraint system. The use of plywood surfaces minimized the effect of difficult-to-measure force-deflection functions. The lack of any dashboard, steering wheel, or windshield, eliminated the effect of additional contacts.

Obergefell attempted to validate both the H2 and H3 data sets using a single frontal sled test. This was not a validation in the strict sense because only one sled test was simulated; it was really an exercise in calibrating the model to match the experimental results of the single sled test.

The H2 data set was constructed by Fleck [1982] and consists of 15 ellipsoids. The H3 data set was constructed by Kaleps [1988], and consists of 17 ellipsoids, the same ellipsoids as the 15 in the H2 data set, with the addition of hands. Obergefell modified both the H2 and H3 data sets by adding two additional massless contact ellipsoids, one at the upper torso and one at the lower torso. These additional ellipsoids did not alter the mass or inertial characteristics of the dummy but were added to provide a more realistic geometry for the belts to contact. The seat belt webbing stiffness and friction coefficients were not independently measured. The input parameters were simply adjusted to values which seemed to provide the best fit with the experimental data.

The gross occupant motion was assessed by comparing the high speed film to the simulation's graphical output. Both the H2 and the H3 simulations had occupant motion similar to the test data during the initial part of the event. However, the motion in both simulations began to deviate from the test as the event progressed. The simulation's acceleration data for the head, chest and pelvis, also matched the test data reasonably well early in the event, but then developed substantial deviation. The match of head acceleration was much worse than that of the chest and pelvis acceleration. Neck forces were not reported. Interestingly, the older H2 data set matched the experimental data better than the newer H3 data set, even though the H3 data set was derived using more precise measurements of the dummy.

The inability of the simulations to match the experimental data was attributed to difficulties with the belt model. The authors noted that even small changes in the belt parameters significantly affected the simulated occupant motion. Since the sled test belt forces were the most significant forces acting on the dummy, the belt model was clearly critical to simulating the dummy motion. However, the belt parameters were not independently measured in this exercise; the indication being that the model was simply not capable of matching the experimental data.

Khatua, et al. [1988] attempted to validate the same H3 data set using a pair of sled tests from the same series by Prasad. However, a more rigorous validation protocol was followed; the first sled test was used to calibrate the model and the second test was used for validation. Force-deflection data were independently measured by statically pressing the lower torso into a plywood seat cushion. The lap belt characteristics were measured by pushing the H3 dummy against the lap belt

TABLE 1 - PROPOSED VALIDATION INDEX

Level 0	No agreement between predictions of model and a "reference event."
Level 1	Qualitative Agreement a. Trends of predicted parameters same. b. Kinematics correspond qualitatively. c. Contacts between occupant and vehicle interior are the same in general.
Level 2	HIC and similar indicators predicted by simulation are within 20% of those obtained in reference event.
Level 3	Peak values of important occupant responses limited to a relative error of 20% (20% on vector magnitude, 11.31 degrees on vector direction).
Level 4	Same as above except 5%.
Level 5	Timing of peaks of important vector responses limited to 5% relative.
Level 6	All peaks and valleys in the duration of time-dependent predictions must match the reference event within 10%.
Level 7	Same as 6 except 5%.
Level 8	1% relative error, point by point, over the duration of the reference and predicted event.

in a quasi-static fashion. A generic dynamic amplification factor of 1.25 was applied to the measured data. The shoulder belt characteristics were not directly measured, but were adjusted to provide the best fit with the experimental chest acceleration and shoulder belt load data.

Certain adjustments were required in the H3 data set in order to simulate the "calibration" test. The model predicted substantial bending at the occupant's waist. No such bending was seen in the films. The bending was eliminated by locking the joint between the middle and lower torso. The head and neck motion in the simulation indicated that the neck stiffness parameters in the model were too stiff by a factor of 8. The neck stiffness was reduced to one-eighth of its original value for neck rotations up to an angle of 10 degrees, and then increased to its original value at 20 degrees of rotation. Even with these modifications, the head motion of the calibration test was not accurately simulated because the neck parameters did not include energy absorption (the reason for this is discussed later in this paper). The knee joint values resulted in simulated femur forces that were too low, but attempts to find a combination of parameters that more accurately simulated the test results were unsuccessful.

Once the input parameters had been adjusted in the calibration run to give the best possible match to the test data, the crash pulse was modified to that of the second sled test. The validity of the model was then determined by comparing the second sled test to the validation simulation. The chest accelerations and the shoulder belt forces were in reasonably good agreement, which is to be expected since the shoulder belt parameters had not been independently measured, but had been adjusted to give the best fit in the calibration run. The head accelerations, however, were too high and the lap belt forces were not reasonable. It was concluded that the simulation results did not fully agree with the test results and that the measured stiffness values in the H3 data set for the neck joints, torso joints and knee joints needed to be re-evaluated.

Neither of these attempts to validate the new H3 data set were successful. Obergefell concluded that the data set was probably valid, and the belt model was responsible for the bad results. Khatua concluded that the data set was the problem. It is likely that there are problems with both the data set and the belt model, in addition to other limitations inherent in the program.

The remainder of this paper will explain some of the difficulties in validating the ATB program for even simple frontal sled tests. These limitations exacerbate the difficulty in attempting to simulate a real-world accident.

MODEL LIMITATIONS

With any math model, it is necessary to understand the underlying equations, assumptions, and simplifications in order to evaluate the validity of the output. The more complex the model, the more important this understanding is. This paper does not address all the inner workings of ATB in detail, but presents a description of specific factors which clarify the difficulties in validating simulations for reconstructing accidents.

CONTACT MODEL - The ATB contact model is what "drives" the program. It computes the contact forces which act on the occupant and produce the occupant motion. It is a simplistic model of what is in reality a very complex

event. Even though the ATB program simulates occupant motion in three dimensions, the contact model is essentially one-dimensional.

The user must define a set of "allowable contacts" between the various body segments and vehicle surfaces. Each individual contact definition specifies the force vs. deflection properties which govern that contact. Contact is deemed to occur when an ellipsoid of the occupant intersects a vehicle surface. If a contact is not defined between a specific body segment and vehicle surface, the body segment will pass through that part of the vehicle structure as if it did not exist. Even when the contact has been defined, the ellipsoids and planes do not deform, they still pass through each other, but the geometry of the overlap is used to determine three aspects of the contact: depth of penetration, direction of force application and the point of force application.

Penetration is defined as the perpendicular distance from the plane to the deepest point on the overlapping ellipsoid (Figure 1). The magnitude of the contact force is determined by applying the depth of penetration to a user-defined force-deflection function. For oblique contacts, this is not the actual length of deflection. Therefore, force-deflection data measured in perpendicular tests will not appropriately represent contacts at oblique angles. A single force-deflection function represents the mutual crush of both surfaces. If separate data for the vehicle component and the body segment are available, they must be combined to form a single function for use in the model. Ignoring the compliance of the body segment is equivalent to modeling a rigid occupant, which will result in erroneous occupant accelerations and joint forces.

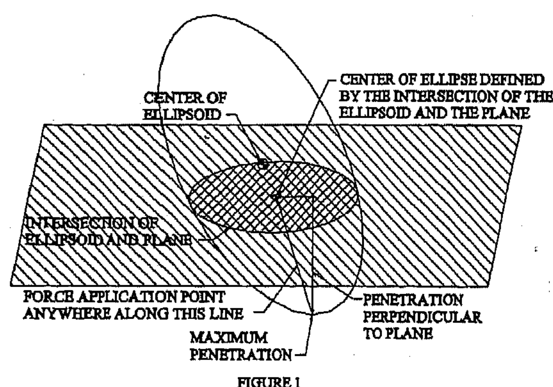

FIGURE 1

The contact force is the resultant of the normal and the friction components. The normal component is always perpendicular to the contact plane. The frictional force is parallel to the plane and directed so as to oppose the ellipsoid's motion. Its magnitude is a function of the normal force. When the magnitude is modeled as being directly proportional to the normal force, the direction of the resultant contact force will be at a constant angle relative to the plane (Figure 2). This does not appropriately describe the pocketing effect which often occurs when body parts contact deformable surfaces and the direction of the contact force changes as the deformation increases.

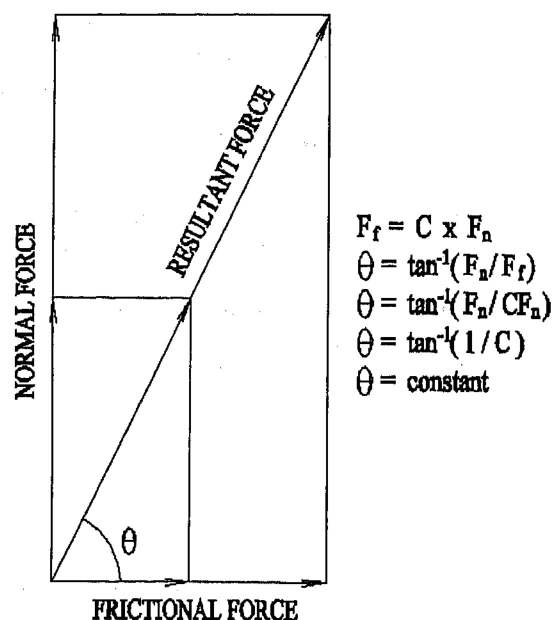

FIGURE 2

Since the ATB program does not model the deformation of the contact surfaces and the resulting pressure distribution, the entire contact force must be applied at a single point. The location of the force application can be defined by the user anywhere along the line connecting the point of maximum penetration on the ellipsoid and the centroid of the ellipse created by the ellipsoid/plane intersection (Figure 1). The location of the force application remains constant for all magnitudes of deflection. It should be chosen based on how much each of the two surfaces deform. For example, if a rigid head form contacts a soft dashboard, the contact force should be applied closer to the surface of the head form (Figure 3a). Whereas, a deformable abdomen contacting a stiff, unyielding plane would be better modeled by choosing the point of force application closer to the surface of the plane (Figure 3b). For contacts where there is deformation of both the plane and the ellipsoid, care must be taken in defining the point of force application, especially when large deformations occur.

The contact model used in ATB has difficulty when ellipsoids contact narrow planes or the edge of larger planes. There are several program options from which the user may choose. The default option results in no contact force unless the center of the ellipse defined by the intersection of the ellipsoid and the plane is within the plane boundary. This can result in very unrealistic results because the contact force can change instantly from a high value to zero as the center of the ellipse moves beyond the edge of the plane. Another option treats the plane as if it were infinitely large as long as any part of the ellipsoid intersects it within the original plane

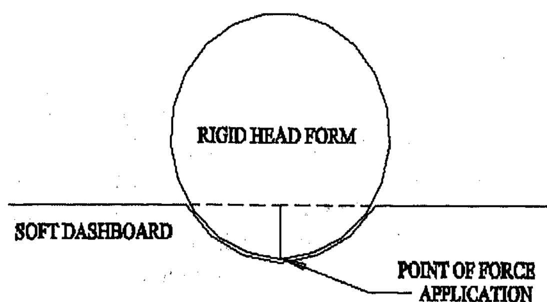

FIGURE 3A

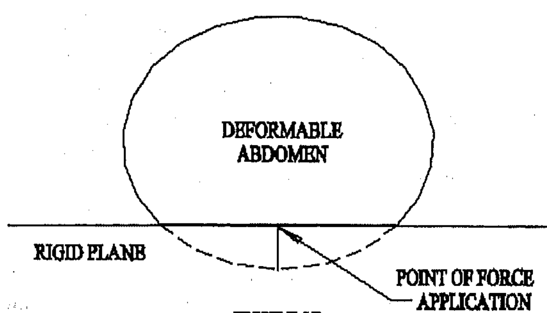

FIGURE 3B

boundaries. The third option reduces the magnitude of the contact force proportionately to the area of the intersection; however, the direction of the contact force is not modified. None of these program options adequately models the true interaction between a body segment, such as the head and narrow vehicle surfaces like the A pillar or steering wheel rim. Creative modeling by the user, however, can be used in some circumstances to overcome this program limitation.

FORCE-DEFLECTION DATA - When defining an ATB input file, every potential occupant segment/vehicle surface contact must be individually defined. If no definition is made, the occupant segment will pass through the plane as if it was not present. Since a single force-deflection function is used to define the mutual deformation of both surfaces, different force-deflection functions are necessary to define the contact between the same vehicle surface and the various occupant segments.

Very few data are available to characterize these force-deflection properties. They are different for each vehicle make and model, and they are difficult to measure. Segal developed a test methodology to statically and dynamically measure properties for several vehicles [Segal 87]. It was hoped that "generic" values could be developed for use in many applications. Unfortunately, the testing indicated a wide range of stiffness values that were very sensitive to slight variations. Interior surfaces of 19 different automobiles were tested using both static and dynamic tests. "Typical" or "average" stiffness characteristic for vehicle interior surfaces could not be determined. They also found that static tests were not representative of dynamic tests, and that there was no consistent amplification factor which could be used to convert static test results to dynamic force levels. Small changes in the direction of loading and the specific location of loading resulted in large variations of measured force-deflection properties.

One cannot expect accurate simulations using generic force-deflection values. Even force-deflection values which have been established for a specific area of a specific vehicle can have substantial variations depending on the location of loading, the angle of loading, and the rate of loading. This extreme variability is one of the most significant problems with using ATB for accident reconstruction. It is not as significant a problem when using ATB as a design tool because the force-deflection values can be modified within reasonable limits until a fit with the test data is achieved.

OCCUPANT PARAMETERS - An ATB occupant is represented by a group of ellipsoids connected together by joints. Each ellipsoid must be defined in terms of size, mass, location of the center of mass, moments of inertia, and joint locations. There are readily accessible sources of data which can be used to compile the ellipsoid data for standard crash test dummies, and also for various size occupants.

As mentioned previously, Fleck [1982] has developed a data set for the Part 572 (Hybrid II) dummy and Kaleps developed a data set for the 50% Hybrid III dummy, with both the seated pelvis and the standing pelvis [Kaleps, 1988]. A program called GEBOD has been developed to create data sets for occupants of various sizes [Cheng, 1994]. The user specifies the occupant's height, weight, or both, and GEBOD will appropriately scale the relevant occupant parameters. The data for adults is based on surveys of Air Force personnel [Grunhofer, 1975, Clauser, 1972] as well as other Air Force studies [McConville, 1980, Young, 1983, Engin, 1987]. The data for children's sizes comes from the Snyder anthropometry for children [Snyder, 1977] and the joint torque data comes from Kaleps [1982].

Recently Ma, et al., developed a partial set of "human" joint parameters [Ma, 1995]. An undocumented set of "human like" joint parameters is included in GEBOD version 4.1.

The joint parameters which are most critical in evaluating occupant injury exposure are also the most difficult to define; namely those characterizing the neck. Head and neck injuries represent the majority of injury in automobile impacts. However, accurately simulating head motion, and predicting head/neck loadings is an area of research that is still developing. The current ATB head/neck model consists of a rigid neck segment connected to the head and the upper torso with a pair of joints. The joints allow rotation between the neck and the adjacent segment, but there is no compliance in the axial or shear directions (Figure 4). Physical neck models, on the other hand, such as the Hybrid II and Hybrid III necks,

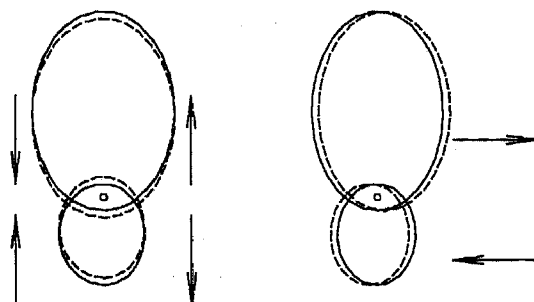

FIGURE 4

are flexible segments with a fixed attachment to the upper torso and limited joint rotation at the head attachment.

The neck of the Hybrid II dummy consists of a single rubber cylinder with a cable running through the center axis. It has bending characteristics which are the same in each direction, i.e., flexion, extension and lateral bending can be modeled with the same characteristic. The human neck, however, does not have the same characteristic in each direction, so the Hybrid III dummy neck was designed to have resistance to extension motion be about half the resistance to flexion motion. It is constructed of six aluminum disks separated by rubber disks, held together by a cable running through the center of the structure. Cuts on the anterior portion of the rubber disks are used to create the different resistance to flexion and extension.

Data sets of the H2 neck have been developed by Paver [1987] and Doherty [1986]. Several attempts have been made to create joint parameters to simulate the H3 neck [Kaleps, 1988, Doherty, 1987, Seemann, 1986, Wismans, 1988]. There is a particular problem, however, with modeling the Hybrid III neck. ATB allows joint characteristics to be defined by either an equation, or by specifying tabular data. When the equation method is used, damping properties can be defined, but only one equation can be used to specify the torque vs. angle characteristic for all directions of bending. When the tabular data method is used different characteristics can be defined for different direction of bending, but no damping can be modeled. The Hybrid II neck can be modeled using the equation method (because it has the same bending characteristic in each direction), and damping properties can be defined. However, the tabular method must be used to model the Hybrid III neck (because it has different bending characteristics) and damping properties cannot be defined. Head motion cannot be accurately simulated without the damping.

The rigid neck model may, with proper evaluation, be used to simulate gross kinematics of head as long as the head does not hit anything. However, better models and more data are necessary before accurate simulations of head contact kinematics and forces can be achieved. A more sophisticated neck model for the ATB program has been developed by Deng [1989]. It more closely approximates the flexible H3 neck by treating each of the six aluminum disks as an individual ellipsoid.

BELT RESTRAINT SYSTEMS - The ATB program has two options for modeling belt restraint systems: The "BELT ROUTINE" and the "HARNESS ROUTINE." The belt routine does not yield reasonable results in most situations, is generally not used, and will not be discussed [Deng, 1989, DYNAMAN User's Manual 2.3.2]. The harness routine is a more sophisticated model, but it is still incapable of accurately simulating occupant belt interactions in many situations.

Each belt in the harness routine is modeled as a series of webbing segments that contact the occupant at user-specified points. The belt length is not a user input but is a function of the occupant's initial position and the belt anchorage locations. Additional webbing can be specified by adding belt slack. Using the harness routine in an accident reconstruction context can be misleading because some of the important input parameters are unknown, or cannot be measured directly, and the simulation output can be very sensitive to small changes in the inputs [Obergefell, 1986].

There are readily available data on seat belt webbing characteristics from standard elongation tests. Unfortunately, these data are not useful for ATB applications because the webbing stress-strain input parameter must account for several additional factors in addition to webbing stretch. For example, Deng [1988] modeled sled tests using independently measured webbing force versus strain characteristics. It was noted that the dummy motion in the sled tests was greater than what would have been expected based solely on the webbing stretch. Additional factors such as anchor deformation, retractor spool-out factors, and occupant compliance must be accounted for in order to correctly simulate the occupant motion.

Shimamura, et al., [1987] used a series of bench tests to independently measure webbing strain, webbing unloading characteristics, retractor spool-out (film spool effect) and movement of webbing through the D ring. All of these effects were then combined into a single belt load versus strain characteristic. The retractor spool-out, or film spool effect, was directly related to both the webbing elongation characteristic and the length of webbing on the reel. These researchers note that it is also important to correctly define the hysteresis characteristics (webbing unloading curve) because the maximum occupant displacement occurs after the maximum belt load is achieved.

Dummy (or occupant) compliance must also be accounted for in the belt model. The ATB code has the capability to independently define the compliance of the occupant, but this feature is infrequently used because it leads to numerical instabilities [Obergefell, 1992]. Modeling the upper torso as two separate ellipsoids connected by a spring-damper system can be used to account for chest compliance (and can also be used to determine chest compression and the VC criteria). The other alternative is to adjust the belt strain

characteristics to include the effect of occupant compliance. The same belt characteristics cannot be used for both the lap belt and the shoulder belt because of the differences in body segment stiffness and webbing length.

One might be tempted to use the actual webbing stiffness values in the model and just add a few inches of belt slack to account for other factors. In practice this introduces additional errors because the occupant gets a running start at a stiff belt, resulting in unrealistically high belt loads which alters the occupant motion. The "softening" factors need to build up over time to realistically simulate the occupant motion.

When using ATB in a design context, it is possible to simply adjust the belt input parameters within a reasonable range until the best fit is achieved with the test data. In an accident reconstruction context, it is not possible to do this because there is no test with which to compare, and the actual occupant motion and webbing loads are not known.

PADDING - Head and neck loadings are difficult to model using ATB not only because of the neck model limitations, but also because of the difficulty ATB has simulating impacts with padded surfaces. Modeling the response of energy absorbing interior padding requires a more sophisticated contact model than that used by the ATB program; the impact algorithm must take into account both the deformation of the padded surface and the complex properties of the padding material.

Padding materials are typically nonlinear and visco-elastic; their dynamic properties are strongly strain rate dependent. As a curved object such as the head impacts a padded surface, three things are happening: 1) the area of involved padding increases as the penetration progresses; 2) the strain rate decreases as the head is slowed by the padding; and 3) the stiffness of the padding increases as the material compresses. Therefore, at each instant there are different conditions for each location within the deforming pad material. The model cannot relate these changing factors without actually modeling the deforming padded surface. It is possible to simulate a specific test using ATB because the strain rate and force-deflection input can be matched, but those inputs are for a specific impact velocity and geometry, and are not valid for general application.

A study by Orringer, et al. [1986], demonstrated the difficulties associated with developing accurate math models of energy absorbing interior padding materials. They developed two complex empirical models of padding materials for ATB. One model had nine parameters and the other model had twenty-one parameters. Even with these elaborate models, they had difficulty matching actual test data.

Finite element analysis, however, has been shown to suitably model head impacts with energy absorbing interior padding materials [Barbat, 1995, Chang, 1994, Chou, 1995, Sherman, 1995]. Substantial improvements in ATB will be achieved as finite element neck models and finite element padded surfaces models are merged with the current program. However, until that occurs ATB is not capable of accurately simulating head impacts with padded surfaces.

INTRUSION - The effects of intrusion on occupant response are receiving increased attention. ATB has the capability to model intruding surfaces, however ascertaining the intrusion experienced in a vehicle impact is a very difficult task. The program does not compute the intrusion motion. The user must specify the position of the intruding surface relative to the vehicle at specific times. This user input defines not only the magnitude or extent of the intrusion, but also the velocity of the intruding surface. There are very few test data with which to evaluate the velocity of intruding surfaces. Intrusion parameters are not commonly measured in crash tests and are difficult to measure using high speed film.

When the intrusion deformation is the result of contact with a fixed object or the ground, the ATB intrusion input parameters must be carefully coordinated with the vehicle motion defined by the crash pulse. Without careful coordination, the intruding surface will simulate unrealistic contact velocities between the occupant and a surface that should have no velocity relative to the ground.

When the intrusion deformation is the result of a car-to-car impact, the timing is critical. There is only a small window of time in which the intruding surface is moving. If occupant contact occurs within that window the contact velocity may be higher, resulting in higher forces and accelerations on the occupant. The simulation output will be very sensitive to slight changes in the inputs. In order to use the program to analyze intrusion, good test data is necessary to determine if the timing of the intrusion motion and the timing of occupant contacts are accurate. When reconstructing an actual accident the detailed information necessary to create an accurate intrusion simulation is almost never available. This does not completely preclude the study of initial gross occupant motion, but greatly hampers the reliability of the simulated occupant contact forces and the subsequent occupant motion due to contact with the intruding surface. As finite element models improve and become more accessible, reliable intrusion motion may become available for use in occupant motion simulations.

CONCLUSIONS

ATB can be a powerful tool in the design process when used in conjunction with a series of vehicle or sled tests. However, it is difficult to develop well validated simulations with only one or two tests. The predictive power of the program is generally limited to gross occupant motion. Factors which limit the accuracy of ATB simulations include the simplicity of the contact model, lack of reliable dynamic force-deflection data, limitations on occupant joint parameters, sensitivity of belt restraint model, and an inadequate neck model.

Adjustments in the input parameters can sometimes be made to simulate specific tests. However, there are limitations to using the ATB program for reconstructing occupant kinematics in actual accidents. Some of these

limitations are due to modeling difficulties, and some are due to the inherent lack of data available with real world accidents. As research and development of occupant simulation programs, such as ATB, continues, the ability to model both test data and real world accidents will improve. Merging finite element codes with the existing ATB code may improve the accuracy of simulations in the future, given proper validation.

Control and Application of Intelligent Restraint Systems

John A. Musiol, Lynette M. Norgan-Curtiss, and Michael D. Wilkins
AlliedSignal Safety Restraint Systems

ABSTRACT

Conventional restraint systems designed to meet US FMVSS standards only have one level of operation. The seat belt imparts a restraint force to the occupant reflective of belt stiffness characteristics and the airbag is either inflated or not inflated. The system is tuned to one crash scenario, typically a 30 mph (48 kph) barrier crash with an unbelted 50^{th}%ile MHIII dummy. Situations involving other occupants, crash speeds or belt usage conditions may result in tradeoffs to maintain acceptable results for all conditions. Currently, there is considerable interest in adaptive restraint systems that can detect various crash conditions and adjust the restraint system to provide increased levels of protection. There is also a great deal of interest in systems that can detect an out of position occupant and adjust the airbag deployment to lessen the possibility of deployment induced injuries.

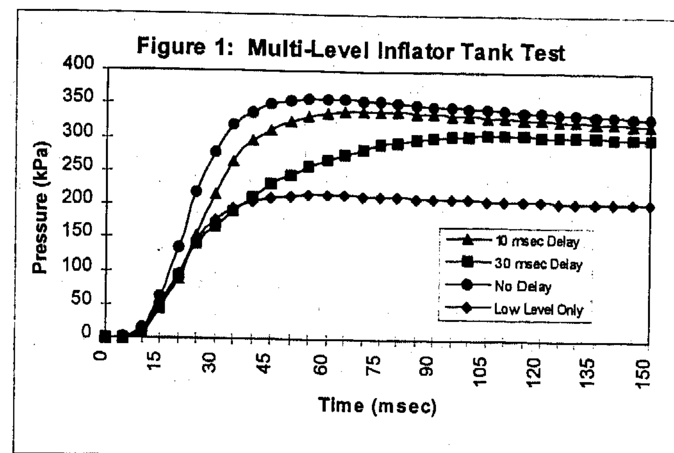
The development of restraint hardware has been on-going for some time and testing shows that these devices can provide enhanced occupant protection. The next logical step is to begin to combine these components with appropriate sensing technologies and control systems that understand the implications of the decision making process. The value of the adaptive restraint system has been demonstrated in its ability to adjust for different crash conditions and a degree of real-time decision making capability has been demonstrated in sled testing. Furthermore, significant reduction in airbag deployment induced injuries are made possible by detecting an out of position occupant and altering airbag inflation parameters.

INTRODUCTION

Airbags installed on automobiles sold in the United States are designed to meet Federal crash test requirements (Federal Motor Vehicle Safety Standard 208). Fundamentally, this crash test standard requires automobile manufacturers to provide protection to an unbelted, average sized male occupant in a 30 mph (48 kph) crash into a rigid barrier, by means of an inflatable restraint [1]. Although the crash energy associated with a 30 mph (48 kph) barrier crash is significantly higher than the majority of collisions that occur on US highways [2], the federal standard requires automakers to design systems for relatively severe conditions. Significant among the airbag system design parameters that require tuning for FMVSS 208 are the speed of deployment and the firmness of the airbag. The airbag must be quite firm to dissipate the energy of an unbelted 50^{th}%ile MHIII dummy at the required crash velocity. However, that degree of stiffness may be greater than is necessary for smaller occupants or for occupants involved in crashes of lesser severity. Additionally, an occupant who is restrained by a seatbelt as well as an airbag, will not require an airbag with the same degree of firmness as would an unbelted occupant. The result is that too much restraint energy may be applied to occupants under certain accident conditions.

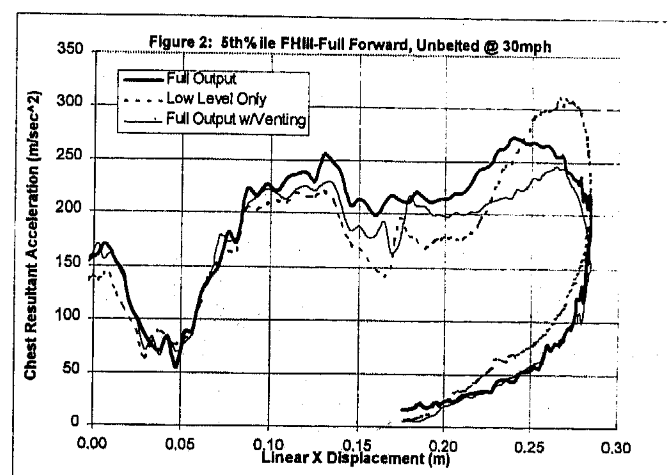
During a 30 mph (48 kph) barrier crash, the velocity of the occupant movement within the vehicle interior typically requires that the airbag must be substantially full 30 milliseconds after initiation of deployment [3]. This is necessary in order to allow the airbag time to provide adequate space for the absorption the occupant's kinetic energy. This deployment speed dictates the need for very high inflation flow rates that translate into very high forces in close proximity to the airbag. While these forces pose no threat at distances involving normally seated occupants, they may impart injurious forces to occupants who happen to be positioned too closely to the deploying module. Real world crashes have a high degree of randomness. Despite designer's best efforts to predict and test for various crash scenarios, some crash situations may result in an unbelted occupant being too close to the module upon deployment. The problem is particularly acute when small children are involved, since their lower mass increases the possibility of injuries. [4]

Restraint systems of the future will incorporate adjustable components that will be tuned for various factors such as occupant weight, crash severity, seat



belt usage and occupant position within the passenger compartment [5]. Appropriate sensors must be employed to detect these conditions and a control system must be developed to use the information to produce an appropriate response. This entire assembly of sensors and adjustable restraints can be considered to be part of an advanced "Adaptive Restraint System". This paper presents the state of development of this system and presents the results of testing and analysis.

DESCRIPTION OF PROPOSED SYSTEM



Typical restraint system performance can be improved when one considers the variety of actual crashes that occur on our highways. For example, the vast majority of seatbelts on the road today are simple retractable bands that hold an occupant in place. In a crash, the tension in the belt increases nearly linearly with the amount of stretch imparted to it by the occupant. Thus, the tension in the belt is ever increasing, translating into increasing force levels imparted to the chest of the occupant. Since injuries are related to peak forces and accelerations sustained by occupants, this type of restraint presents possibilities for improvement. "Constant force" seatbelt systems are under development that limit the amount of tension in the belt (and therefore the force placed on the occupant) by allowing compliance at a pre-determined constant force level. Additionally these seat belt systems utilize electrically actuated high-output pre-tensioners to impart a pre-load to the belt to further increase its effectiveness. [6]

The constant-force seatbelt and airbag together create a system that can be finely tuned to provide nearly optimal restraint performance in a given crash situation [6]. However, this still represents a system that is optimized for only one particular crash scenario. Various size occupants require different restraint force levels. A system tuned for an average male at 35 mph (56 kph) will be more firm than is desirable for a smaller, lighter occupant. Similarly, a system tuned for the average person may have too little restraining capability to keep a heavier person from impacting the windshield or instrument panel. The optimal restraint force changes as other factors such as crash severity and belt usage vary. Ideally, restraint systems should be able to adjust for these factors.

To provide optimal restraint, multi-level restraint devices should be capable of adjusting restraint forces, to particular situations. For instance, a constant force retractor is under development that offers three levels of load limiting, adjustable in real time in response to the conditions present at the time of collision. Likewise, two methods will be presented to adjust the restraint force provided by an airbag. The first is a multi-level inflator to alter, not only the volume of gas introduced into the airbag, but also the velocity at which this gas is delivered. This output is varied by the manner in which the inflator's two initiators are actuated. For a low level deployment, only one squib is fired. For a high level deployment, both squibs are fired simultaneously. If an inflation level between the high and low is desired, a delay can be programmed between the actuation of the two squibs to finely tune the output. This is shown in Figure 1. The second method of adjusting an airbag's restraint force is to vary the amount of gas that is vented out of the bag during occupant restraint.

For normally seated occupants, it is desirable to introduce a full airbag early in the event to initiate occupant restraint as soon as possible utilizing all available space for energy absorption. [7]

This suggests that so long as an occupant is not in close proximity to the airbag module, the inflatable restraint should be actuated at high inflation levels. However, the particular conditions present at the time of the crash may dictate that different restraint forces be applied depending upon those conditions. In order to adjust the restraint force provided by an airbag for normally seated occupants, the amount of gas vented out of the airbag will be adjusted by means of vent openings in the airbag housing. These openings are electrically actuated at the time of the crash to control airbag stiffness during the crash event. Figure 2 illustrates the chest acceleration levels as a result of adjusting both the venting characteristics and inflator output as predicted by

MADYMO simulation. A study was set up with a PAB system designed to FMVSS 208 requirements, except that a 5th%ile FHIII replaced the 50th%ile MHIII in our model. As can be seen from the figure, if the inflation level is lessened in response to the lower mass of the occupant, the peak accelerations actually increase. When the inflator output is left unchanged and the venting is increased, the chest accelerations are decreased as compared to the baseline system.

This venting system cannot replace a multi-level inflator. For occupants who might otherwise be injured by the high deployment speed of an airbag, the multi-level inflator's ability to decrease flow rates can have a significant effect on injury criteria. Figure 3a-c shows the results of static out of position testing with a 5th%ile FHIII at distances of 25, 150 and 250 mm from the PAB module. The tests were run with an FMVSS 208 inflator and also with a low level inflator to quantify improvements in injury criteria. As can be seen from the figure, reducing inflator output may significantly decrease the potential for deployment-related injuries.

Figure 3a: HIC

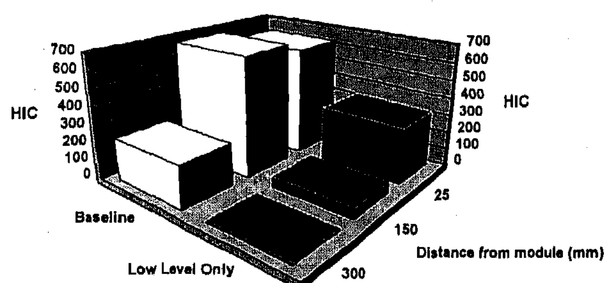


Figure 3b: Chest g's

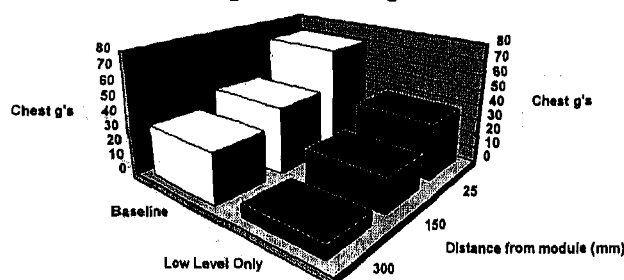

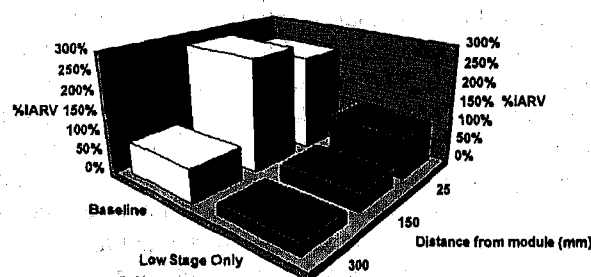

Figure 3c: %IARV-Neck Tension

Figures 3a-c: Static Test Results For a 5%ile FHIII

In summary, a sensor system will need to detect the following inputs:

1) Seat belt usage

2) Occupant proximity to airbag

3) Occupant weight

4) Crash severity

A control system in turn will take these sensor inputs and utilize them to adjust:

1) Airbag fill velocity

2) Gas volume introduced into the airbag

3) Airbag venting area

4) Seat belt load limiting.

Accurate sensing of these various factors is critical for an effective system. The following sensors are being developed to control the adaptive restraint system presented.

Occupant Position - The proximity of an occupant to the airbag module is a very important factor in determining correct airbag deployment forces. An electric field occupant presence and proximity system is under development. This system consists of a series of copper foil sheets embedded into the instrument panel and oriented in such a way as to act as a capacitor. Rather than a traditional capacitor, however, where the electric field flows between two plates, the orientation of these plates acts to project an electric field outward, toward the occupant. Since humans have enough moisture in their bodies to act as a dielectric, the presence of a person in the electric field will change the capacitance of the sensor. The magnitude of change in capacitance varies with the proximity of the person to the sensor. Therefore, measuring the change in capacitance can determine the proximity of an occupant to the module. A particular benefit to electric field technology is its ability to discriminate between humans and most inanimate objects which are poor dielectrics.

The electric field also can penetrate objects such as newspapers that may block ultrasonic or infrared beams utilized in other occupant sensors. Perhaps the most important benefit to the electric field occupant sensor under development is the system's ability to react in under 2 milliseconds. This response time is fast enough to allow the sensor to detect an occupant being thrown forward in the passenger compartment due to panic braking or a long crash pulse/late fire time event.

Occupant Weight - Several companies have weight classification sensors under development. Typically,

these sensors are positioned in the seat cushion. For purposes of this analysis and the physical sled testing presented in a later section of this paper, four load cells were positioned at the seat mounting locations to measure the weight of the occupant in the seat.

Seatbelt Usage - Seatbelt buckle switches have long been used to determine if the belt has been fastened and to actuate an audible reminder. While these switches can be used during the early development of adaptive restraint systems, they are not adequate for production level adaptive restraint systems. Hall Effect sensors will be necessary to provide adequate reliability levels when used as an integral part of a production level adaptive restraint system.

Crash Severity - A current, state of the art single point sensor system includes accelerometers inside the electronic control unit that measure the reaction of the passenger compartment and a microprocessor to analyze these inputs and make the fire/no-fire decision. Virtually all major single point sensor manufacturers are developing systems that will not only determine if an airbag is needed, but also will be able to discriminate the level of severity of the crash.

Integrating all of these variables is a fairly complex problem. Control of each restraint factor depends upon all of the sensed conditions of crash severity, belt usage, occupant weight and position. Moreover, those factors are also interdependent upon each other. For example, the amount of seat belt load limiting required is dependent upon the stiffness of the airbag. A computer algorithm was developed to analyze these factors and determine the appropriate settings for adjustable restraint components.

COMPUTER MODELING:

MADYMO crash simulation was used to develop appropriate levels to which adjustable restraint factors should be tuned for various crash conditions. A model was assembled to simulate a passenger in a generic vehicle environment and a generic pulse. The model was correlated to a 35 mph (56 kph) crash with a belted occupant using the results of HYGE sled testing. The following factors were modeled:

Occupant Sizes:

5th%ile FHIII, 50th%ile MHIII, and 95th%ile MHIII

Restraint system:

Airbag/Seatbelt with Pretensioner and Airbag only

Occupant Position:

Full Forward, Mid-position, and Full-Forward

Crash severity:

14 mph (22 kph), 18 mph, 30 mph (48 kph), 35 mph (56 kph)

For the purposes of this study, crash severity was defined as impact velocity into a rigid barrier at 0°. Simulations were run with various combinations of the above factors and several combinations of airbag venting and seatbelt load limiting. For the initial study, only normally seated occupants were investigated. Previous analysis determined that regulating airbag venting characteristics was more effective than regulating inflator flow characteristics when adjusting restraint forces for normally seated occupants. Consequently, only seatbelt load limiting and venting were varied. Table 1 illustrates the results of the modeling for one of the cases, (50th%ile MHIII, mid-position at 30 mph (48 kph) barrier crash). This process was repeated for other cases until enough information was available to determine optimal restraint characteristics for the anticipated situations. That information, in turn, was used to produce a control algorithm.

Table 1: Modeling Results For a 50%ile MHIII-Midposition using a 4-inch Pretensioner at a 30 mph Barrier Crash

CONTROL ALGORITHM:

The entire system that can sense various aspects of a crash and tune the restraint system accordingly is referred to as an "Adaptive Restraint System". A system schematic is presented in Figure 4. Once the various inputs are known, there must be a decision making process to determine appropriate settings for the restraint devices. If only one input is taken into account, occupant weight for example, the restraint system tailoring can be a simple linear adjustment from low-level for a light occupant, to high level for heavy occupants.

However, taking several factors into account increases the complexity of the decision making process.

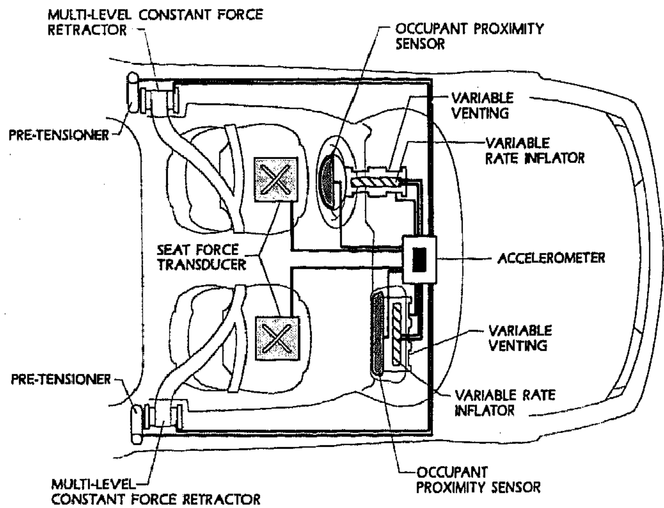

Figure 4: System Schematic

The first step in validating the algorithm was to pick various crash scenarios with different factors as defined. Those conditions were then input into a computer program with the algorithm to see what restraint adjustment levels would be chosen. MADYMO simulations were performed on each scenario to compare predicted injury criteria utilizing restraint settings recommended by the algorithm with predicted injury criteria utilizing a baseline system. In this case, the baseline system was a current, restraint system that included a single level load limiting seat belt system and airbag. This number will be used in a mathematical formula to set levels of the adaptive restraint components. See Table 2 for one possible configuration of these factors.

Table 2:

Factor	Magnitude
A-Crash severity	1-mild crash, 10-severe crash
B-Occupant Mass	1-light person, 10-heavy
C-Seatbelt Use	1-belted, 2-unbelted
D-Occupant to IP proximity	0-touching, 10-normally seated

The entire system would be controlled by an electronic module that monitors all relevant factors such as those in Table 2 and chooses the appropriate airbag and seatbelt settings. The first decision to be made is whether the crash is severe enough to fire the pretensioner and set the load limiting level of the constant force retractor. The second decision is whether the crash is severe enough to fire the airbag. At that point, all the factors must be taken into account and the control system must manage the adjustment of the restraint system. An algorithm based on a set of mathematical equations was derived to calculate restraint adjustment levels. This algorithm operates on the assumption that there is a condition where all factors are maximized, calling for the maximum restraint force to be applied. For the airbag inflator, the highest output occurs when the occupant weight, the occupant distance from the airbag, and crash severity are at maximum levels and the occupant is not wearing a seat belt. For airbag venting, the maximum restraint force (and therefore the minimum venting) occurs when the occupant weight, the occupant distance from the airbag, and crash severity are at maximum levels and the occupant is not wearing a seat belt. For the constant force retractor, the maximum restraint force occurs when the occupant weight and the crash severity are at maximum levels but occupant distance from the airbag is minimum.

A separate control equation is used for each of the restraint components. The equation compares the state of the actual input factor such as crash severity, occupant weight, etc. to a maximum value and this difference is used to modify the restraint system from the maximum. Weighting factors are then assigned to each input, giving more weight to those factors that will have a greater influence on the particular restraint component setting. For example, a large weighting factor is applied to the occupant proximity sensor signal when it is used to control airbag inflation. This results in a significant decrease in airbag inflation velocity which, in turn, should lessen the possibility of deployment-related injuries.

The equation approach allows for a continuous response to the input parameters as opposed to a look up table that has been proposed for these systems. The MADYMO study presented earlier was used to determine appropriate weighting factors for each restraint component. The control of this system is based on the assignment of a number (from 1 to 10, for example) to each of the inputs to represent its magnitude. As illustrated in Table 3, there was significant improvement in injury criteria for all of the crash situations investigated.

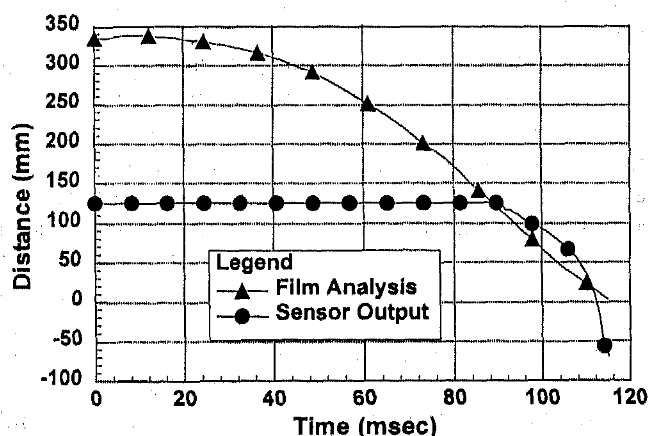
Table 3: Adaptive Restraint Modeling

SLED TEST VALIDATION

A sled test was performed to further validate the adaptive restraint concept. The main purpose of this testing was to determine if the various conditions could be sensed and the systems actuated, all in the time frame at which a crash event occurs. This particular test condition was designed to determine if the system could recognize an occupant that was thrown out of position due to the crash forces in a late fire event and respond by lowering the output of the inflator.

The electric field occupant sensor has been shown to have an extremely rapid response time. Figure 5 illustrates the output of the electric field occupant sensor during a previous sled test. In this case, the output was not used for decision making, but was simply monitored to compare with the actual dummy trajectory. As can be seen by Figure 5, the occupant sensor tracked the head location quite closely, once the head came within the range of the sensor. It should be noted that this test was performed with an earlier version of the sensor having less range than current versions of the device.



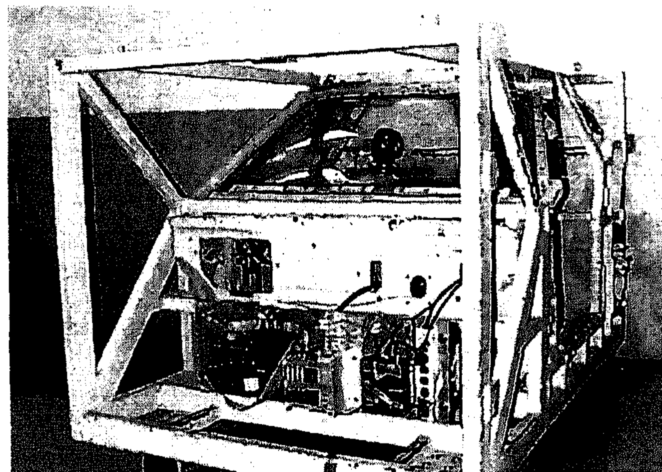


Figure 5: Comparison of Occupant Position for Capacitive Occupant Sensor vs. Film Analysis (22.4 km/hr velocity hyge sled test.)

The simulated crash test was conducted on a 9-inch HYGE sled. The generic test fixture, or "buck," consisted of sheet metal reinforced with rectangular steel tube. A 5th%ile FHIII Anthropomorphic Test Dummy (ATD) was situated without a safety belt in the right front passenger seat in a full-forward position. The airbag module consisted of a multi-level inflator, nylon airbag, steel housing with variable venting capabilities and an electric field occupant sensor located within the airbag door. The forward sensing range of the occupant sensor was approximately 14 inches (356 mm). Therefore, the nose of the ATD was positioned slightly beyond that distance so that the occupant would not be detected until it moved into range of the sensor during the simulated crash event. The control electronics were mounted on the sled buck and included a microprocessor to run the control algorithm. During the event, the control electronics would determine airbag firing time and vary the output of the dual-level inflator based on the input from the occupant sensor. The control system also controlled actuation of the airbag variable venting system, although the tailoring of the inflation rate was expected to have the greatest effect on airbag performance in this out of position test. The sled buck with microprocessor and related components are shown in Figure 6.

Figure 6: Test Setup

The Sled was fired at 20 mph (32.2 kph) with a pulse that represented an angular collision. This pulse was chosen because of its relatively late fire time. To ensure that the occupant was quite close to the airbag during deployment, the fire time was further increased to 97 msec.

No external signals were sent to the sled buck for control of the restraint devices. The output of the sled carriage accelerometer was routed to the adaptive restraint control electronics which used that signal to determine the initiation of the crash event. The initial fire time of the first squib was programmed into the microprocessor prior to the test, but the second squib fire time, as well as the decision to actuate the venting devices, were all controlled by the algorithm. The timing of the control system's decision-making process for this test is shown in Figure 7. As can be seen, the algorithm chose a delay time of 28.3 msec between the firing of the first and second squibs based on the proximity of the occupant's head to airbag door. Because of the relatively low weight of the occupant and moderate crash severity, the system chose to open all of the airbag vents as well.

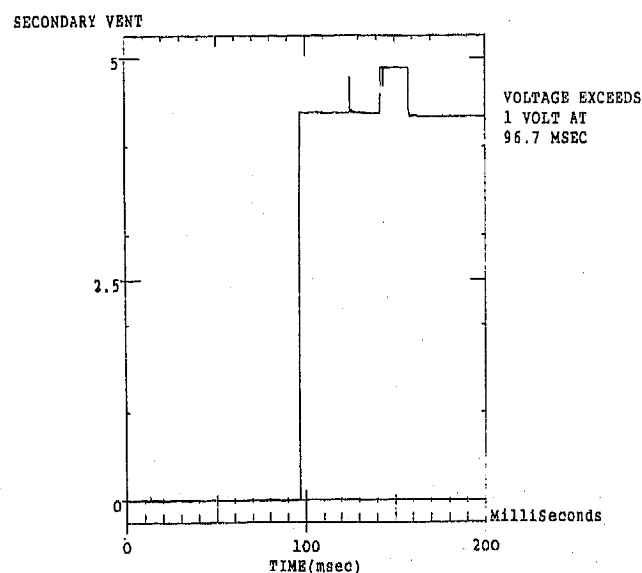

Figure 7d: Secondary Vent

CONCLUSION

Although much work remains to be done in the area of adaptive restraints, initial efforts appear to be quite promising. The value of the adaptive restraint system concept has been demonstrated through computer simulation. Initial sled tests show that the electronics can react quickly enough to be effective. Considerable work remains to test and tune all of the parameters to specific vehicles. Given all of the variables involved with real world conditions, and the limits of presently-available sensing technology, it is probably not reasonable to expect precise restraint system optimization for all of the situations which are likely to be encountered. It is the opinion of the authors that the goal of the adaptive system should be simply to demonstrate significant performance improvements over current, non-adjustable systems. Future work will involve a substantial number of sled tests to demonstrate the benefits of such a system in many more situations, and ultimately, the application of this system to an actual production vehicle.

ACKNOWLEDGMENTS

The authors would like to express their gratitude and appreciation to Shari Lyn, Kiran Sambutar and Jeff Sikorski for their contributions in the preparation of this paper.

Evaluation of Angular Displacement Measurement Techniques for Tracking the Motion of Anthropomorphic Test Devices

Jacqueline Marshall
Ford Motor Co.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The measurement of angular rotation has many applications in crash testing, particularly in tracking the motion of crash dummies. There are currently a few devices for determining angular rotation. These include accelerometer arrays, magnetohydrodynamic (MHD) sensors, potentiometers, and high speed films. However, there are problems associated with all of these methods. Systron Donner has developed a new device called a "Quartz Rate Sensor" or "QRS". The QRS utilizes a piezoelectric chip which produces a DC voltage proportional to the rate of rotation of the sensor about its sensitive axis. Angular displacement can then be determined from a simple integration. Results of preliminary tests performed at The U.S. Department of Transportation's Vehicle Research and Test Center suggest that the QRS's yield very accurate results.

BACKGROUND

The need to measure the angular displacement of an ATD has become increasingly vital to injury assessment. Traditional injury assessment techniques tend to rely on translational head acceleration, engineering quantity effectively measurable by translational accelerometers. However, modern injury assessment techniques are based more on angular quantities rather than translational, and the instrumentation required to measure these quantities is not as readily available.

A study was conducted by Viano and Arepally (16) to consider the adequacy of injury criteria and tolerance levels specified by FMVSS 208, the standard that measures the safety performance of restraint systems and supplements. They suggested that additional criteria be added to the standard to represent fundamentally important aspects of a vehicle occupant's kinematic response. These additional criteria include: the change in torso angle (used to evaluate injury to the rib cage), rotation and rebound of the chest and pelvis (necessary to study the effects of submarining), and the bending of the neck.

Submarining occurs when the pelvis of a belted passenger slides underneath the lap belt, causing the load of the impact to fall across the abdomen instead of the hips. This phenomena, which may result in serious injury, is not accounted for in traditional injury assessment techniques. Both Freeman and Bacon (4) and Viano and Arepally (16) agree that monitoring pelvis angle may provide a means of quantifying submarining. Freeman and Bacon, using a three-dimensional high speed video system to measure occupant motion, performed extensive tests to evaluate how changes in seat belt anchorage and seat adjustments affected whether or not submarining occurred.

The measurement of angular displacement is also necessary for predicting neck injury. The widely used Mertz and Patrick neck injury criteria relates neck injury to the bending moment of the head developed about the occipital condyle and the angle of the neck at the first thoracic vertebra. This quantity could be evaluated using an existing upper neck load cell along with angular displacement data. An additional neck injury assessment technique, created by Gadd, relies on the angle between vertebra to determine an injury threshold. This criterion could be evaluated directly with angular displacement measurement (12).

A new ATD device, the Cervical Omni-Directional Bending Apparatus (COBRA), was recently evaluated at the Vehicle Research and Test Center. The COBRA, which fits inside the neck of an ATD, is designed to characterize the shape response of the neck to an impact. The angle of the head relative to the top of the neck, however, must be determined through additional angular motion sensors to completely define the motion of the head/neck complex.

An additional potential need for accurate angular displacement data may be for brain injury evaluation. Brain injury is traditionally predicted from head acceleration data. Many researchers believe that injury to brain tissue is more closely related to the relative displacement between the brain and the skull than it is to head acceleration. A brain compliance model is under investigation at General Motors to assess brain injury risks in the Hybrid III ATD. This model consists of a lumped-mass model of a brain attached to the skull with a series of springs and dampers (15). If this brain

compliance model becomes available, the displacement of the brain mass and the skull could be compared to develop a new brain injury criterion.

While the need for measuring angular displacement accurately has been well established, the means for doing so has not. There are currently a few devices used to determine angular displacement. These include accelerometer arrays, high speed films, potentiometers, and magnetohydrodynamic (MHD) sensors. All of these methods are evaluated in (7). A new angular velocity sensor manufactured by Systron Donner, the "Quartz Rate Sensor", is included in this paper.

Perhaps the most widely used method of determining angular displacement is the linear accelerometer array. These exist in a variety of configurations which differ mainly in the placement and number of redundant accelerometers used. At least nine linear accelerometers must be used to obtain angular motion in three dimensions. Viano (15) cites several potential causes of error in the angular acceleration data. These include transverse (cross-axis) sensitivity, mismatch of accelerometer pairs, misalignment of accelerometer pairs, signal noise, and numerical analysis. When angular acceleration is integrated to obtain angular velocity, then integrated again to obtain angular displacement, the error is compounded.

Angular accelerometers do exist, but they are much less common than the linear accelerometers. The angular devices are seldom used because they are notorious for producing very noisy signals.

High speed film or video provides another means of measuring angular displacement. This system uses a video camera or cameras capable of high resolution at minuscule time intervals to track specific targets. The film is then digitized to obtain the displacement of the targets. A primary problem with the use of film occurs when the camera's view of the moving target is obstructed by flailing dummy arms, air bags, or the automotive structure. A second problem occurs when the target is not perpendicular to the line of sight of the camera.

Rotary potentiometers provide a direct measurement of angular displacement, and are generally believed to be very accurate. NHTSA commonly uses angular pots for calibrating ATD's. The primary deficiencies of potentiometers are their size and mounting restrictions. The pots can not be mounted inside a dummy because they must be rigidly attached to two members experiencing relative displacement. Pots mounted on the outside of an ATD can not be used in most crash tests because they will be damaged by any direct impact to the sensor. In addition, the rotary pot's ability to withstand deflection at high accelerations is limited.

A relatively new angular velocity sensor, the MHD, has been used in recent years. Several organizations, including the NHTSA, the Naval Biodynamics Lab, Systems Research Laboratories and the Biodynamics and Biocommunications Division at Wright Patterson Air Force Base have evaluated the sensor in detail. While the sensor's packaging and post-processing requirements seem appealing, all evaluations have shown considerable error in many instances which has not yet been explained. In addition, many researchers express uncertainty over the post-processing requirements.

The QRS relies on piezoelectricity to determine angular velocity. A block diagram of the QRS is illustrated in Figure 1. The double-ended tuning fork and its supporting structure are all fabricated chemically from a single wafer of monocrystalline piezoelectric quartz. Two drive tines are

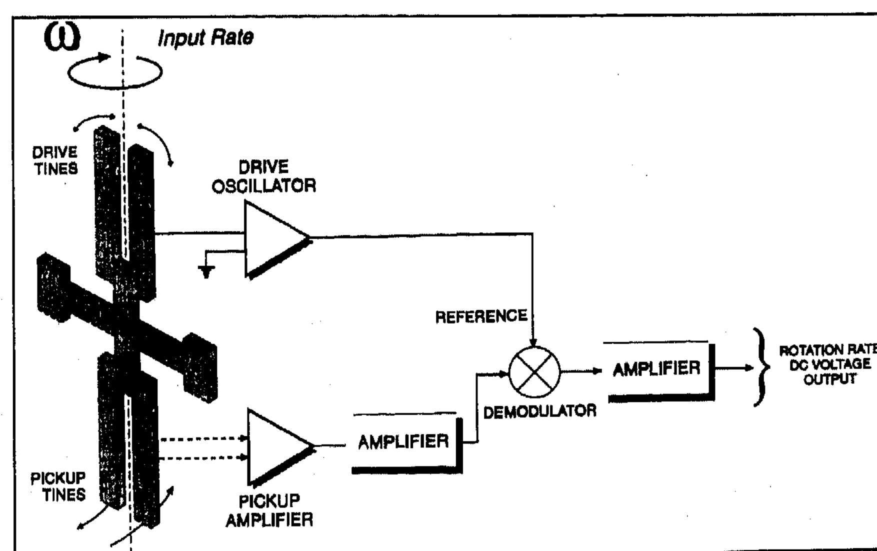

Figure 1 Quartz Rate Sensor Block Diagram (modified from Systron Donner, 1994)

driven at a precise amplitude by an oscillator circuit. This amplitude causes the tines to move toward and away from each other at a high frequency. Each tine has a Coriolis force acting on it of:

$$\overline{F} = 2m\overline{\omega_i} \times \overline{V_r} \tag{1}$$

where m is the mass of the tine, $\overline{\omega_i}$ is the input angular rate, and $\overline{V_r}$ is the instantaneous radial velocity.

The Coriolis forces resulting from the drive tines act perpendicular to the plane of the fork assembly in opposite directions. This produces an oscillating torque proportional to the input rotational rate. The pickup tines respond to the oscillating torque by moving towards and away from the plane of the fork, producing a signal at the pickup amplifier. This signal is amplified and then demodulated into a DC signal, which is proportional to the angular velocity of the sensor.

The use of a single piece of piezoelectric quartz simplifies the sensor, resulting in excellent stability. The QRS will produce an output signal only in response to angular motion about the tuning fork's axis of symmetry. This results in a very low cross-axis sensitivity. Systron Donner reports that the device has no cross-axis sensitivity.

METHODS

Test Procedure

Low-frequency testing was performed using the pendulum impact simulator at VRTC. The pendulum, shown in Figure 2, is typically fitted with a head and neck at its base. The pendulum can then be raised to specific heights and dropped. As the pendulum reaches the vertical position, it impacts a fixed block of aluminum honeycomb. The impact of the pendulum with the honeycomb simulates a step input similar to that of an actual crash. The honeycomb also acts to reduce rebounding and vibration of the pendulum upon impact.

Measurement techniques evaluated during this test include the QRS, the MHD sensor, and a 2-accelerometer array. The dummy head/neck configuration typically used on the end of the pendulum was replaced by a steel block. The block was carefully machined to allow proper positioning of each sensor. After the sensors were attached, the block was rigidly mounted to the base of the pendulum.

The QRS sensors were first secured on a T-shaped QRS tri-axial mounting block recommended by Systron Donner. The mounting block was then bolted to the bottom of the test fixture block so that each sensor's sensitive axis was correctly aligned. Only the data from the sensor measuring velocity about the y-axis were used in this test, with the y-axis being lateral, the z-axis vertical and the x-axis longitudinal. The QRS's measuring velocity about the x-axis was included to study cross-axis sensitivity.

The MHD used in this test was an ARS-09 model in the tri-axial cube configuration. This cube is designed to be directly mounted to the flat surface of the block. Four holes were carefully machined to provide proper alignment. The tri-axial cube contains three sensors such that it is capable of measuring velocity about all three axes. However, the velocity about the y-axis was the only that sensor that was wired.

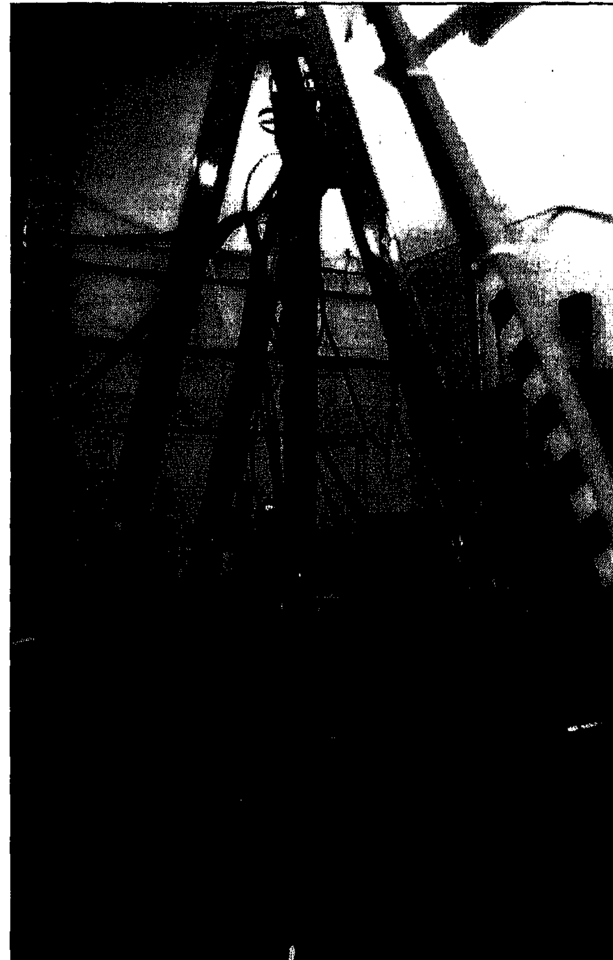

Figure 2 Pendulum Impact Simulator

Test Results

Displacement data from the linear accelerometers produced very poor results. It was determined that the operating range of the sensors was too high for the conditions experienced in this testing series, and the measured signals were of the same order of magnitude as the noise. Although accelerometers with more appropriate specifications are available on the market, they were not available at VRTC at the time the testing took place. The item of primary interest in most crash tests is the peak value of the quantity being measured, whether it be acceleration, velocity, force or displacement. Because the peak displacement values are known for this particular test series, it was not necessary to calculate theoretically exact angular displacement curves. The initial and final values and the general shape of the curves are known. The angular position curve should start

from zero degrees, increase parabolically, and reach the drop angle at impact.

For clarity, one representative displacement plot for each drop angle is included in this section. The plots obtained from the full test series are included in Reference 7. Figure 3 illustrates the displacement obtained from the QRS and MHD sensor when the pendulum was released from a 30° incline. Displacement at drop angles of 75°, 90°, and 110° are given in Reference 7.

The results from the QRS appear superior to the results from the MHD sensor. In each case, the QRS data exhibit the expected shape for the drop. The curve shows that the pendulum bounces back slightly at impact and rests near the expected angle. The MHD data exhibit a somewhat similar shape, but consistently exhibit displacement data that is higher than the actual value.

The peak displacement measured by both sensors is compiled in Table 1 for all of the tests run, along with the

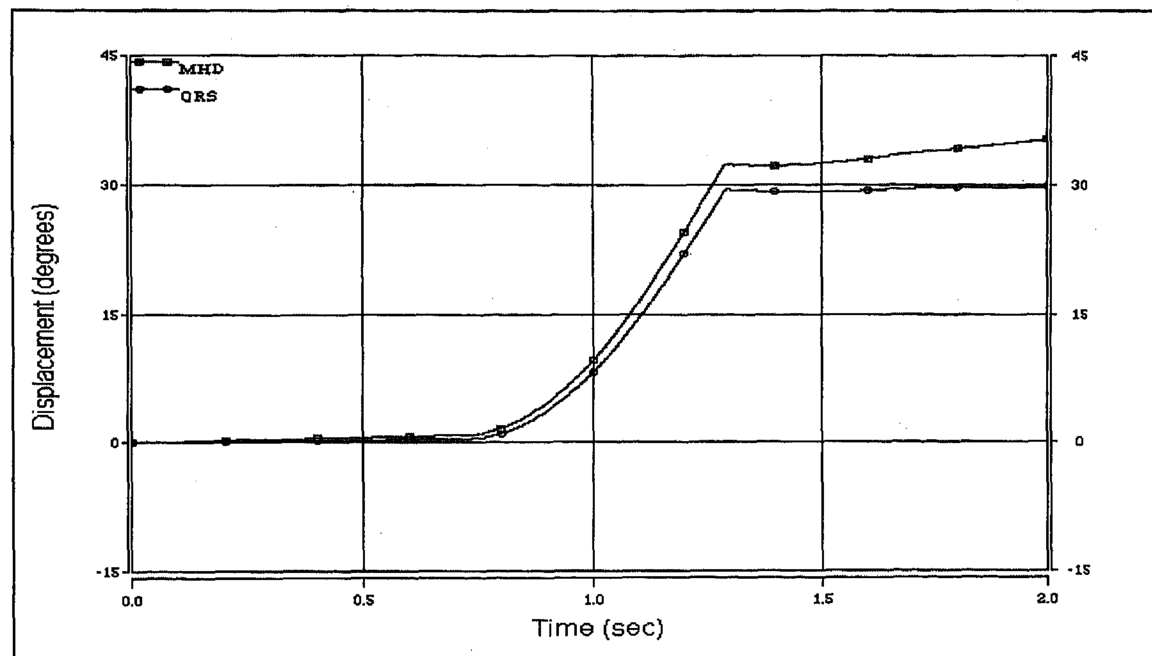

Figure 3 Angular Rotation Measurements for 30° Pendulum Drop

Table 1 Peak Displacement Error for Low-Frequency Test Series

Test Number	Pendulum Displacement (deg)	Peak QRS Displacement (deg)	Error (%)	Peak MHD Displacement (deg)	Error (%)
135	30	29.45	1.83	32.34	7.81
136	30	29.72	0.95	32.57	8.57
137	30	29.79	0.71	32.65	8.82
147	75	76.13	1.50	83.04	10.71
148	75	76.13	1.50	81.93	9.25
149	75	76.48	1.98	81.73	8.98
141	90	89.38	0.69	97.05	7.83
142	90	89.35	0.72	94.83	5.37
143	90	89.14	0.95	95.47	6.08
144	110	110.58	0.53	117.82	7.10
145	110	110.91	0.83	118.88	8.07
146	110	110.49	0.45	119.04	8.22

error as compared to the expected result. The table shows that the QRS exhibited an error of less than 2% for all of the tests run. The MHD, however, produced errors no better than 5.37%, and as high as 10.71%.

Discussion of Low-Frequency Test Results

The results of this test series indicate that the QRS is a viable alternative to traditional angular measurement sensors in the low-frequency environment. The calculated error of between 0.45% and 1.98% is acceptable for the vast majority of crash test applications. Additionally, the post-processing required to achieve displacement from the raw data was much simpler than that required for the other two methods evaluated here.

One disadvantage of the QRS is its size. It is much larger than the accelerometers tested, and slightly larger than the MHD sensors tested. The T-shaped block required to mount the sensor adds to the bulk of the instrumentation. For most applications, the QRS and its mounting kit are sufficiently compact. However, some applications may have space or weight limitations that may prevent its use. Figure 4 illustrates a size comparison between the tri-axial QRS, MHD, and accelerometer instrumentation. Note that the QRS and MHD configurations shown here are sufficient to measure rotation in three dimensions. Three additional accelerometer cubes, with a total of six additional accelerometers, would be necessary for three-dimensional calculations.

The MHD sensor did not achieve impressive results in this test series. Large error values were calculated for the entire range of drop angles. An additional disadvantage is the cumbersome post-processing required by the compensating routine.

Head/Neck Pendulum Testing Without Forehead Impact

A Hybrid III head and neck were rigidly attached, upside down, to the end of the pendulum arm. Figure 5 illustrates this configuration. The pendulum is released from a preset drop angle and impacts the aluminum honeycomb when vertical. As the pendulum arm impacts the honeycomb, the head and neck rotate freely about the base of the pendulum.

Measurement techniques evaluated during this series include the QRS, the MHD sensor, an accelerometer array, rotary potentiometers, and high-speed video. Figure 6 illustrates the mounting of the head instrumentation. This special edition Hybrid III head is designed to accommodate four precisely machined and positioned accelerometer mounting blocks which allow easy instrumentation of a nine-accelerometer array. Endevco 7264 linear accelerometers were mounted at the cg on the x- and z-axes, and at the top of the head on the x-axis. Also included in the head was a GSE three-axis neck transducer, designed specifically to fit in the base of the Hybrid III skull. This transducer measures

forces in the x- and z-axes, and the moment about the y-axis.

VRTC technicians created a special fixture for this test by modifying a Systron Donner tri-axis mounting bracket. A single ARS-01 MHD sensor and a QRS11-03600-100 were mounted to the fixture, and the fixture was mounted to the base of the inner skull. The fixture was carefully created such that each sensor's sensitive axis would be fixed along the appropriate axis. Assuming the dummy skull undergoes rigid-body motion, all points on the skull will experience equivalent rotational velocity and acceleration. It was therefore unnecessary for the sensitive axes of the rotational sensors to align with the head cg. Additionally, potentiometers were mounted to the outside of the head/neck assembly. Figure 7 illustrates this configuration. Tabs were welded to both the outside of the skull at the head cg and to the base of the neck. These tabs anchored each rotary pot. A linear sliding potentiometer was attached between the two so that the head potentiometer measured the head angle relative to the neck angle. The linear pot was used for a convenient sliding axis; linear data were not necessary for angular calculations. The tests were recorded with a nac high-speed video system. An endevco 2262-200 accelerometer measured the rotation of the pendulum arm.

Test data were recorded using the VRTC's DSP Technologies data acquisition system with all circuit parameters as specified by the sensor manufactures. Data were sampled at a rate of 10 kHz. All sensor data were filtered to 1650 Hz in accordance with SAE Class 1000.

To obtain varying impact velocities, the pendulum was dropped from heights of 60°, 90°, and 110°, with 90° being a drop from the horizontal position. Two trials were conducted at each height to ensure repeatability.

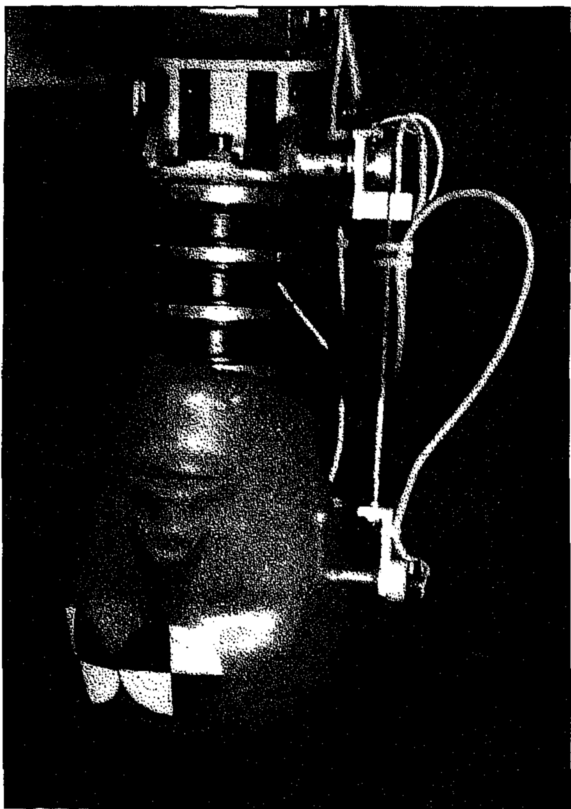

Figure 7 Potentiometer Mounting

Test Results and Discussion

A major obstacle in the analysis of these test results is the lack of exact theoretical data by which to gage the performance each measurement method. A theoretical simulation with sufficient accuracy would be quite complex and beyond the scope of this study. It was therefore decided to gage each method's performance against the result from the potentiometer instrumentation. NHTSA accepts potentiometers as a legitimate method for ATD calibration. When used within their specifications, rotary potentiometers produce very accurate results. In addition, potentiometers take a direct measurement of angular displacement so that error is not introduced from any post-processing requirements. The plots obtained for the full test series are included in Reference 7. Figure 8 illustrates the displacement of the head cg after the honeycomb impact when the pendulum was dropped from 60°.

One may note several interesting trends in the plotted data. The QRS data follow the potentiometer data very closely in both shape and magnitude. The video data also adhere well with the pot data, but the curve is quite choppy. This choppiness is due mostly to limitations on the resolution of the digitizing process. The accelerometer data are very close to the potentiometer curve up until the maximum displacement. After this point, however, the curve begins to taper off. This occurrence is not unexpected since the accelerometer data undergoes multiple integrations. Because integration is a cumulative process, it is likely that the error will increase as time increases. The compensated MHD data appear to follow the shape initially, but then taper off before the peak is reached. Although this test is shorter than the specified time for which compensation is required, using the compensating routine on the data did improve the results. However, the peak results are still low in all cases. The difference seems to become worse as time progresses.

Table 2 shows a compilation of the peak displacement values calculated from each measurement method along with the percent difference as compared to the potentiometer data. This table also demonstrates some interesting trends. While the difference in the QRS data is generally small, the value increases as the drop angle increases. The MHD data exhibit differences as large as 7.27%. The differences in the MHD data decrease as drop angle increases. Both the accelerometer array data and the video data exhibit small differences for all drop heights.

A power spectral density (PSD) analysis was performed on each test in this series to determine the frequency content of each signal. Figure 9 illustrates the power spectrum for a pendulum test dropped from 110°. PSD plots (see Ref. 7) illustrate the relative quantity of a signal that exists at a particular frequency. Peaks on the PSD plot occur at the dominant frequency or frequencies which

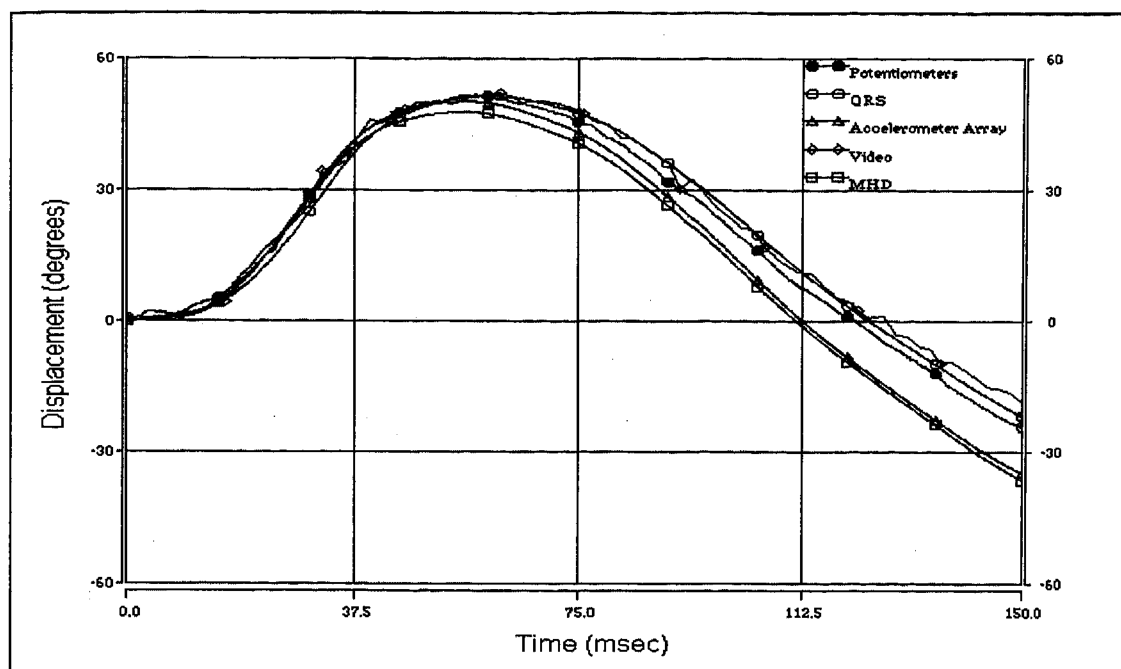

Figure 8 Rotation Measurements for Head/Neck Pendulum Drop from 60°

Table 2 Peak Displacement Values for Head/Neck Pendulum Test Series

Test Number	Drop Height	Potenti-ometers	QRS	Difference (%)	MHD	Difference (%)	Acceler-ometers	Difference (%)	Video	Difference (%)
019	60°	49.39	48.99	0.81	45.80	7.27	47.16	4.51	50.21	1.66
020	60°	51.40	50.86	1.05	47.79	7.02	50.16	2.41	52.20	1.56
021	90°	67.18	69.00	2.71	63.53	5.43	65.88	1.93	71.13	5.88

023	110°	71.23	74.24	4.23	68.09	4.41	72.15	1.29	75.12	5.46
024	110°	71.85	74.53	3.73	68.36	4.86	72.16	0.43	75.54	5.14

are in a particular signal. The value of power magnitude is a relative number and can not be compared directly from test to test.

The PSD results are very similar for all drop heights. The PSD plots show that most of each signal is concentrated around 4 and 5 Hz. There is no significant frequency content above 7 Hz, and essentially zero content exists above 20 or 30 Hz.

In this particular head/neck application, the QRS appears to perform well. Results from all six tests agree with the potentiometer results within 4.23%. Additionally, a single integration of the test data provided the displacement results.

The reasons for the percent differences increasing slightly as the drop angle increases have not been determined. The PSD analysis demonstrates that all of the tests were run well within the frequency range of the QRS sensor. It is possible that the difference is due to higher inaccuracy in the potentiometers in this range. However, the slight increase is not significant enough here to cause alarm.

Although we were able to mount the QRS sensors in the Hybrid III head, the physical characteristics of the QRS are less than ideal for this application. Measuring the rotation about all three axes would require the use of three QRS's mounted on a tri-axial mounting kit. By itself, the kit fits fairly easily inside the skull with some minor modifications to the existing hardware. However, the kit takes up most of the skull's space, making it difficult to include other instrumentation in the head. A more significant problem may be that the total weight of three QRS's and the mounting kit is 320 grams (11.3 ounces) before cabling is added. ATD heads are precisely constructed and calibrated to model representative human weights and cg locations. Heavy instrumentation in the head alters both the weight and cg location. Most ATD heads have ballast which can be moved, added and subtracted to adjust for the weight and cg

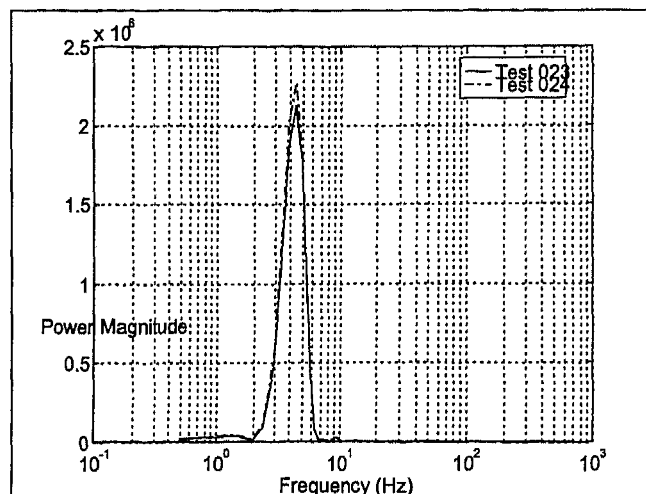

Figure 9 Power Spectral Density of Head/Neck Pendulum Tests from 110°

location, but this is a trial and error process that usually takes considerable time. This modification may or may not be a problem, depending on the nature of the test being performed.

Somewhat larger discrepancies were noted between the MHD and potentiometer measurements. These discrepancies ranged from 4.41% to 7.27%. These results are surprisingly poor based on several other publications (11, 13, 6, 18) which reported moderately better results in similar experiments. None of the publications detail the post-processing of MHD data, including whether or not a compensating routine was used, and what variable inputs may have been used. The Laughlin and Willems reports compared angular velocity measurements, not displacement, to angular velocity calculated from accelerometer arrays. The error may be smaller in the velocity measurement, and then magnified when the data are integrated to obtain displacement.

ATA has rated the bandwidth for the ARS-01 model used for this test at 0.3 to 1000 Hz. All significant frequency content was found from PSD analysis to be within this range. It is conceivable that the performance of the MHD sensor declines towards the low end of its bandwidth.

For the tests discussed here, the peak displacement value occurred sooner than 100 milliseconds. It was assumed that the compensating routine would not improve results because of this short duration. However, the routine did improve results significantly. This is most likely due to the fact that the MHD sensor is in motion for several hundred milliseconds while the pendulum is falling. This motion occurs before the initial test event, the honeycomb impact, occurs. Any pre-event motion must be added to the test duration when making decisions regarding use of the compensating routine.

The MHD sensor has some advantages over other methods. When the compensating routine used in the low-frequency test series is not needed, displacement results are obtained by a simple integration. Also, at 200 grams (7.05 ounces), a tri-axial MHD cube is lighter than the QRS and less likely to significantly affect the cg location in the head. Finally, unlike the QRS's, the MHD sensors can be used singly without the mounting cube, making them much more compact in applications requiring measurement about a single axis.

The peak displacement values calculated from the accelerometer data agreed fairly well with the potentiometer data. Discrepancies ranged from 0.43% to 4.51%. These differences are within the allowable range for most crash test applications. However, the trend of the accelerometer data to increasingly stray from the pot data as the test progresses should be mentioned. In tests of a longer duration, the accelerometers will produce poorer results because of the accumulating integration error.

One reason accelerometer arrays are so commonly used for head instrumentation is because the mounting fixtures and related hardware are readily available. The Hybrid III head, as well as most ATD components, is available with built-in accelerometer mounting utility. Although the number of sensors required is high, the mounting hardware usually does not have to be created or modified.

The high-speed video results are reasonably good. Peak displacement differences range from 1.56% to 5.88%. The video curves tend to follow the potentiometer curves throughout the duration of the test. However, in these particular tests the head motion was constrained on the X-Z plane. The video targets were not prone to a parallax effect nearly as much as they would be on an unbelted ATD in an automobile crash. In addition, this test was set up so that no obstructions were present, although they may necessarily appear in other tests.

As mentioned earlier, this test series presented an ideal environment for potentiometer usage. The type of destructive modification necessary to affix potentiometers to

the ATD is not always acceptable. Nor is the obtrusiveness of the configuration tolerable in all experiments. These limitations are particularly true in crash and sled tests. The mechanism used here measures rotation about the y-axis only. If measurement of rotation about any other axis were required, finding points to anchor the rotary pots to would be much more complex. A potentiometer configuration that measures rotation about all three axes simultaneously would be extremely complex and obtrusive.

Head/Neck Pendulum Testing with Direct Forehead Impact

This test series is very similar to the head/neck pendulum testing previously described. The difference is that after the initial honeycomb impact, the head swings around and strikes a steering wheel. The steering wheel was instrumented with a six-axis load cell. Only three of the axes were recorded for this test: the normal and tangential force, and the moment about the y-axis. A special fixture, illustrated by Figure 10, was designed to attach the steering wheel to the load cell and hold the wheel at an adjustable distance from the head. The steering wheel force data were collected to determine how the instruments respond when impact to a rigid object occurs in a crash or sled test, such as to the steering wheel or A-pillar.

The pendulum impact simulator and the Hybrid III head and neck are identical to that discussed previously. As before, measurement techniques evaluated during this series include the QRS, the MHD sensor, rotary potentiometers, and high-speed video. Accelerometer data was not collected from this test due to channel limitations. The data acquisition process is also identical to the process described previously.

Two pendulum drops were conducted at 60°, and three were conducted at 90°. Higher drops were not attempted for fear of damaging the ATD head and its instrumentation during the steering wheel impact.

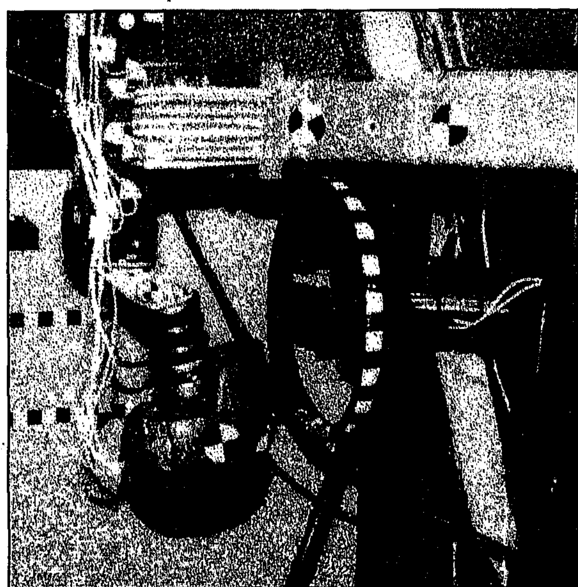

Figure 10 Steering Wheel Impact Simulator

Test Results and Discussion

As in the previous test, results from this test series are compared against the results from the potentiometer instrumentation. Since the results vary from test to test, even when the tests were conducted at the same pendulum drop angle, all five of the tests in this series are included and discussed in this section.

Figure 11 illustrates the head displacement after the honeycomb impact for test 004, which represent a drop angle of 60°. Figures 12 illustrates the head displacement for test 007, which was a pendulum drop from 90°. Table 3 explicates the peak displacement values calculated from each measurement method along with the percent difference as compared to the potentiometer data.

Greater variation exists in this test series than in the previous two. The QRS agrees well in both shape and magnitude for all tests except Number 007. For this particular test, the QRS measures 9.48% higher than the potentiometers. The MHD shows percent differences ranging from 3.10% to 9.59%. The video results demonstrate significant differences, as high as 29.25%. The video data is also very choppy. There is probably significant error in the high-speed video data. As the forehead hit the steering wheel, one of the digitized targets became difficult to track. This is particularly true at the peak displacement which occurs during the steering wheel impact.

A power spectral density (PSD) analysis was performed on each test in this series to determine the frequency content of each signal. Figure 13 illustrates the power spectrum for pendulum tests dropped from 60°. The PSD results are very similar for both drop heights. The PSD plots show that all of the signals exhibit peaks at 5 Hz. There is no significant frequency content above 7 Hz, and essentially zero content exists above 20 Hz or below 2 Hz.

Size, weight, and post-processing considerations are identical here to those in the previous test, and will not be repeated here. However, the performance characteristics will be discussed in detail.

There is significant variability in the peak displacement between the first pendulum test from 90° and the third 90° test. The same steering wheel was used for all the tests in this series. It is very likely that the first 90° test, number 007, hit the steering wheel hard enough to deform the wheel and change its stiffness. In the second test, the forehead hit a softened wheel and was able to travel further. This effect was even more significant on the third test.

The QRS appears to perform well in all of the trials except Test Number 007. Tests 004, 006, 008, and 009 exhibit differences between 2.33% and 4.49%, and follow the shape of the potentiometer curve throughout its range of motion. It is unclear why the result of test 007 is so poor compared to the other tests. The PSD analysis of the entire test series shows no significant difference between the frequency concentration in this particular test and the rest of the test series.

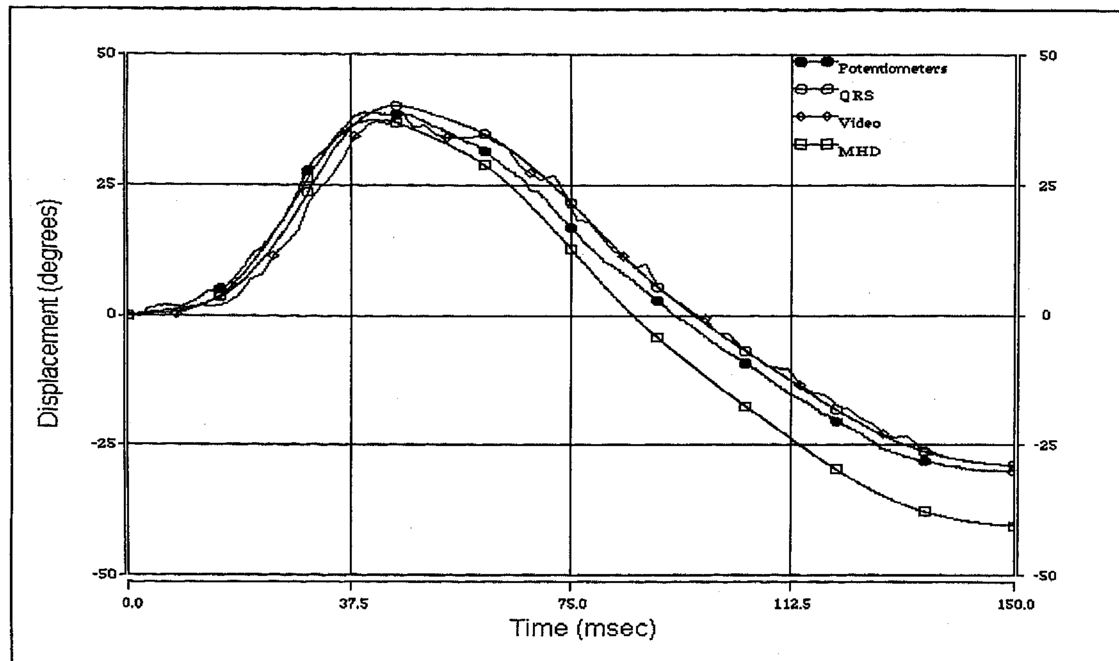

Figure 11 Rotation Measurement for 60° Drop, Test Number 004

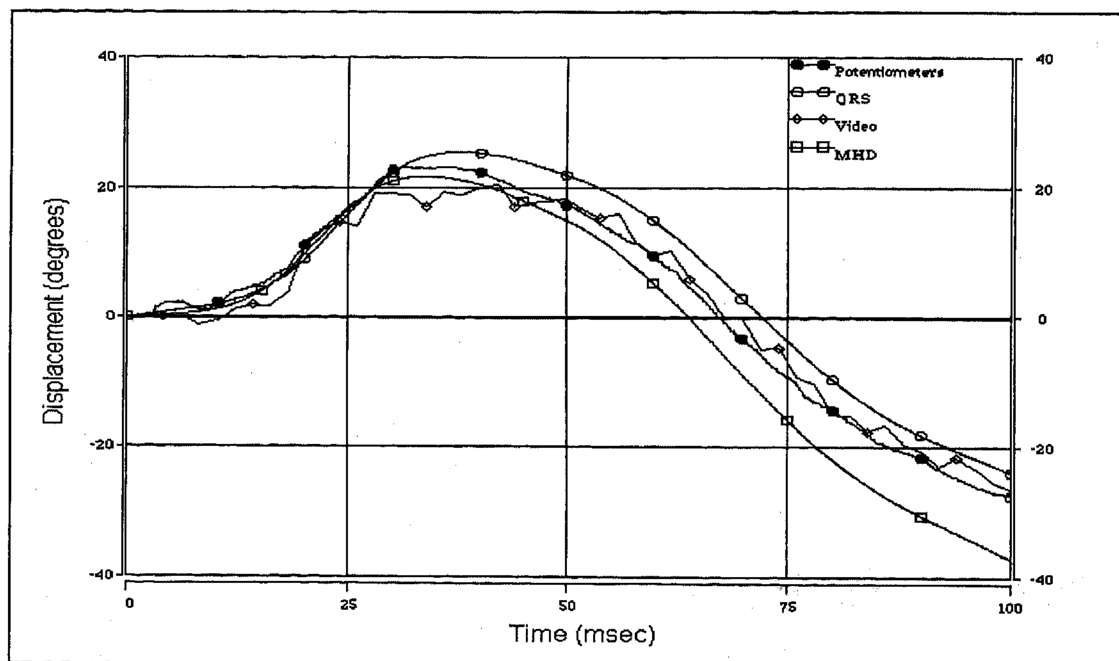

Figure 12 Rotation Measurement for 90° Drop, Test Number 007

The MHD data were examined in their compensated and uncompensated forms, and again compensation improved the data. Therefore, the compensated data are presented here. The discrepancies found for tests 004 and 006 were relatively small. The discrepancies were a bit higher for tests 007 through 009.

The video data here showed very poor results. Following any one of the displacement curves, one notices a large deviation from the potentiometer data right around the peak. This deviation decreases after the peak and then seems to catch back up several seconds after the peak. Apparently, the digitizer loses the target as the forehead strikes the steering wheel and then finds it again after the head rebounds. This problem could be corrected in this case by

Impact Test Series

Test Number	Drop Height	Potenti-ometers	QRS	Difference (%)	MHD	Difference (%)	Video	Difference (%)
004	60°	38.72°	40.12°	3.62	37.52°	3.10	38.91°	.49
006	60°	39.02°	39.93°	2.33	37.21°	4.64	36.17°	7.30
007	90°	23.20°	25.40°	9.48	21.72°	6.38	20.26°	12.67

repositioning the targets so that they are in better view of the video camera.

CONCLUSION

Evaluation of Measurement Techniques

Five different measurement techniques were evaluated for this study. These techniques include direct measurement from rotary potentiometers, digitized video analysis, and indirect measurements from QRS's, MHD sensors, and translational accelerometers. Each technique has unique characteristics which make them suitable for different applications.

Quartz Rate Sensor Evaluation

The QRS has proven to be a viable alternative for measuring displacement in many typical ATD tests. Test results indicate that the QRS provides accurate results in both low and medium frequency environments. Unlike some other methods, only one sensor is required to measure rotation about each axis, which simplifies the test configuration and data acquisition.

There are some characteristics which may make the QRS undesirable for a particular test. Systron Donner specifies the QRS's bandwidth as "greater than 60 Hz", with a -3 dB point at 75 Hz. Signals from tests such as direct windshield impacts, which may contain frequency content above 60 Hz, should not be recorded with this sensor. Tests with strict weight limitations may not allow the 320 gram sensor. Additionally, the size of the QRS limits it to use in the larger body components such as the skull, chest, or pelvis.

Ideal applications for the QRS include measurement of the angle of the chest and pelvis. The QRS is also suitable

for head measurements in low and medium frequency tests. The QRS is also ideal when one needs to reduce the number of data channels required due to limited channel availability.

MHD Sensor Evaluation

The MHD has limited uses in ATD applications. The MHD showed decent accuracy in the both of the head/neck tests, but is marginal for the low frequency pendulum block test. There is the possibility of additional "user error" in MHD test results because of potential misuse of the ill-defined compensating routine.

The primary advantage of the MHD is that it has very high frequency capabilities, much higher than the QRS's or potentiometers. Like the QRS, only one MHD sensor is required for obtaining data about each axis. For measurements in three dimensions, the MHD is available in a compact tri-axial cube.

Ideal applications for the MHD include any measurement of motion which contains extremely high frequencies for which more accurate sensors are not available. These applications may include examination of some non-biofidelic responses in an ATD.

Accelerometer Evaluation

Accelerometers have long been used for ATD response measurements. The data presented in this study show good accuracy from the accelerometers in the medium frequency range. Because accelerometers have been widely used in the past, the fixtures required to mount them are already in place inside many ATD components. This availability makes them convenient to use. In addition, an accelerometer can be added by drilling two small holes, which can be considered a minimal alteration to the dummy.

The use of translational accelerometers to measure angular rotation also has some drawbacks. Typically nine accelerometers are used to measure rotation about three axes. The MHD and QRS methods require only three sensors. With many data acquisition systems, accelerometer usage will limit the number of channels available for other purposes. The post-processing required to obtain rotational displacement need also be mentioned. The multiple integration process accumulates error in the displacement data. Longer tests will continue to accumulate error as the test progresses.

Accelerometer arrays are ideal for measuring angular rotation when a test requires the array for other purposes such as acceleration data. For an application such as this, no additional instrumentation would then be required for the displacement calculation. Tests in which excessive instrumentation is not an issue could make use of an accelerometer array.

Rotary Potentiometer Evaluation

Rotary potentiometers do provide accurate results, but their mounting requirements restrict their use significantly. Obtaining rotation about a single axis requires two potentiometers to be rigidly attached to the ATD with a sliding axis between the two. This configuration must be mounted externally on the ATD. Necessary modifications require permanent alteration of the ATD component. The sensors and their sliding member can not be subjected to any direct impact. Therefore, potentiometer use is restricted to tests in which motion is very constrained. Ideal uses for rotary potentiometers include constrained tests such as the head/neck pendulum tests, as described in this study.

High-Speed Video Evaluation

High-speed video is very useful in ATD testing, but should not be used as a primary means of obtaining angular displacement data. The video's accuracy ranged from excellent to terrible in the medium frequency tests. When used in ideal settings with optimum lighting with motion constrained on a small single plane, the video is very accurate. However, few applications are this ideal. Many potential problems may arise from video analysis, including the parallax effect described earlier and obstructed views of targets. The resolution of the digitizing process is also limited, which results in choppy data.

Despite its limitations for providing accurate displacement data, high-speed video is a very useful tool. The digitizing process is simple and inexpensive, and provides a quick ballpark check on other data. More importantly, video provides a visual record of a test. When oddities surface in sensor data, video data can provide important clues about their origin. For instance, unusual data spikes or broken body components may be the result of an unexpected collision between a body part and a test fixture or another body part.

ACKNOWLEDGMENTS

The authors would like to thank all of the many people who assisted in this project. The authors are grateful to the National Highway Traffic Safety Administration for sponsoring this research. Finally, all discussions and conclusions in this paper represent the opinion of the authors and not necessarily those of the NHTSA, TRCO, or The Ohio State University.

Topsy - A Modular Chassis Parameter Measurement System

Edward J. Heitzman and Edward F. Hietzman
Heitz Chassis Lab., Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Topsy is a modular system designed for occasional measurements of all composite inertial, kinematic, and compliance parameters which appear in today's sophisticated mathematical simulation models. The emphasis in its design is not "production-line" testing, but research: the operator can observe the vehicle's reaction to developing forces; and as insights develop he can modify the test program as he goes along. Test errors are minimized by running all tests under servo control with continuous display of all data and recording of all known error sources, while the operators closely monitor the test and the developing data.

The test facility is organized around an "infrastructure" consisting of baseplates, vehicle locating fixtures, scales, hydraulic and pneumatic power sources, interchangeable valve assemblies and actuators, and transducers. These are organized along with specialized devices into the several forms required for the different tests.

When not in use, Topsy can be disassembled and stored on shelves and in cabinets.

This paper describes the overall system and the methodology, components, and instrumentation used in the various measurements.

INTRODUCTION

Like its namesake, the little slave girl in *Uncle Tom's Cabin*, Topsy "was never born, but just grew". Archival records indicate that it was being used for center of gravity measurements on various small cars in 1982 and on a Chevrolet Suburban in 1988; structural shake of a Mercedes convertible in 1986; Audi ride steer and Mazda lateral acceleration weight transfer in 1987; etc. Over the years it has grown in a process driven by anticipation of customer test requests and the practice of determining after each test how it could have been done better. Topsy has developed into a modular system because of the way it has grown: whenever possible the equipment on hand is revised, modified, or redesigned to perform new tasks or to do old tasks better. In some cases new and old approaches are used interchangeably until one proves its superiority, then the "loser" is discarded. In construction or acquisition of any new equipment, strong consideration is given to possible multiple uses.

The methodology for measurement of CG height, roll moment of inertia, and roll/yaw product have evolved from the methods used by Cornell Aeronautical Laboratory in measurements on a 1953 Buick, as described in unpublished memoranda written in 1956. Compliance methodologies were inspired by the "Nedly-Wilson" Vehicle Parameters Facility built at Chevrolet in 1971 [1]. More recently, development has been guided by SAE J1574 [2].

Topsy has now reached a state of maturity at which its developers feel that it is worth reporting on. We will first describe the "infrastructure", and then how these components are organized with special-purpose devices for the different tests: whole-vehicle inertia; compliance and steering; kinematics; shocks and struts.

INFRASTRUCTURE

BASEPLATES - The various test devices utilize three baseplates: the laboratory floor; a vertically-mounted aluminum I-beam; and the Frame/elevator assembly.

The lab floor is concrete overlaid with industrial tile. Threaded steel inserts are installed in the concrete wherever necessary to locate fixtures. When not in use the holes are filled by flat-head stainless steel capscrews. When desired hole locations change the old holes are covered with new tile.

The 150 mm vertical I-beam is permanently attached between the floor, the cinderblock lab wall, and

several ceiling joists of the adjacent electronics laboratory room. It serves as the baseplate for measuring springs, struts, and shock absorbers, and as the reaction member in sidepull testing.

All inertial, kinematics and compliance measurements are made on the Frame/Elevator assembly which is shown in lowered position in Figure 1. This assembly forms a testing baseplate which is assembled when needed. It can be raised and lowered to a convenient working height, and can be pitched for a "drive-on" capability.

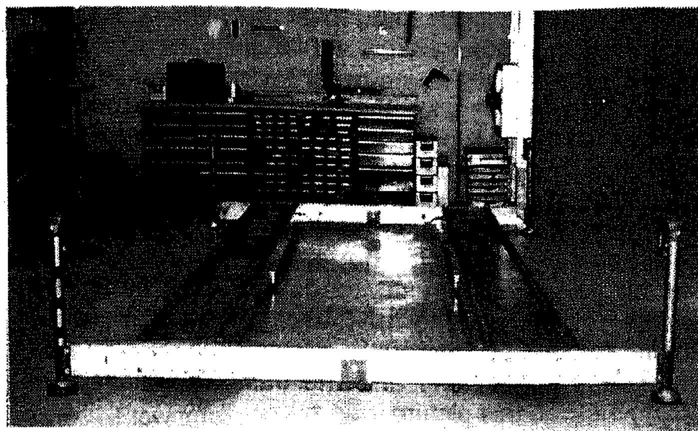

Figure 1: Frame/elevator assembly in down position

FRAME DESIGN - The Frame consists of two transverse beams and two longitudinal siderail beams. The transverse beams are rectangular aluminum tubes, reinforced by aluminum plates welded on the upper and lower surfaces, and by welded-on plates where attachment is made to the siderails. The siderails are 380 mm wide welded assemblies, 4090 mm long, made up of three rectangular tubes capped by welded-on 3 mm aluminum plates and 13 mm thick endplates. Galvanized "Unistrut" steel channels with rolled-over edges are attached to top and bottom edges and along the bottom centerline of the longitudinal beams. These are bolted at 152 mm intervals to flush-mounted "Rivnut" threaded inserts. The Unistrut rails add considerably to bending stiffness, and with the many available clamps and fittings provide a convenient system for attaching equipment to the Frame.

The basic moment of inertia of each siderail is estimated to be 1500 cm^4 of aluminum. The Unistruts add 500 cm^4 of steel. The composite moment of inertia is therefore approximately 3000 cm^4 of aluminum. The effective moment of inertia of a current transverse beam is about 625 cm^4 of aluminum, which will soon be doubled by welding on another upper and lower cap. Bending deflections are generally low because the distance from vehicle wheel centers to support members is short. The mass of each side rail is 98 kg and that of each transverse beams is 15 kg without elevators.

The attachment between a siderail and transverse beam is through 12 bolts at each end, with holes tapped into the siderail ends. Spacing between siderail centerlines is adjustable from 1270 to 1702 mm to accommodate vehicles of various trackwidths. Wider trackwidths will require welding on more plate and drilling more holes in the transverse beams, or welding up longer ones. The side beam length of 4090 mm accommodates vehicles of up to 3300 mm wheelbase.

Ramps attach to the end of the siderails. With the Frame Elevator Assembly at maximum pitch angle, a vehicle can be driven onto the frame assembly.

The Frame has secondary use as a general-purpose work table to which components can be clamped for testing. When its space is needed for other projects, it is disassembled and stored on a shelf above the laboratory entrance doors. Assembly takes one man about one hour.

FRAME ELEVATORS - The Elevator Assembly consists of four motorized ball- screw linear actuators, attached vertically to the end rails at each corner of the Frame. Each actuator is capable of over 9000 N and has a stroke of 460 mm. The actuator ends are fitted to rubber or polyethylene feet through spherical bearings.

The actuator motors are connected through the inside of the Frame beams and a single cable to a hand-held control module, where they are controlled, singly or together, by toggle switches. The elevators provide a table height range of 215 to 675 mm, and a pitch range of ±6 degrees.

Each elevator actuator has a mass of 19 kg. They are stored in a closet when not in use.

VEHICLE LOCATING JACKS

SCISSORS JACK - The two scissors jacks, one of which is shown in Figure 2, were designed to lock the vehicle to the Frame at selected ride heights, for inertial and compliance measurements. When raised or lowered by turning the Acme-threaded screws with a wrench or air wrench they remain horizontal, so that front and rear ride heights can be adjusted without worry about introducing roll. They are laterally stiff, since parallelogramming requires bending the 19 mm diameter screw into a sine wave. Nevertheless, during early lateral compliance testing, in which displacement transducers were referenced to the Frame rather than the vehicle body, it became necessary to put adjustable threaded spacers under each threaded block to reduce the lateral compliance resulting from this sine wave bending. With the spacers installed, lateral deflections were reduced to 0.2 mm at 4100 N sideforce. The mass of each scissors jack is 19 kg. When not in use they are stored vertically in the "crossmember corner" of the laboratory.

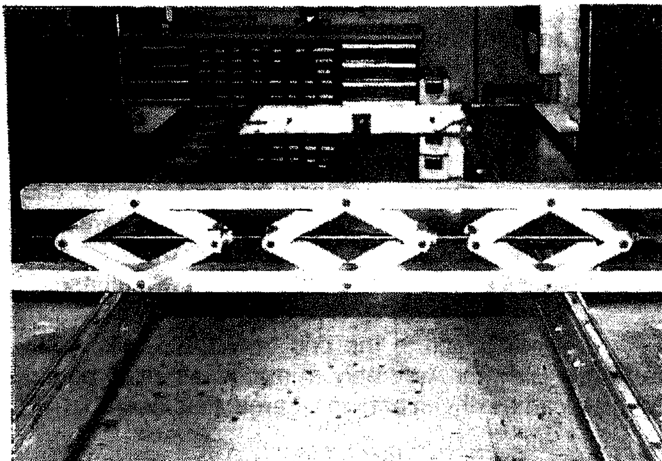

Figure 2: Scissors jack assembly

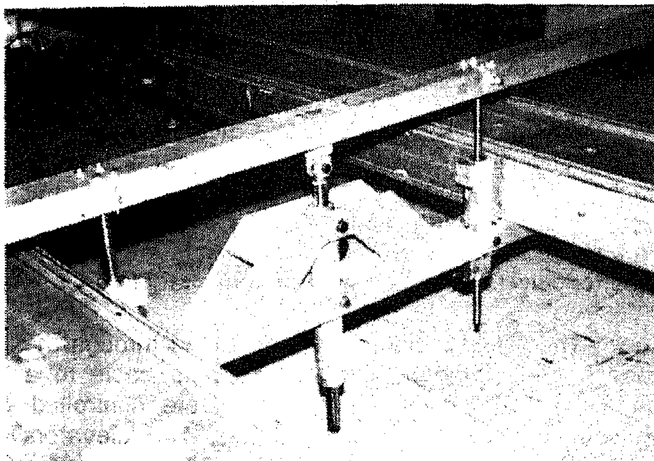

Figure 3: Ride/Roll crossmember mounted below Frame, with servo cylinders

RIDE/ROLL CROSSMEMBER - The "Ride/Roll" crossmembers, one of which is shown in Figure 3, were designed to exercise the vehicle suspension in kinematics testing, but can also be used in compliance tests. The center restraint for this crossmember is a 32 mm diameter steel shaft running in linear ball bearings in a cylindrical housing, which is attached to the lower crossmember "bridge truss" by shaft collar-trunnions. The cylindrical housing is adjusted up or down to optimize the loading on the vertical shaft. The inner shaft attaches by a spherical bearing to a clevis welded to a 38 mm diameter screw, which is threaded into a block in the upper crossmember. The location of the spherical bearing defines the point about which the vehicle rolls, provided that the shaft is vertically locked by tightened shaft collars. That point can be adjusted by screwing the clevis into or out of the crossmember. With the vertical shaft free, the vehicle finds its own roll center, which can be computed from the vertical shaft motion or by other means.

The ride/roll crossmembers can be assembled "upside down" or "rightside up", and they can be attached to either the bottom of the Frame as in Figure 3 or to the top side. One of the four configurations is chosen for a particular test according to test vehicle road clearance and ease of installation.

The vertical displacement and roll angle of the upper crossmember is controlled by any of several trunnion-mounted linear actuators. For compliance testing slow-moving electric motor ball screw actuators are used, or hydraulic cylinders are locked vertically by shaft collars. For kinematics and frequency response testing, a variety of hydraulic actuators are used, depending on force, stroke, and piston velocity requirements.

Removal of an actuator requires only pulling out a spring-loaded hitch pin from the upper spherical rod-end, and removing two trunnion bolts.

The housing for the vertical slider is normally located rigidly at top and bottom for lateral stiffness. However, for measurement of roll/yaw product in dynamic testing one end is located as shown in Figure 4. Here the housing is pivoted about its lower mount, but the upper end is free to move laterally except for the load cell restraint. Fore/aft loads are taken by the ball bearing, which tends to roll on either the front or rear surface of the channel with a clearance of about 0.2 mm. The vertical slider and the truss sides have been enlarged since this picture was taken.

The lower "truss" crossmember has a mass of 15.6 kg, and that of the upper crossmember is 11.6 kg. They store in "crossmember corner". The vertical bearing and shaft assembly has a mass of 5.3 kg, and stores in a closet.

ATTACHMENT TO VEHICLE - Where possible the Scissors or Ride/Roll crossmembers bolt to "rivnuts" installed in the vehicle frame or underbody. (After testing the rivnuts are plugged with setscrews.) For passenger cars, they are more often clamped to rocker pinch welds, using machinists vises modified for air-wrench installation. The vises bolt to or are clamped to the locating crossmembers.

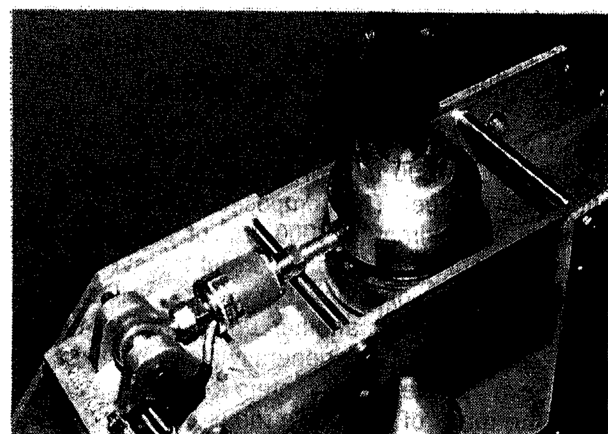

Figure 4: Side force measurement in roll dynamic testing

ACTUATORS - An array of electric motor and raulic actuators are used interchangeably, with a ındard" trunnion mount. For essentially static itioning jobs, Saginaw ball-screw actuators are used, er with Saginaw motors or smaller Dayton motors ı higher-ratio gearing. With one exception, motors 90 volts, run off rectified 115 Vac and controlled by ɟle switches or by operational amplifier-driven relays. the pull-point locators in sidepull testing, the ɹators use 12 volt motors driven by general-purpose ʌo amplifiers.

Hydraulic cylinders or servo cylinders are used ɜnever variable force or motion is needed. Four sizes hydraulic cylinders are used, depending on force, ıke, and matching of piston velocity requirements to ted pump capacity. Piston areas (on the rod side) are ıroximately 1.3, 2.6, 6.5, and 12.9 cm^2 respectively.

The three smaller size cylinders use the same ıic design, which may be configured as single-ended, equal-area/double ended, by selection of end-caps I piston shafts. The photo in Figure 5 shows the same nder in three configurations: a single-ended, end unt in the foreground; with double-ended, trunnion unt and a double-ended, end mount in the rear.

Flow into and out of the cylinder is controlled by nifold blocks. The input end may be fitted with a ıple ported block or with servo valve manifold blocks. ɜ manifold blocks can be fitted with servo valves, or ı red or blue "dummy blocks". Blue dummy blocks ɾe the same flow direction as the simple porting cks, and red dummies have porting of the opposite ɜction. Cylinders are easily changed from parallel to ɔosing directions by switching dummies.

The cylinder end opposite to the porting block ; provision for a geared potentiometer, which is ɾen by a rack gear running in a groove milled into a ner of the cylinder. The potentiometer provides direct dback without intervening compliance or backlash ɜn the cylinder is used as a position servo.

The "big" cylinder is similar in design but is not fitted with a servovalve. The cylinder body is simply a section of thick-wall extruded tubing, which is drilled and tapped for end caps and fittings, then honed. Because it does not have to be bored, it is easy to make any length cylinder.

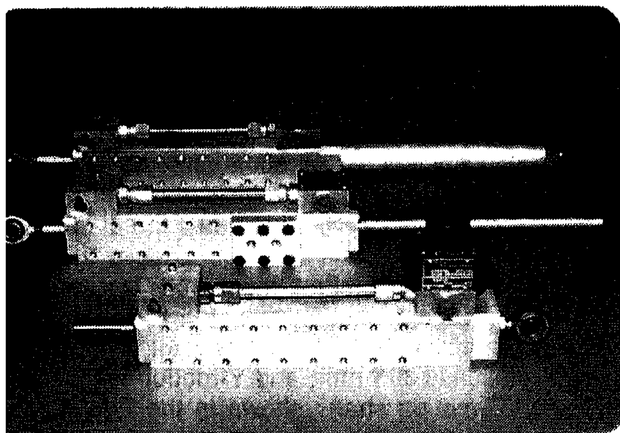

Figure 5: Hydraulic cylinder configurations

All cylinders use O-rings with less squeeze than that normally specified, for low friction.

The "bad news" about hydraulics is given by the approximate equation:

$$cm^3 / s = \frac{kW \times 10^6}{kPa}$$

At 10 000 kPa, a 4 kW pump supplies an average flow of about 400 cm^3/s. Since a single 6.5 cm^2 cylinder with a 5 cm peak-to-peak stroke at 1 Hz requires an average flow of 65 cm^3/s, the smallest diameter cylinder that will do the job is the one to be used in dynamic testing.

SERVO VALVES - Flow control servovalves are used for position servos, and pressure control servovalves for force generation. The pressure control valves are mounted in assemblies containing a filter, valve, and differential pressure transducer. All servo valves are driven by standard operational amplifiers.

HYDRAULIC SUPPLIES - Two similar hydraulic supplies in roller cabinets are employed. Both are shown in the photo of Figure 6. One has a variable displacement pump driven directly by a 1.2 kW, 115 volt motor; the second one has an identical pump belt-driven by a 4.4 kW, 230 volt motor. The pump in the 4.4 kW cabinet can run at 10 000 or 20 000 kPa by changing the compensator spring and the belt pulleys. Both cabinets have the necessary filters, reservoir, accumulator, etc. The smaller one is fitted with two servovalves with outputs fed through solenoid valves for locking cylinders in place, for the sidepull system. The larger one is used in kinematics and compliance testing.

The hydraulic pump cabinets connect by flexible hoses to a floor-mounted distribution system, which for kinematics/compliance testing runs lengthwise under the Frame. The distribution system consists of parallel stainless steel lines with accumulators on each end, and

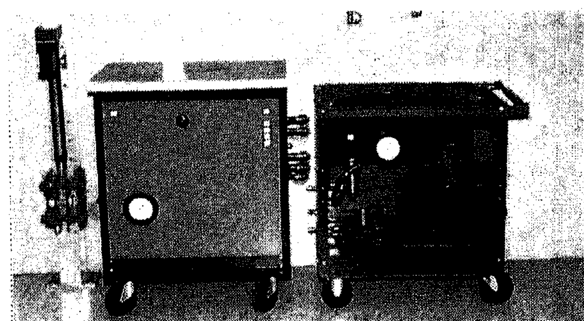

Figure 6: Hydraulic cabinets

servovalve manifolds or outlets where required. Relatively large accumulators are used to provide flow capacity well in excess of pump capacity for periods of several seconds. The accumulators are charged by a motor-driven 20 000 kPa air compressor.

WHEEL-LOAD SCALES AND BEARING PADS- Four strain-gage platform scales are used for vehicle weight and individual wheel loads. Each scale platform is 381 mm square and 100 mm high. An accuracy of ±0.02 percent is specified with the load located anywhere on the platform. Maximum load is 8900 N per scale. Accuracy certification is to NTEP Class III, one part in 6000.

The scales are not "drive-on": the vehicle must be raised and then lowered onto the scales.

For measurements of suspension kinematics and compliances, each wheel scale is fitted with ball-bearing low-friction pad assemblies. Each assembly consists of upper and lower hardened steel plates, separated by an array of hardened steel balls. Each upper plate is fitted with mounting ears for a wheelpad forcer assembly, and has a serrated steel friction surface.

POSITION TRANSDUCERS - Two types of position transducers are used. Spring-loaded rectilinear potentiometers are used for small, well-defined deflections such as lateral vehicle motion or deflections of the Frame in CG tests. For all other work we now use "home-made" string pots or string encoders. A string device (Figure 7) consists of a spring motor with its output cable wrapped in a single turn around a pulley mounted on a pot or encoder shaft. Spring motors come in several tension levels, and are inexpensive and reliable. Since the "chassis" is just a piece of flat stock it can be modified for a given application and replaced for the next. Precise encoder scaling is accomplished by selecting pulses per revolution and then machining a pulley to the correct diameter.

Encoders are used wherever possible because they have good resolution with infinite "stroke", and are zeroed anywhere in that stroke with a pushbutton switch. Potentiometers are used only when position data should not be lost when power is turned off.

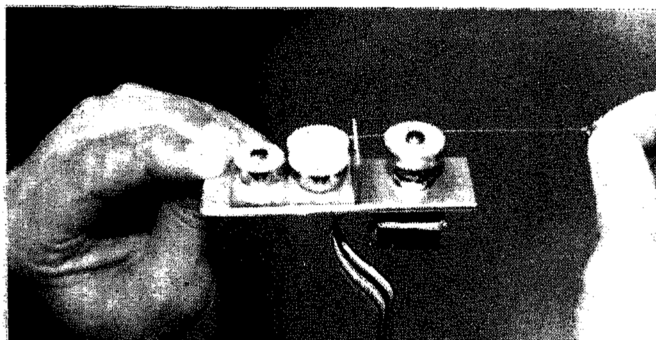

Figure 7: Small string encoder

ACCELEROMETERS/INCLINOMETERS

Force-balance servo accelerometers, either Systron-Donner Model 4310 or Sundstrand Model 303B, at 0.25, 0.5, or 1.0 g full scale, are used as inclinometers. These units have linearities of 0.05 percent full-scale, and resolutions of 0.0006 degrees. A Systron-Donner force-balance servo angular accelerometer with ±10 radians/second full scale, 0.1 percent linearity, and 0.005 percent resolution is used in angular inertia testing.

STEERING WHEEL - A "second steering wheel" instrumented to measure angle and torque is used in compliance and steering system measurements.

WHEELHUB TRANSDUCER PLATE - Wheelhub transducer plates shown in Figure 8 are designed for steering ratio and geometry, kinematics, and compliance measurements. Adapter plates are attached to lugnut extensions through four or five slots which guarantee accurate centering. The resulting spin axis extension is a threaded shaft containing a ball bearing hanger for a plumb bob or a tire deflection encoder, and a lockable attachment to the wheelhub transducer plate. This plate contains camber and caster inclinometers, a bubble level, a rearward-facing laser pointer for steer angle zeroing, a ±45 degree, 0.05 degree resolution "coarse" steer angle encoder, and attachment points for the fine steer angle encoders required for kinematics and compliance measurements.

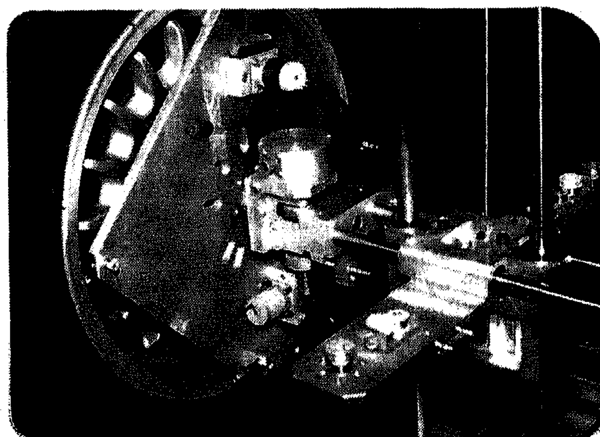

Figure 8: Wheelhub transducer plate

BALL-SLIDE FOLLOWER MECHANISM - The ball-slide mechanism shown in Figure 9 was designed to measure wheelcenter motion in kinematics and compliance testing, and vehicle bumper motion in sidepull testing. It consists of three orthogonal, dual-shaft, linear ball-bearing sliders, in X-Z-Y configuration, with motion measured by spring-motor encoders. Range of motion as determined by lengths of the slider shafts is arbitrary. At present, X-motion is 460 mm, Z-motion is 305 mm, and Y-motion is 230 mm, but the short Z-motion shafts shown in the figure are used for closet storage. Transducer range is arbitrary since the encoders can be zeroed anywhere. The encoders

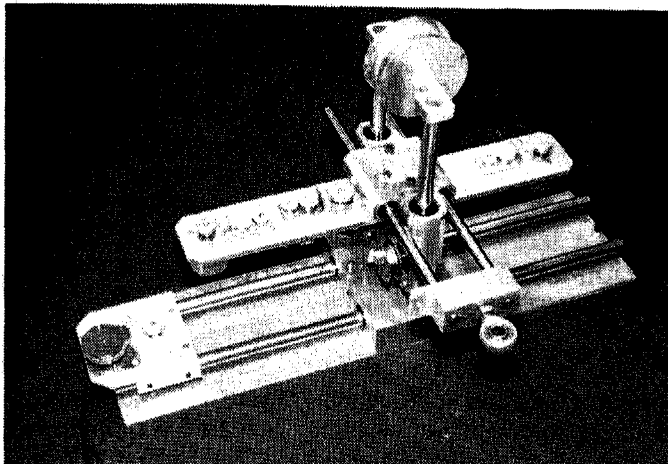

Figure 9: Ball-slide follower mechanism

installed for X-Z-Y motion have 256 pulses per revolution and 20.7 mm diameter pulleys, which with the 12-bit data acquisition conditioners result in ±127 mm full-scale with 0.06 mm resolution at 4X, and ±508 mm full-scale with 0.25 mm resolution at 1X. Force levels are 4 N in the X-axis and 1.6 N in the Y-axis, determined by the spring motors. In the Z-axis the weight of the Y-axis portion and the pull-down Z spring motor are counterbalanced by a vertical spring motor.

For compliance and kinematics testing small steer angles are measured by two additional encoders, spaced 356 mm apart to match attachment points on the wheelhub transducer plate, as shown in Figure 8. These steer angle encoders have 1,000 pulses per revolution and pulleys chosen for a 4X full-scale of ±4 degrees with 0.002 degrees resolution, and a 1X full scale of ±16 degrees with resolution of 0.008 degrees. As the slider mechanism follows the X and Z wheel motions, no corrections for such motions are needed.

DATA ACQUISITION SYSTEM - The proprietary data acquisition system shown in Figure 10 allows close monitoring of a test in progress, and useful review of completed test programs. All testing is videotaped, with raw transducer data recorded in serial binary form on one or more lines at the top of the picture. Voice, noises, and transducer outputs are recorded in synchronism continuously during the entire test on two-hour tapes, so that anomalies that might occur during or between test runs can later be investigated. Throughout the test, data is displayed as columns of numerics, twelve channels to a column, overlayed on the video picture, for visual monitoring. The displayed overlay does not have to be recorded, as it can be recreated and recorded at any time. All processed data is referenced to hours, minutes, and seconds of tape time, so that final plotted data can be referenced to the video. Figure 11 shows a typical compliance test screen with numeric overlay.

Transducer data is conditioned in general-purpose, strain gage, shaft encoder, or frequency input amplifiers; and in tenth-order 14.2 Hz

Figure 10: Data acquisition console

Butterworth active filters. All signal conditioners have manual and autozero capability, and on-board calibration (E-Cal, R-Cal, Excitation Off, Fixed-Count, or crystal oscillator) appropriate to their function. The filtered data is sampled 60 times per second, digitized to 12 bit accuracy and resolution, and stored with 12 channels on one horizontal line of the video recorder. Each data line appears as a dot-dash line across the top of the visible video picture. Figure 12 shows a screen with 24 channels of binary data on two video lines.

The system is designed to use a maximum of nine "data lines" with 12 channels per line, for a total of 108 10-Hz data channels sampled at 60 Hz. However, it is also possible to devote some data lines to "high-speed" use, with two data channels sampled at 480 Hz or one data channel sampled at 960 Hz.

Interface between the Pentium-PC computer and either the data acquisition system or the replayed

Figure 11: Screen with numeric overlay

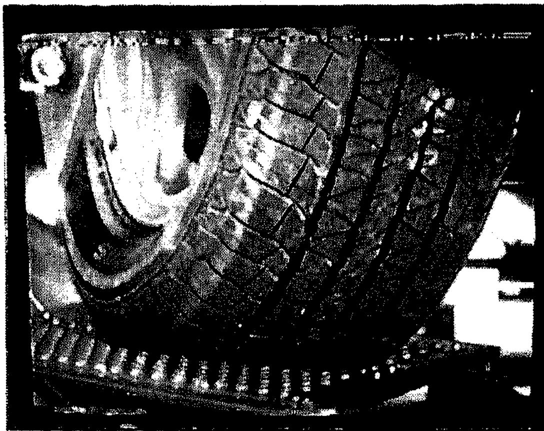

Figure 12: Screen with only binary data

tape uses a "RAM Buffer" module. Through this module, the computer sees the data being produced or reproduced as RAM which is updated with twelve 12-bit data samples, (or high speed equivalents) in 53 microsecond bursts occurring sixty times per second.

CALIBRATION OF INSTRUMENTATION - Wheel scales are calibrated by recording the placing of 24 NBS Precision F (±0.002 percent) test weights (each 50 pounds, approximately 222 N) on the scale, one at a time, then transferring them one at a time to the next scale, etc., plotting the results, and computing the best straight line through the data for each scale.

The CG moment arm load cell and roll inertia springs are calibrated in the same way: by putting the weights on the Frame against a Unistrut rail one at a time, then transferring them one at a time to the same location on the other side and plotting the result.

The small tension/compression load cells are calibrated by screwing several in series with a master load cell used only for that purpose, and loading the composite with a hydraulic cylinder and a triangle wave generator. Individually they are single-point checked with precision test weights. Sidepull load cells are single-point checked by hanging precision 2500 pound and 5000 pound test weights (approximately 11 000 N and 22 000 N), in visits by the New Jersey State Weights and Measures truck.

All load cells generally use identical 9 meter cables, both in calibration and in use. During calibration each load cell has its R-Cal checked against its own history for its output with a Micro-Measurements ±0.02 percent R-Cal resistor. Ordinary one percent resistors are then installed for checking during a test program. If for some reason a non-standard cable is used for a test the precision R-Cal can be used to adjust excitation level to compensate for cable wire resistance.

Amplifiers are checked before each use with an Electro-Services Corp "Transducer Simulator", in 0.5 millivolt/volt increments to 3.0 millivolts/volt.

Calibration of inclinometers are checked periodically on a sine table with machinist's gageblocks.

Before each use string encoders and pots are checked over 450 mm travel by a Starret metal ruler, and rectilinear pots are checked by a vernier caliper.

EQUIPMENT FOR WHOLE-VEHICLE INERTIA PROPERTIES

For measurement of CG height, the Frame sits on strain-gaged knife-edges (Figure 13), with roll motion forced by a ball-screw linear actuator equipped with a 2225 N load cell (Figure 14). The actuator attaches between a transverse torque arm bolted to Unistrut rails on both sidebeams, and the lab ceiling. The actuator motor and position potentiometer connect through a ceiling plug to a wall-mounted speed control box and to the data acquisition system. For CG measurement the actuator forces constant-speed roll motion between reversing limit stops set at ±12.5 degrees.

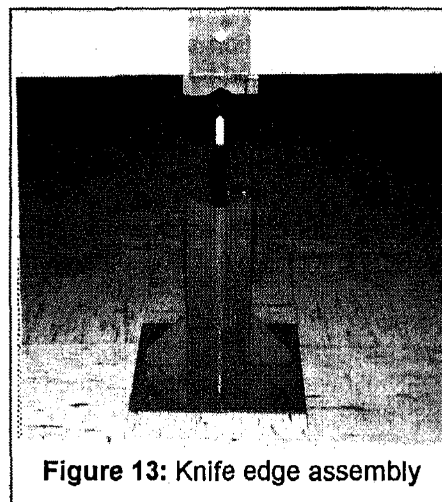

Figure 13: Knife edge assembly

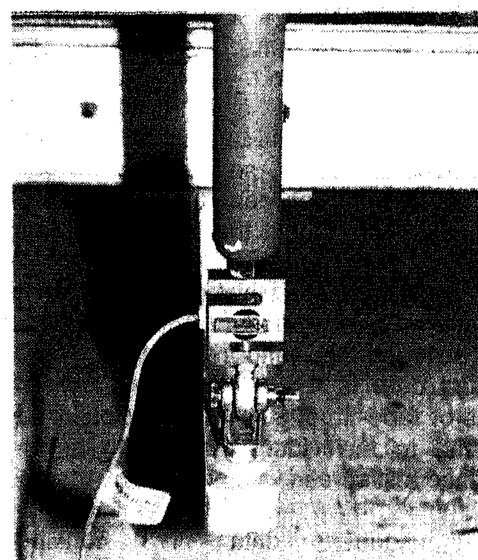

Figure 14: Torque arm with actuator load cell for CG height

An unloaded, rectangular tube, "longitudinal reference beam" is installed between the front and rear knife-edge pads. Transverse channel sections are clamped to the Frame lower-surface Unistrut rails below the front and rear wheelcenters to position vertically-mounted rectilinear potentiometers with their spring-loaded shafts impinging on the longitudinal reference beam, to measure Frame deflection. Vertical string potentiometers are installed between the reference beam and vehicle at front and rear axle locations to monitor ride height during a test.

For roll moment of inertia calibrated coil springs are bolted between the Frame ends and the floor. The Frame rocks back and forth at a frequency of approximately 1 Hz, determined by the spring rates and the inertia of the vehicle-plus-Frame. The knife-edge strain gages measure side forces which result from roll/yaw coupling. The oscillation period is measured by the angular accelerometer.

Pitch moment of inertia is measured in the same way, with the knife-edges relocated to the midpoint of the side beams.

For yaw moment of inertia the Frame sits on a "Yaw Cradle". The "cradle" (Figure 15) is a frame made up of welded rectangular aluminum tubing bolted to the lab floor through a 500 mm Rotek ball bearing. The Rotek bearing was chosen because it has bolt flanges on both inner and outer races, and does not require extreme flatness in mounting surfaces.

The cradle inner and outer races are connected through a torsion bar for angular restraint. The torsion bar is a strain-gaged BMW axle shaft, complete with constant-velocity universal joints. Test frequency is about 0.33 Hz.

When not in use the Yaw Cradle stores vertically, chained to a storage cabinet to ensure against tipping.

Figure 16 shows the storage system for everything except the Frame: calibration weights, scales, turntables, knife edges, Yaw Cradle, and "crossmember corner" are external, and everything else fits inside the cabinets.

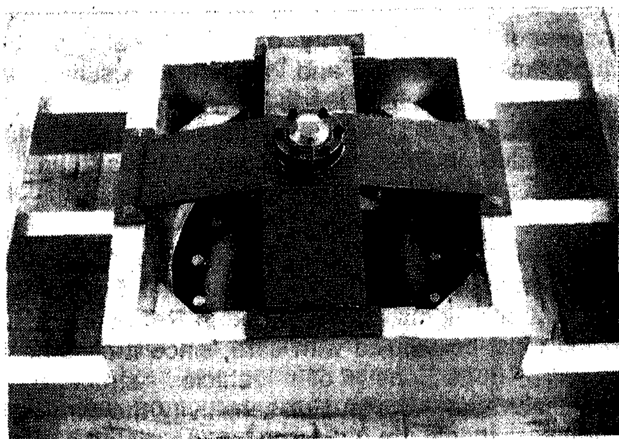

Figure 15: Yaw Cradle

Figure 16: Equipment storage

MEASUREMENT PROCEDURES FOR WHOLE-CAR INERTIA MEASUREMENTS

VEHICLE INSTALLATION - The vehicle is cleaned to remove accumulated dirt and its fuel tank is filled to overflowing; then it is weighed and the longitudinal and lateral location of its CG is computed. The longitudinal reference beam is installed, and the Frame-deflection potentiometers are attached below the calculated wheel center locations. No-load Frame deflection is recorded, and then the vehicle is driven on. The scissors jacks are attached to the vehicle, by bolting to Rivnuts installed in the vehicle underbody or frame or by clamping to rocker weld flanges. The vehicle is rolled to locate its longitudinal CG at the Frame midpoint, then rollers are placed under the scissors jacks. The vehicle is lifted slightly and centered laterally, then it is lowered and the rollers are removed. The scissors jacks are bolted to the Unistrut rails and the vehicle is set to the specified ride height.

Pots or encoders are installed to measure lateral deflection under load and any ride height changes. Supplementary, monitoring vertical stringpots are installed between the Frame and the rocker midpoints, the radiator support crossmember and the rearmost available point on the vehicle structure. All transducers are zeroed.

If moments of inertia are to be measured, scales are placed under the four corners of the Frame elevators, and barbell weights are attached to the Frame ends to adjust the longitudinal Frame CG location to its midpoint, compensating for equipment location. The vehicle is now located so that its CG and that of the Frame are directly over the Frame center.

CG HEIGHT - The Frame is lowered onto the knife edges, the vertical actuator is installed, and then the elevators are totally retracted.

The vertical actuator is set to cycle through its ±12.5 degrees range at its "fast rate" of 1 minute per cycle, while the data are observed. Any excessive deflections, or shifts as motion goes through center, require correction. The front and rear inclinometers must read the same, and they must agree with the potentiometer in the vertical actuator. The video recorder is turned on, and the actuator is then set to its 3 minutes per cycle "test rate" for at least six additional cycles. If cycle-to-cycle transducer readings are identical in each cycle, the test run is over.

If desired, the ride height is then reset, and the procedure is repeated.

After all vehicle-on inertial testing is completed the location and heights of the scissors jacks is noted, and they are removed. The vehicle is removed, and the vehicle-off readings of the Frame deflection potentiometers are recorded.

The scissors jacks are re-installed on the Frame, the gain of the load cell signal conditioner is switched to a 10x higher sensitivity, all vibration-creating devices (overhead fan, any rotating machinery) are turned off, and the measuring process is repeated for computation of the Frame tare.

Data processing, as described in Appendix 1, consists of plotting the restoring force and vehicle lateral deflection versus the tangent of the tilt angle over 3 cycles, and computing the slopes for the vehicle-plus-Frame and for the Frame alone. The computation is summarized in the following equation:

$$H_v = \frac{R}{W_v}\left[\frac{dF_{V+F}}{d\tan\theta} - \frac{dF_F}{d\tan\theta}\right] - \frac{dY_s}{d\tan\theta}$$

where

H_v = height of the total vehicle CG above the knife edges

R = torque arm length

W_v = weight of the total vehicle

θ = roll angle

$dF/d\tan\theta$ = slope of the force/angle relationship for the vehicle-plus Frame and for Frame alone

$dY_s/d\tan\theta$ = slope of the lateral shift/tilt angle relationship of the vehicle CG

Typical data plots are shown in Figure 17. Forces are corrected before plotting as discussed in Appendix 1. A single slope is shown for $dF_{V+F}/d\tan\theta$ in Figure 17; however, an incompletely-filled fuel tank will cause a small, but noticeable local slope increase through the zero tilt angle point. For this reason we also compute individual slopes for positive and negative tilt angles, eliminating the center ±0.5 degree.

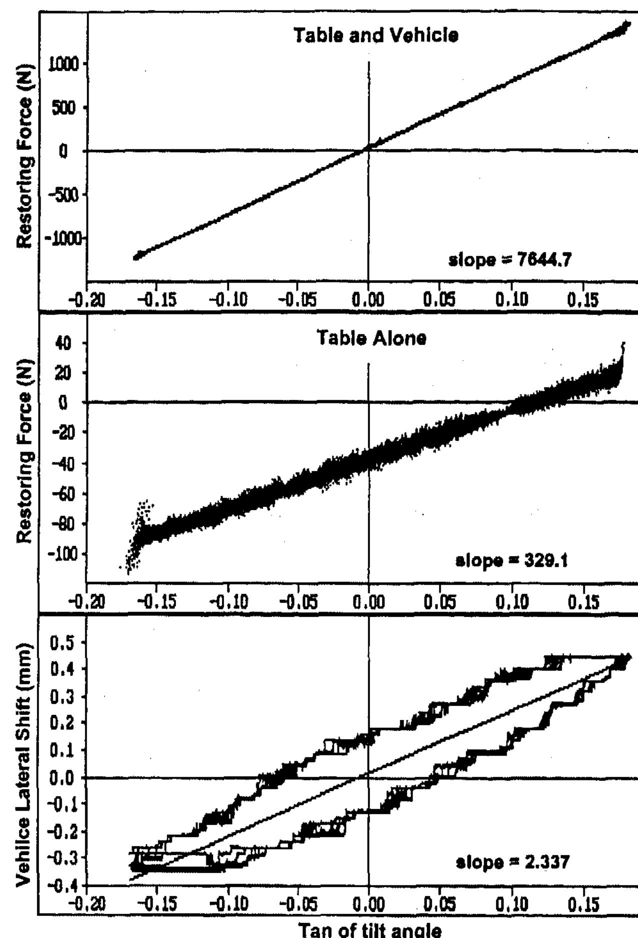

Figure 17: CG Height Test

The height of the "road surface" above the knife edges, including the measured Frame deflections, is then subtracted to obtain the total-vehicle CG height above the road surface.

CG height is usually measured at curb weight, and at additional trim heights to encompass loading conditions. We prefer not to test at different loads, because of the complexity of locating and securing "equivalent dummies" and adjusting resulting ride heights. We believe that loaded CG height can better be computed from the spring deflections due to added load, the individual heights of any applied load, and the vehicle CG measured at different ride heights.

The CG heights of sprung and unsprung masses can be separated by measuring the total CG height at different trim heights, as described in Reference 3. This method must be utilized with care, since it assumes no resulting deflections of vehicle structure or engine/subframe mounts. For sensitivity the trim height differences should be as large as possible: however,

too-large differences can create nonlinear displacements of heavy components which in some vehicles may create significant errors. Especially, unloading to the point where independent suspension rebound stops are engaged should be avoided. Since it is easy to re-measure at different trim heights, we feel it advisable to measure at three trim heights encompassing the loading range, plus one about 2.5 cm in rebound, and plot the result to evaluate the trends. Since it is also easy to add stringpots or encoders, it is advisable to monitor deflections of the engine cradle and the body structure, and make corrections if necessary.

ROLL MOMENT OF INERTIA AND ROLL/YAW PRODUCT

THEORY - In the test setup, the pitch axis is considered as being perpendicular to the plane of symmetry. The system is then one of two degrees of freedom for which the equations of motion are:

$$I_{xx}\ddot{\phi} - I_{xz}\ddot{\Phi} = L$$
$$-I_{xz}\ddot{\phi} + I_{zz}\ddot{\Phi} = N$$

where

I_{xx} = moment of inertia about the roll axis

I_{zz} = moment of inertia about the yaw axis

I_{xz} = product of inertia

$\ddot{\phi}$ = angular acceleration in roll, deg/sec^2

$\ddot{\Phi}$ = angular acceleration in yaw, deg/sec^2

L = Moment about roll axis

N = moment about yaw axis

The knife edges prevent any yaw displacement; therefore the equations of motion reduce to:

$$I_{xx}\ddot{\phi} = L$$
$$-I_{xz}\ddot{\phi} = N$$

ROLL MOMENT OF INERTIA - The Frame, with the vehicle installed and centered as described above, is lowered onto the knife edges, and calibrated coil springs are bolted to the corners of the Frame and to the laboratory floor. The angular accelerometer is attached to the vehicle. A string encoder is installed to measure roll amplitude. The knife edge strain gages are connected. The elevators are completely retracted. The recorder is turned on, and the Frame is oscillated by hand to about ±6 degrees amplitude and released. Settling time for the resulting oscillation is around 150 periods of about one second each. Transducer data is fed to the computer for immediate generation of stripcharts. These are checked to identify any glitches or inconsistencies. If everything looks good the vehicle test is over.

The test is repeated for the Frame and vehicle restraint equipment alone.

The moment of inertia of the total vehicle and Frame about the knife edges is found by equating the moment exerted by the springs to the angular acceleration. The moment of inertia of the sprung mass about a horizontal axis through its CG is then obtained by subtracting the moments of inertia about the knife edges of the Frame and the various unsprung masses, and then correcting this result to the sprung mass CG by the Parallel Axis Theorem.

$$Ikk_T = (4Ka^2 - W_T h_T)(P/2\pi)^2$$

$$Ixx = Ikk_T - Ikk_F - Ikk_{UM} - (W_S/g)h_S^2$$

where

Ixx = Moment of inertia of sprung mass about a horizontal axis through its CG

Ikk = Moments of inertia about knife edges of vehicle plus Frame, Frame alone, and Unsprung Masses

a = Lateral distance from knife edge to centerline of spring

K = Rate of each spring

h_T = height of Vehicle & Frame CG above knife edges

h_S = height of vehicle sprung mass above knife edges

W_T = total weight on knife edges

P = Period of oscillation

ROLL/YAW PRODUCT OF INERTIA

When the frame is oscillating about the horizontal knife edge roll axis, the lateral acceleration of the mass CG produces a side force on the knife edges, and the angular acceleration produces a yawing moment which is reacted by the knife edges. The product of inertia is found from the yaw moment by the following equation:

$$Ixz = (T/\phi_0)(P/2\pi)^2 - Ixz_{um} - (W_s/g)(x_{st}h_s)$$

where

Ixz = product of inertia about longitudinal and vertical axes through the cg of the sprung mass

T = moment reacted by the knife edges

ϕ_0 = roll displacement, in radians

$P =$ oscillation period, in seconds

Ixz_{um} = estimated product of inertia of unsprung mass with respect to the knife edge axis and the vertical axis through the CG of the test configuration

$W_s =$ weight of sprung mass

$g =$ gravitational acceleration

$x_{st} =$ longitudinal distance of sprung mass cg from cg of test configuration

$h_s =$ height of cg of sprung mass over knife edge axis

Note that the Frame is symmetrical, and so does not contribute to roll/yaw moment.

PITCH MOMENT OF INERTIA - The knife edges are located under the midpoints of the side beams, and the angular accelerometer is installed to measure pitch motion. Otherwise the procedure is identical to roll.

YAW MOMENT OF INERTIA - The elevators are raised to full height, the longitudinal reference beam is removed, and the yaw cradle is slid underneath and bolted to the floor. The Frame is lowered onto the Cradle, centered by mating wedges on the Cradle and Frame, and the elevators are fully retracted. The Frame is bolted to the Cradle. The yaw accelerometer is attached to the vehicle, a linear accelerometer is attached to the end of the Frame, the cradle's torsion bar strain gage is connected, a yaw amplitude encoder is installed, and the recorder is turned on. The Frame is oscillated manually in yaw to about ±10 degrees and released. (Settling time is 10 - 12 cycle periods of about 3 seconds each). Transducer data is fed to the computer for immediate generation of stripcharts. These are checked for glitches or inconsistencies in torsion bar or accelerometer output signals, and for vehicle movement with respect to the Frame. Corrections are made if necessary. Five or six data runs are then made. After removal of the vehicle, the test is repeated for the Frame alone, to obtain the tare value.

The moment of inertia is computed from the amplitude and frequency of the oscillation and the torsional spring rate, or from the angular acceleration and the spring torque.

DRIVETRAIN INERTIA - Simple pendulums consisting of 23 kg cylindrical weights on 610 mm rods, attached to the wheelhubs are used to measure rotating inertia.

EQUIPMENT FOR KINEMATICS TESTING - The Ride/Roll vehicle location crossmembers are used, with hydraulic cylinders in double-ended/equal area configuration.

The front Ride/Roll crossmember is rigidly attached to the Frame. The rear crossmember is attached to the Frame through spherical bearings, which permit a 5-degree fore/aft rocking motion to accommodate "cosine foreshortening" when the vehicle is pitched.

The vehicle sits on the bearing-equipped scales, restrained only by the two ball-bearing vertical sliding shafts. Those shafts are unrestrained in ride, and may be unrestrained or locked in roll.

If unrestrained in roll the vehicle "finds its own" roll centers, which can be located by measuring the vertical displacement of the restraint shafts, or by wheelpad displacement or force equilibrium methods. If used, each vertical restraint defines a point on the roll axis, which can be located from 25 to 100 mm below the bottom of the rocker panels, and to the ground if spacers are added.

Wheel adapter plates are attached to lugnut extensions, then the transducer plates are added and leveled. The transducer plates carry camber and caster inclinometers, and rearward-facing lasers for setting wheels in the straight-ahead position. They mate to the ball-slide wheel follower mechanism.

The ball-slide wheel followers are attached to the vehicle, on beams clamped to the Ride/Roll upper crossmembers. Tire deflections are measured separately, by an encoder attached between a ball bearing on the transducer plate axis, and the wheelpad.

For parallel ride motion the cylinders are plumbed in parallel, with all dummy blocks blue, with the two front cylinders driven by one pressure control valve and the two rear cylinders by another. The front valve is driven by a triangle-wave generator, and the rear nulls an inclinometer to keep the vehicle level. For roll the dummy valve blocks on one side are changed to red, and both valves are driven by the triangle generator for equal front and rear moments.

KINEMATICS TEST PROCEDURE - The Ride/Roll Crossmembers are installed, scales fitted with ball-bearing pads are located under each wheel, and the various displacement transducers are attached. The instrumented "second steering wheel" is installed, and the steering wheel angle is set for straight-ahead road wheels and fixed. The brakes are locked ON.

The vehicle sprung mass is exercised by hydraulic servos through several cycles of jounce, pitch, and roll motions from compressed bump stops to wheel-off, at about one cycle per minute. Throughout each run measurement is made of wheel loads; steer angle; displacements of wheel centers, tires and shock absorbers; wheelpad rotation and lateral translation; and anything else that may be of interest. Test runs are normally made with anti-roll bars both connected and

disconnected. All data is recorded for each run on the test videotape.

In data processing all data is plotted against time and inspected for smoothness and consistency. Three cycles of all desired data are plotted against the selected motion variable. Third-order least-square equations are fit to data plots except spring rates, where segmented first-order fits are usually required.

If roll centers are defined as the center of rolling motion in the absence of side forces, their heights can be computed from wheelpad displacements in ride or in roll [2], or from the vertical motion of unlocked lateral restraint shaft.

Figure 18 shows typical results for steer angle, camber, and wheelcenter Y-deflection. Figure 19 shows typical results for a roll test.

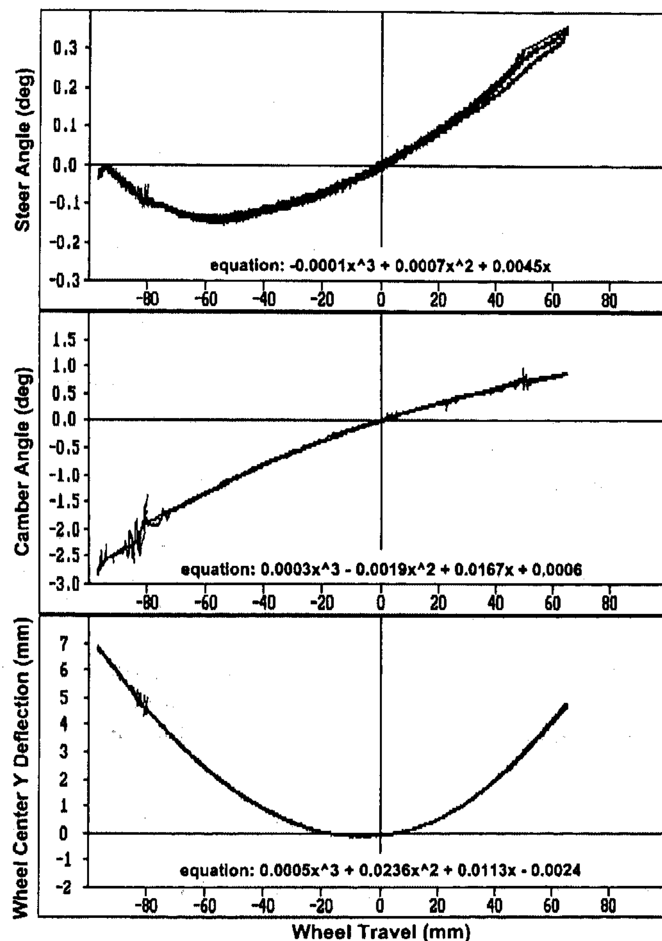

Figure 18: Ride Kinematics Test

EQUIPMENT FOR COMPLIANCE MEASUREMENTS - Either the Ride/Roll or Scissors Jack crossmembers can be used. If the Ride/Roll crossmembers are used, the hydraulic cylinders are locked in position by rod-mounted shaft collars to prevent vertical motion.

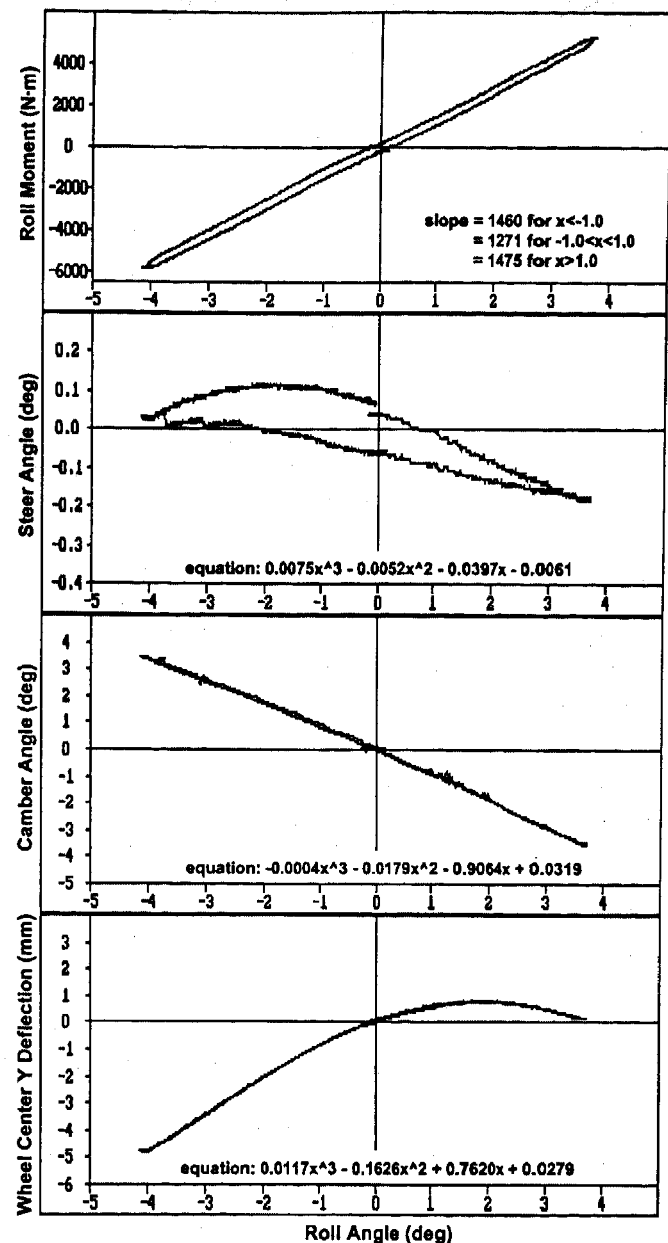

Figure 19: Roll Kinematics Test

The vehicle sits on the wheelscale-bearing plates. A set of four servo cylinders fitted with load cells are mounted on two transverse Unistrut crossmembers, and attached to mounting ears on the bearing pads, as shown in Figure 20. The four cylinders are driven by a single pressure-control servovalve, so that their force outputs are all identical. A small amount of 40 Hz dither is added to the servovalve signal to eliminate friction. Red and blue dummy valve blocks determine the direction of force output from each cylinder, to create "aiding" or "opposing" forces or moments. The servovalves are driven by a triangle wave generator.

LATERAL FORCE AND MOMENT COMPLIANCES - The vehicle is secured to the frame by either the Ride/Roll or the Scissors jack method at the desired trim height. Transducer plates and ball-slide wheel followers are used as in kinematics

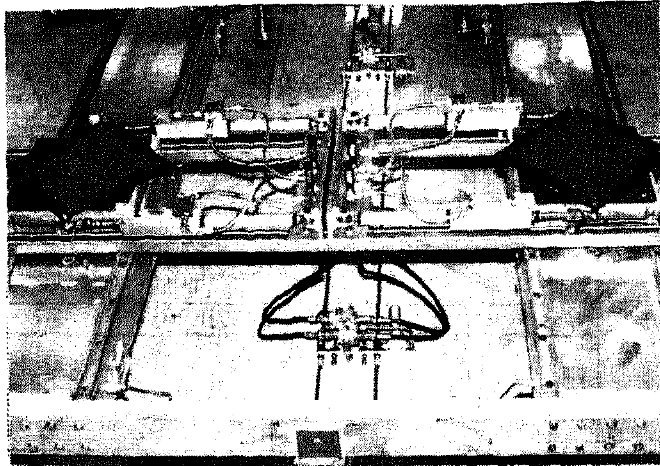

Figure 20: Wheelpad forcer assembly for compliance measurements

measurements. The wheel followers are attached to the vehicle. The force-measuring "second steering wheel" is attached to the vehicle handwheel and fixed by struts and suction cups to the vehicle windshield. The brakes are locked.

Tires are carefully centered on the wheelscale bearings, using a plumb bob or vertical laser for longitudinal and lateral location. A check run is made in "toe in/toe out" configuration to insure that sideforce produced by torque is negligible. The plumb bob or laser point is marked on the wheelpad surface, and the servo cylinder shaft extensions are noted, to restore position after wheelslip.

Test runs are made with aligning torques aiding and opposing, and sideforce aiding and opposing. In each configuration runs are made at incrementally increasing peak force levels, up to wheel-slip. Each run consists of at least four cycles at a rate of one cycle per minute.

When wheelslip occurs, the servos are used to power the tire back into place.

Steer angle and X,Y,Z wheelcenter displacements are measured from the ball slide follower. Camber and caster changes are measured by the accelerometer-inclinometers on the wheelhub transducer plates. Force and moment inputs are measured by load cells on each of the forcing servo cylinders. The cylinder differential pressure is measured as a check of measured forces.

Force and pad displacement inputs are plotted against time and inspected for quality and force/moment crosstalk. Three cycles of all desired data are plotted against input forces or moments, and third-order least-squares equations are fitted to the plots to obtain slopes. Typical plots, for an independent rear suspension measured in "sideforces opposing" configuration, are shown in Figure 21.

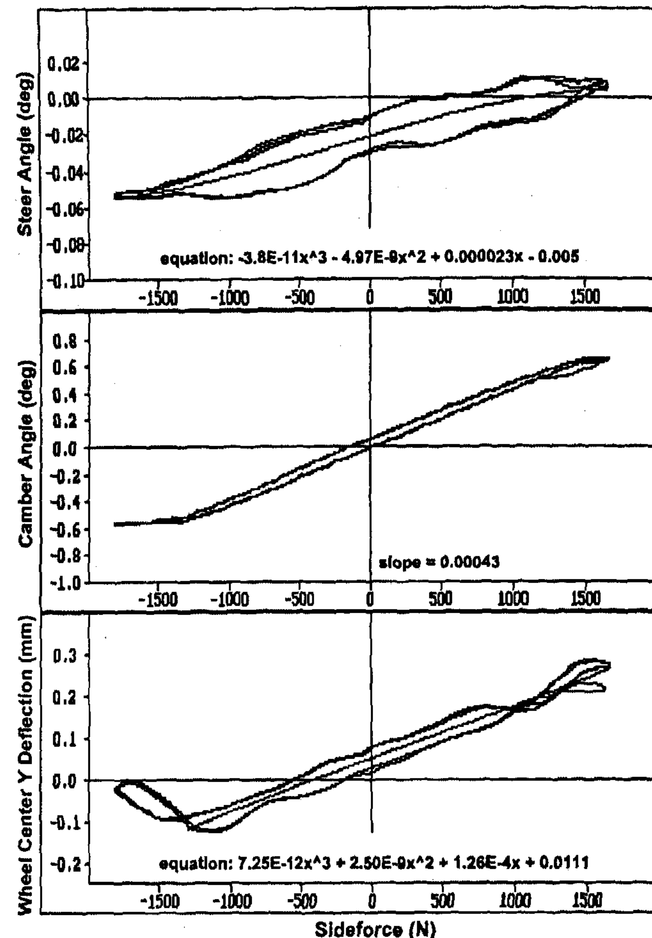

Figure 21: Typical compliance data

If roll centers are defined as points about which forces balance at zero roll angle, their heights are computed from the ratio of vertical load change to applied horizontal force in the sideforce-opposing test.

LONGITUDINAL FORCE AND MOMENT COMPLIANCES - The combined wheelpad- forcer servos are rotated 90 degrees to generate longitudinal forces. Longitudinal forces opposing at each pad produce the same toe in/out and steer moments as in the lateral case. All-forces-aiding measures longitudinal compliance, and one wheel aiding with the opposite opposing simulates unbalanced braking or thrust.

Data plotting is the same as in the lateral case.

STEERING SYSTEM MEASUREMENTS

COMPLIANCE - The compliance of the entire steering system including gearbox and column is measured in the sideforces and aligning torques aiding configuration. Sideforces and aligning torques opposing tend to balance at the steering gear, and so do not load the column. With power steering the only column torque is that required to twist a small torsion bar input to the valve: therefore with the engine running, aiding and opposing results are similar. Figure 22 demonstrates this characteristic. With the engine running in the

"Aligning Moments Aiding" (i.e., steer) configuration the on-center steer compliance, before full boost occurs, is similar to that with "engine off, moments aiding"; while the off-center compliance is similar to the "engine off, moments opposing" configuration.

Figure 23 shows the torque reaction at the steering wheel resulting from total aligning moment (aiding) at the tire contact patch, with engine running and off.

STEERING GEOMETRY - Steering ratio is measured by the rotary encoder mounted between the ball slide follower mechanism and the wheelhub transducer plate. The encoder has a resolution of 0.05 degrees at 4X.

If ground-level steer axis offsets are required, instrumented turntables are used. These are standard units (Mac Tools, Inc.) to which rotary encoders and rectilinear potentiometers have been added. They were formerly fitted with ears for the hydraulic cylinders and used on top of the wheelscales in compliance testing, but they suffered from surface brinelling and were too high, and so they were replaced by the bearing pads. They directly replace the wheelscale/bearing pad units, and measure both steer angle and pad X and Y displacements. The encoder has a resolution of 0.05 degrees, and that of the cermet pots is infinite.

In testing, the instrumented handwheel is turned through its lock-to-lock range, while the outputs of steer angle, pad displacement, camber and caster inclinometers are recorded.

For computation of steering ratio both least-squares and trigonometric equations are fit to the data, to describe the basic linear or nonlinear ratio and the effects of column universal joints. Steer angles of "inside" and "outside" wheels are plotted against handwheel angle, along with Ackerman angles, and Ackerman errors are computed.

Static camber, caster, and steering axis inclinations are computed from the equations presented in Reference 4. Caster is computed by variation of the camber transducer output with steer, and steering axis inclination is computed from variation of the caster transducer output with steer. Steering axis offsets at ground level can be computed from the rotation and translation of the wheelpad or the turntable center, provided that the location of the tire is known with sufficient accuracy. Wheelcenter displacements and steering axis offsets at spin axis level can be computed from wheel follower measurements along with wheel rim offset measurement.

COMBINED KINEMATICS AND COMPLIANCE TESTING - Topsy's mechanization of kinematics and compliance tests are essentially independent. For that reason "partial derivative" testing - varying body motion or wheel loading at constant tire patch forces or moments or *vice-versa* - is simple. For simultaneous variation of kinematics and compliance input variables it is necessary to burn an EPROM with the control program for each servo and clock their addresses in

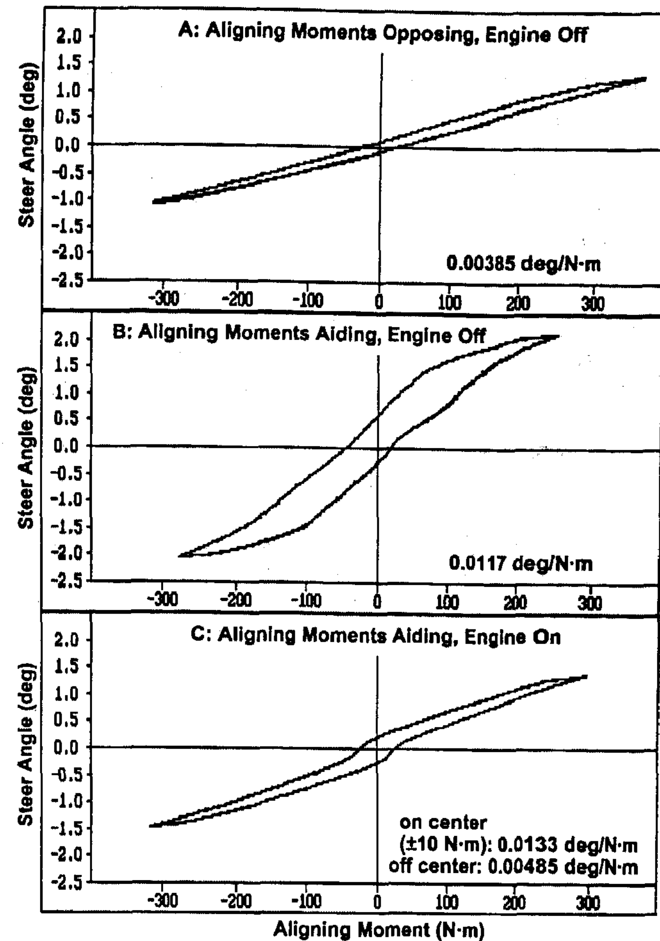

Figure 22: Steer Compliance

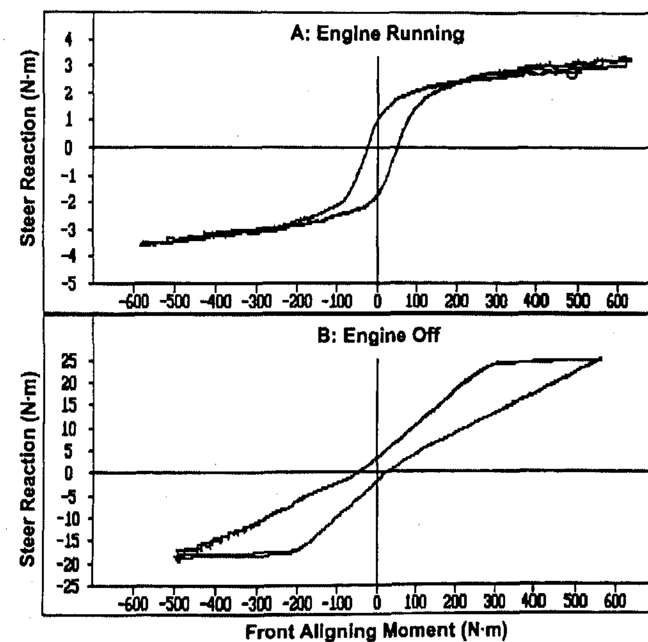

Figure 23: Torque reaction at steering wheel

unison - the electronics hardware required has been developed in another project [5].

SHOCKS AND STRUTS - Shocks, springs, and struts are measured on the vertical baseplate by simple restraining fixtures containing a load cell and a servo cylinder. The cylinder is driven at selected constant rates by a triangle-wave generator. A typical spring-rate result is shown in Figure 24 for a gas-pressurized strut. Determination of one point of a damping curve is shown in Figure 25. At each constant velocity the force is a function of both piston velocity and compression/expansion of the pressurized gas. Damping values are taken at zero deflection.

FREQUENCY RESPONSE METHODS - Frequency response methods (in present software development) utilize the servo cylinders of 1.3 or 2.6 cm^2 area, fitted with load cells, in the ride/roll crossmembers to generate sinusoidal ride forces and roll moments. The cylinders produce continuous off-resonance 2.5 - 5 cm peak-to-peak motion to 3 times resonant frequency. The software computes sprung mass inertial parameters from measured forces, accelerations, and displacements.

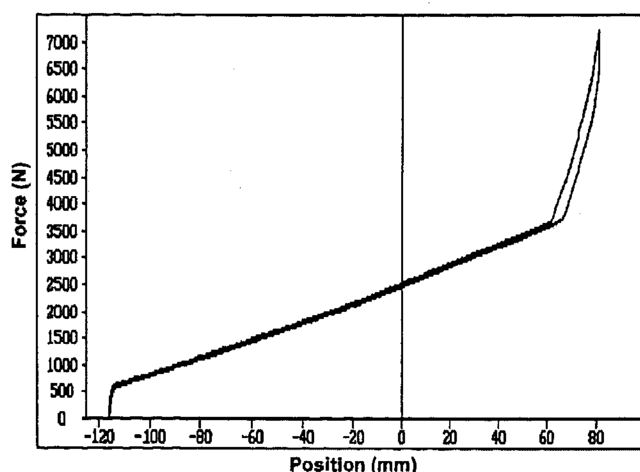

Figure 24: Strut spring rate

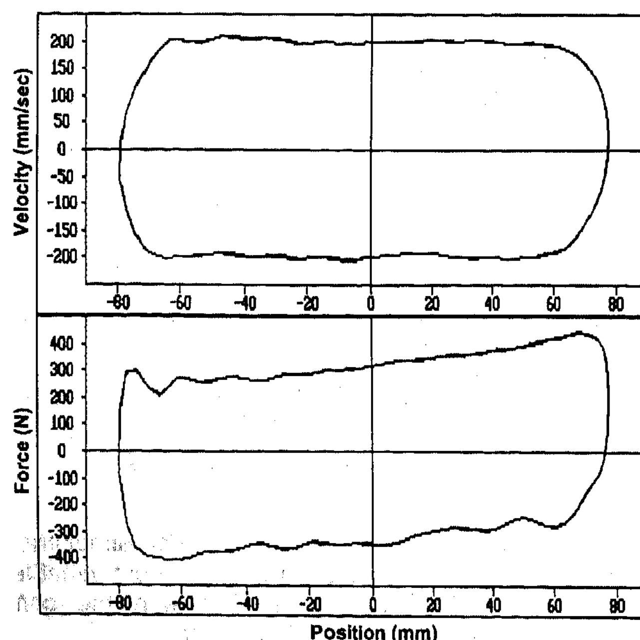

Figure 25: Strut damping

Measurements on the unsprung masses are more difficult, because of tire variations. A tire-supported wheel hub can be oscillated vertically to 30 Hz, and the static spring rate of the combination of tire and suspension spring is measured in kinematics testing. However, non-rolling and rolling tires are significantly different [6], and even the non-rolling tire spring rate is known to double between 0 and 30 Hz [7], so the "easy way" appears to have little value. If the tire is eliminated, the vehicle weight must be carried by bias pressure in the hydraulic cylinders. One system under consideration uses two servo cylinders supporting a beam attached to the wheelhub, replacing the wheel and tire.

Steering system dynamics can be studied by applying sinusoidal steer moments to the wheelpads, up to at least 30 Hz. The handwheel can be fixed with its torque measured by the "second steering wheel"; or it can be free with steering wheel motion measured by a rate gyro or angular accelerometer. The relationship between wheel angles and handwheel can be measured, but the nonrolling tire precludes moment-input relationships.

Some lateral tire dynamics can be estimated simply from lateral tire spring rates as measured in compliance tests, as described in References 8 and 9.

SPECIFYING AND REVIEWING A TEST PROGRAM - Specification of a test program consists of selecting the data required and the form in which it is desired. Identification codes are given in compressed form in Appendix 2. A test specification consists circling the appropriate codes in the complete version contained in Reference 10.

The primary record for each test program is a series of two-hour videotapes. From this record all other data can be generated.

For all test runs raw data (vs time) is supplied to the customer on floppy disks, in his choice of formats. Some or all plotting and curve fitting can be done by the customer to save costs, or it can be done by Heitz Chassis Lab. All data is referenced to hours, minutes, and seconds on the test videotapes, so an engineer can "watch" the test run from which each data plot came.

A typical test program will generate much more data than is actually used. The excess consists of deliberate redundancies in which a parameter is measured in different ways for comparison, and of "checking data" - hydraulic cylinder pressures as well as forces; various vehicle or component deflections; etc.

This information is generated for observation during a test, and is recorded under the adage "It is better to have it and not need it than to need it and not have it." This "excess data" remains available for review if questions arise, and is supplied on floppy disk at customer request.

The voice commentary, miscellaneous sounds of the test, and video camera view, all in synchronism with the instrumentation data, are additional forms of data which remain available for reviewing the testing procedures.

SUMMARY

This paper has described a compact laboratory for measurement of the inertial, kinematic, and compliance parameters required to model automobile control responses. The laboratory is oriented toward research rather than production. The approach is modular, based on an "infrastructure" of multipurpose components which are combined temporarily with a few special-purpose fixtures as required for each type of test. The modular approach permits addition of new capabilities without extensive redesign. The authors believe that in some instances the flexibility afforded by the modular approach may allow test capabilities not possible in "production" facilities. When not in use the facility is stored, so that its space is available for other projects.

APPENDIX 1: DERIVATION OF EQUATIONS FOR CG CALCULATION

Figure A1 shows the table/vehicle assembly in untilted and tilted configurations. For the tilted case, taking moments about the knife edge, we obtain:

$$\begin{aligned} FR\cos\theta = {} & [W_vH_v \tan\theta \cos\theta] \\ & + [W_v(Y+Y_s)\cos\theta] \\ & + [W_tH_t \tan\theta \cos\theta] + [W_tY_t \cos\theta] \end{aligned} \quad (A1)$$

Dividing both sides by $\cos\theta$ and solving for $(W_vH_v \tan\theta)$,

$$\begin{aligned} W_vH_v \tan\theta = {} & FR - W_vY - W_vY_s \\ & - W_tH_t \tan\theta - W_tY_t \end{aligned} \quad (A2)$$

Differentiating, noting that Wv, Wt, Yt, Yv, R, Hv, Ht are constant, while θ, F, Ysh vary;

$$W_vH_v\, d\tan\theta = R\,dF - W_v dY_s - W_tH_t\, d\tan\theta \quad (A3)$$

Rearranging to solve for Hv,

$$H_v = \frac{R}{W_v}\frac{dF}{d\tan\theta} - \frac{W_v}{W_v}\frac{dY_s}{d\tan\theta} - \frac{W_tH_t}{W_v} \quad (A4)$$

For the table alone, denoting the force by F';

$$F'R\cos\theta = W_tH_t \sin\theta + W_tY_t \cos\theta \quad (A1a)$$
$$F'R = W_tH_t \tan\theta + W_tY_t \quad (A2a)$$
$$W_tH_t \tan\theta = F'R - W_tY_t \quad (A3a)$$

Differentiating as above and rearranging;

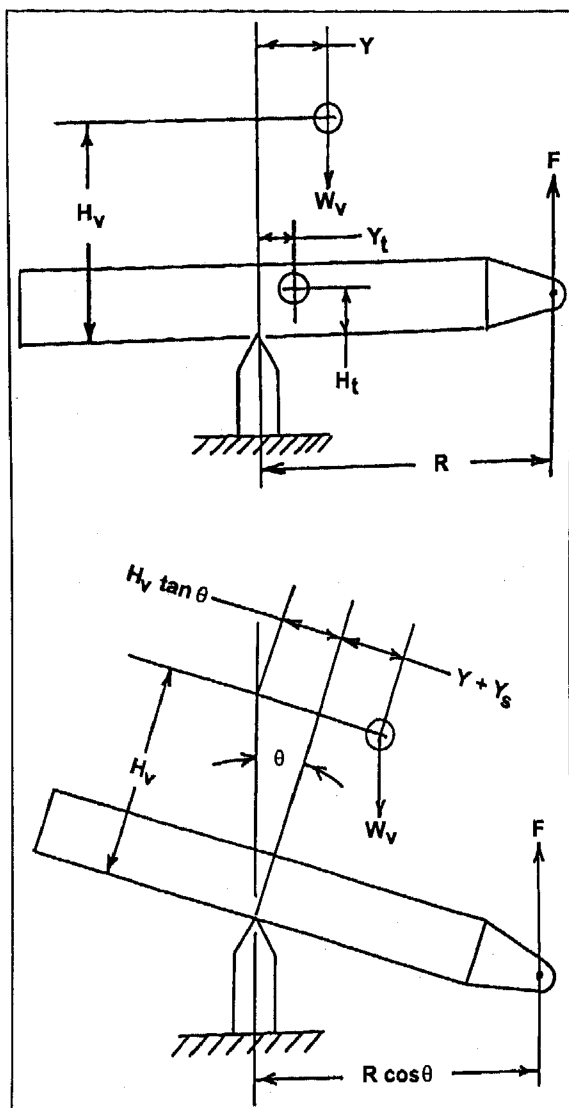

Figure A1: CG Geometry

$$H_t = \frac{R}{W_t}\frac{dF'}{d\tan\theta} \qquad \text{(A4a)}$$

Substituting this value for Ht into equation (A4);

$$H_v = \frac{R}{W_v}\left[\frac{dF}{d\tan\theta} - \frac{W_t}{W_t}\frac{dF'}{d\tan\theta}\right] - \frac{dY_s}{d\tan\theta} \qquad \text{(A5)}$$

H_v, the height of the CG above the knife edge is thus found from the slopes of the total assembly and table alone force/tilt angle relationship, plus that of the lateral vehicle displacement with respect to the table. The weight of the table itself drops out of the equation: however, the force/tilt angle relationship for the table alone must be measured with all ancillary equipment such as locating screwjacks and potentiometers in the same locations as for the vehicle test.

CORRECTION TO PRIMARY DATA - In the derivation of equation (A5) the effect of angularity in the

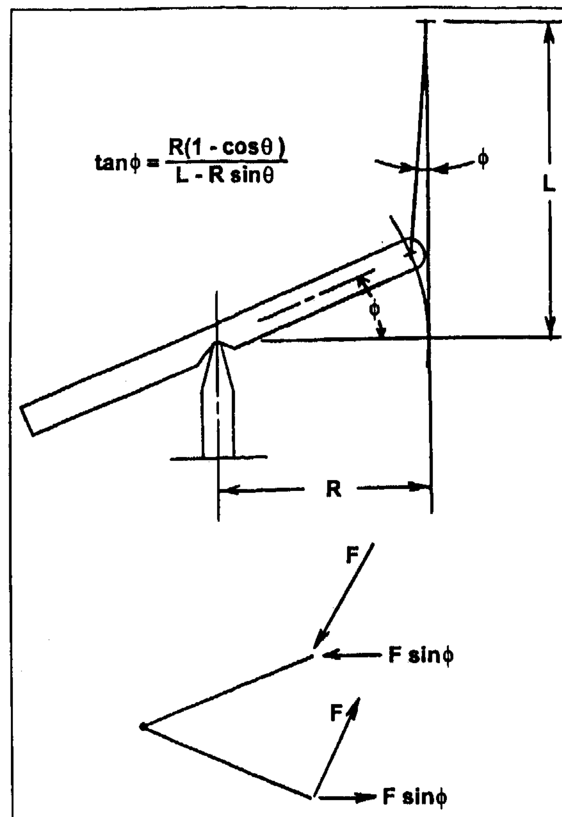

Figure A2: Sine Error

vertical actuator is ignored. This angularity does cause a small error in the slope dF/d(tan θ) for positive and negative tilt angles, with the slope being lower in the "lifting" or "raising" direction. The resulting cosine error is 0.005 percent, but sine error is in the order of 0.1 percent. They are computed and corrected as follows.

Figure A2 shows a shortening of the torque arm, R(1-cos θ), which together with the actuator length (L - R sin θ) forms the angle ϕ. This angle amounts to 0.56 degrees in the raising direction and 0.45 degrees in the lowering direction.

The resulting cosine error, which is always in the same direction, is corrected by computing ϕ and multiplying the load cell output signal by (cosine ϕ). However, correction of the resulting sine error is a little more complex.

In Figure A2 it can be seen that in the raised position the actuator is in compression, producing a clockwise moment equal to (FR cos θ) about the knife edges; while the sine component produces a moment (F sin ϕ) x (R sin θ) which opposes that moment.

In the lowered position the actuator is in tension, producing a counterclockwise moment around the knife edges. However, in this case the sine component produces an added, counterclockwise moment.

The correction for the moment (FR $\sin\phi$ $\sin\theta$) is made as follows. For small enough angles sine and tangent can be assumed equal, so that:

$$F \sin\phi = F \tan\phi = \frac{FR(1-\cos\theta)}{L - R\sin\theta} \quad \text{(A6)}$$

and the moment,

$$FR \sin\phi \sin\theta = FR^2 \sin\theta \frac{1-\cos\theta}{L - R\sin\theta} \quad \text{(A7)}$$

In equation (A1) the moment FR cos θ must be corrected by (A7). Dividing through by (R cos θ), we get a corrected value for force F.

$$F_{corr} = F\left[1+\frac{R(1-\cos\theta)}{L - R\sin\theta}\tan\theta\right] \quad \text{(A8)}$$

With this correction, and with the gas tank filled to overflow to limit fuel slosh, the difference in slopes between positive and negative tilt angles is eliminated.

CG ERROR ANALYSIS - The measurement of CG height is seen from equation (A5) to consist of four separate measurements: the force/angle slopes with and without the vehicle, the lateral deflection/angle slope, and the "road" height above the knife edges. The maximum error in the resultant CG height is therefore found as the weighted sum of the four individual measurement errors. The weighted error contribution from each source is found as the percentage error in that measurement, multiplied by the contribution of the measurement to the net CG height. The percentage errors in the individual measurements is found by differentiation, as follows.

For the contribution to total error of table plus vehicle, from equation A5,

$$\frac{R}{W_v}\frac{dF}{d\tan\theta} \quad \text{(E1)}$$

At the end points, for "small angles", this equation becomes:

$$\frac{R}{W_v}\frac{F}{\theta} \quad \text{(E2)}$$

Differentiating,

$$dH_v = \frac{R}{W_v}\frac{dF}{d\theta} + \frac{R}{W_v}\frac{Fd\theta}{\theta^2} + \frac{dR}{W_v}\frac{F}{\theta} + \frac{RdW_v}{W_v^2}\frac{F}{\theta} \quad \text{(E3)}$$

Multiplying and dividing by $\frac{R}{W_v}\frac{F}{\theta} = \frac{R}{W_v}\frac{dF}{d\theta}$

$$(\delta H_v)_{v+t} = \frac{R}{W_v}\frac{dF}{d\theta}\left[\frac{\delta F}{F} + \frac{\delta\theta}{\theta} + \frac{\delta R}{R} + \frac{\delta W_v}{W_v}\right] \quad \text{(E4)}$$

Similarly, for the table alone,

$$(\delta H_v)_t = \frac{R}{W_v}\frac{dF_t}{d\theta}\left[\frac{\delta F_t}{F_t} + \frac{\delta\theta}{\theta} + \frac{\delta R}{R} + \frac{\delta W_v}{W_v}\right] \quad \text{(E5)}$$

For lateral deflection,

$$(\delta H_v)_y = \frac{dY_s}{d\theta}\left[\frac{\delta Y_s}{Y_s} + \frac{\delta\theta}{\theta}\right] \quad \text{(E6)}$$

And for the road - knife edge distance

$$(\delta H_v)_h = \delta H_v \quad \text{(E7)}$$

The total error is

$$\sigma H_v = (\sigma H_v)_{v+t} + (\sigma H_v)_t + (\sigma H_v)_y + (\sigma H_v)_h \quad \text{(E8)}$$

The individual percentage errors are found from the full-scale linearity-plus-hysteresis specifications of all transducers, along with the measured end-point parameter values (to obtain percent-of-reading), and measurement resolution.

The total error is dominated by the $(\sigma Hv)v+t$ term and by the "roadway height" over the knife edges, because their "weight" in determination of Hv is greatest. These errors are minimized by calibrating the combination of load cell force and moment arm together, and by measuring the height of the "road surface" over the knife edges directly under the front and rear axles, before each test. In the latter measurement the deflection curve of the simply-supported reference beam under its own weight (1.0 mm at center span) is included in the measurement.

The maximum errors calculated from equation (E8), with all errors stacked up in the same direction, are in the order of 0.6 percent. Rms errors are in the order of 0.3 percent. We believe these estimates to be realistic, because the individual calibrations encompass the testing range; the quantity (Ft x R) is actually a single calibration; hysteresis error is minimized by running three completely reversed test cycles; and resolution error is minimized by taking the best straight line through the resulting 60 000 data points.

In practice we believe the greatest error is most likely to be the setting of ride height, because front and rear ride heights are seldom specified with precision.

APPENDIX 2: SPECIFICATION OF KINEMATICS AND COMPLIANCE TESTS

STANDARD CONDITIONS

- All tests are run at, or referenced to, curb trim height.
- All kinematics tests are run with engine stopped.
- Steering system tests are run with engine running and with engine stopped. Only handwheel torque is plotted for the engine stopped condition.
- Front lateral force and aligning torque compliances with forces or torques adding are run with engine running; and with forces and torques opposing the engine is stopped.
- Front longitudinal force compliance tests are run with engine running.
- All rear compliance tests are run with engine stopped.

EQUATIONS FITTED TO PLOTTED DATA - Third-order least-squares polynomial equations are fitted to most data plots. Where dictated by the character of the data, three-element linear plots (through-center, and positive and negative extremes) are used instead. Examples of the latter are steer tests, where roadwheel steer angle vs aligning torque usually shows a distinct difference between on-center and off-center slopes; and wheel loads in ride and roll, where rates change as bump or rebound stops are engaged.

CHOICE OF DATA TO BE PLOTTED - Raw data (vs time) required for all plots will be supplied on floppy disks for all tests, and will be included in the test charge. All of the plots in the following listing can be generated from the floppy disk format. Since many of the data plots in the listing are useful only in some simulation models, and the quotation for Data Processing includes a separate charge for each plot, costs will be minimized by circling only those plots actually intended for use, or those for which fitted equations are desired.

ORGANIZATION OF DATA PLOTS - Data plots are organized into four groups:

Test type and configuration
    Non-standard test conditions if present
        Test
            Parameter plotted

Examples of non-standard test conditions are engine running or stopped, non-curb ride heights, etc. For example, a front compliance test at 30 mm jounce instead of curb height would be coded as FC-30J-SFA, etc.

Handling Analysis with Vehicle Dynamics Simulator

Katsutoshi Horinouchi, Takashi Yonekawa, Tamio Kanou, Seisyu Utsumi, and Yoshihisa Nagahara
Toyota Motor Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

We have developed a vehicle test system called the Vehicle Dynamics Simulator (VDS). The system measures the handling characteristics in a transient state in the laboratory. The automobile suspensions are moved as on a road with the machine providing relative motion by force transducer platform beneath each tire. The detailed measurements of transitive motions and forces given to the wheel clarify the kinematics and compliance characteristics contributed to the good handling performance and stability.

This paper presents the system introduction and the results of analyzing the suspensions characteristics by the new analytical technique for breaking down into a variety of compliance components in a transient state.

INTRODUCTION

We have developed a vehicle testing system called the vehicle dynamics simulator (VDS) which analyzes the handling characteristics of a vehicle in the laboratory. VDS is outlined in figures 1 and 2. This testing system is featured by its ability to measure the behavior of steering and suspension systems in detail in a transient state by simulating the actual running conditions provided by a platform beneath each tire in the lab.

Figure 1: Vehicle Dynamics Simulator

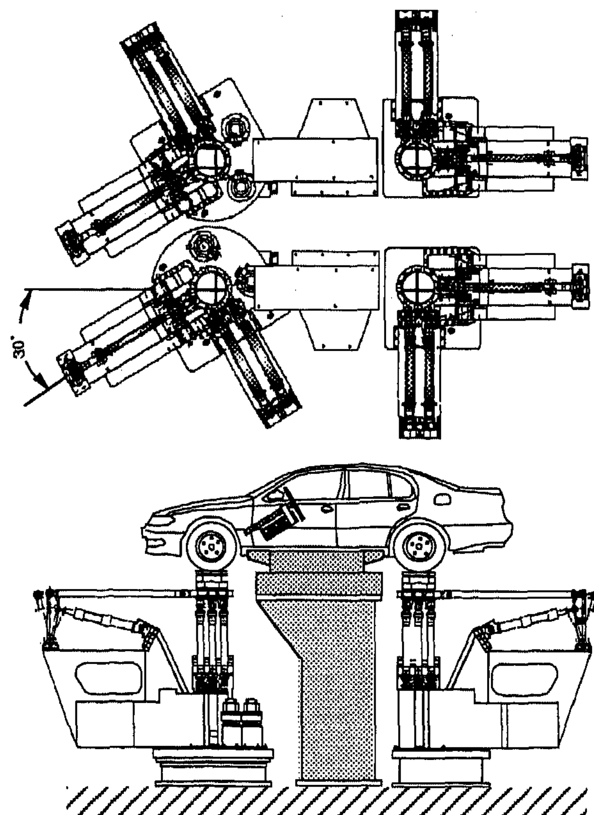

Figure 2: Elements of Vehicle Dynamics Simulator

Currently, the road simulator with four-wheel flat belt is well known as the typical on-road simulation system.[1][2] The four-wheel flat belt system is almost ideal for on-road simulation in the lab since it is capable of simulating even the rotation of tire on flat surface. However, this system has

difficulties analyzing an emergency accident avoidance behavior accompanied by a sudden change in steering since the flat belt unit itself is heavy and the system has a limited response in the steering direction. Moreover, this system involves difficulties controlling reverse input from the tire-contacting surface, therefore the system is unsuitable for in-depth measurement of compliance characteristics of the suspension by reverse input control.

Although there are a variety of systems that measure suspension characteristics by static reverse input [3][4], none of them are capable of simulating the dynamically-compounded inputs under the on-road conditions, and checking the characteristics actually attributable to the suspension for four wheels at the same time. We have prepared this paper since we have succeeded in applying the VDS to measure the transient suspension behavior under on-road conditions, and establishing the analytical technique for breaking down into a variety of compliance components at a transient state by making use of a reverse input controlling function.

SIMULATION TEST

SYSTEM CONFIGURATION - The VDS consists of the tire-contacting surface inputting four-wheel four degree-of-freedom (vertical, lateral, longitudinal and steer directions) plus two degree-of-freedom (steer direction, base steer) hydraulic exciter as the principal system and the steering actuator which has been set to allow synchronized control. Table 1 shows the performance of the main exciter. Unlike a durability tester, the exciter has been tuned with a special attention to the control performance for the low-frequency component because the exciter is intended for analysis of handling performance.

ROAD SIMULATION METHOD - For the control software to simulate the on-road conditions, we have used the RPC[5] control which has been successful with the durability tester. To fix the body, we have mainly employed two methods: one of which uses rigs to fix the rocker section of the body (figure 2), and the other uses cable to fix the hypothetical gravitational center of the body (leaving the body movable in jounce, pitch and roll directions, and fixed in yaw, lateral and longitudinal directions).

We have used a spindle coupled six-component axle meter[6] and a steering wheel meter as the detecting devices

Table 1: Specifications

	Direction :	Stroke,	Load, (Max.)	Frequency

in the simulation. We also have time-series data on the spindle force and the torque in four-wheel four directions (vertical,lateral,longi.,steer), and the steering angle during the on-road test as well as the data on the motions of the body. After the simulation, we can process the behavior of the suspension analyzed in the lab and the motions of the body during the on-road test in synchronization. Figure 3 is the flow chart of road simulation.

While the simulation is impossible without the on-road test at this moment, we will present a solution at the paragraph of Development of the Real-Time Simulator System (RTSS) in this paper.

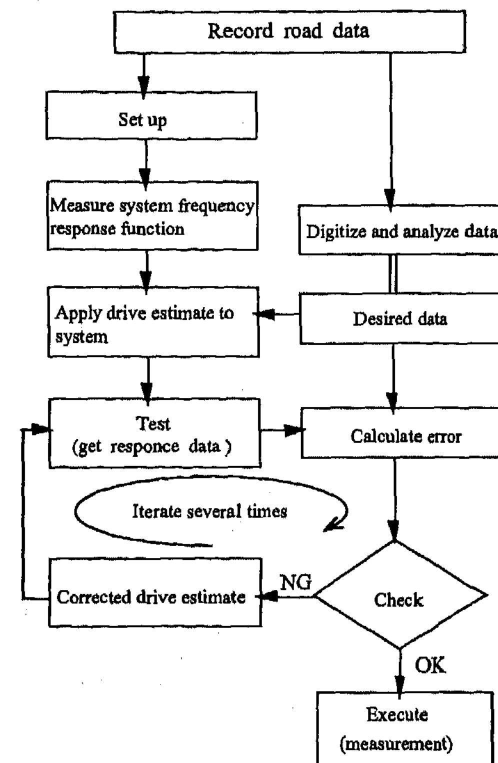

Figure 3: Flowchart of road simulation (RPC)

EXTENT OF ON-ROAD TEST SIMULATION - If the VDS is going to be used effectively as the handling performance analyzer, the system needs to simulate not only from the low turning G area to the critical turning high G area, but also from the low steering rate area to rapid steering area such as emergency avoidance driving.

Figure 4 compares six-component axle force data for the lane change in the low G area, the double lane change in the high G area and the braking in turn from the high turning G obtained in the road test and the simulation. When these data are collected, power steering is on, and the absorber temperature is controlled. In every case, the precision of the six-component axle force meter was good enough (so close that the VDS data overlaps) that, with the exception of braking force from critical turning, conditions could be simulated with an error no greater than 20N, relative to a force of 20kN with 0.1% non-straight-ahead movement.

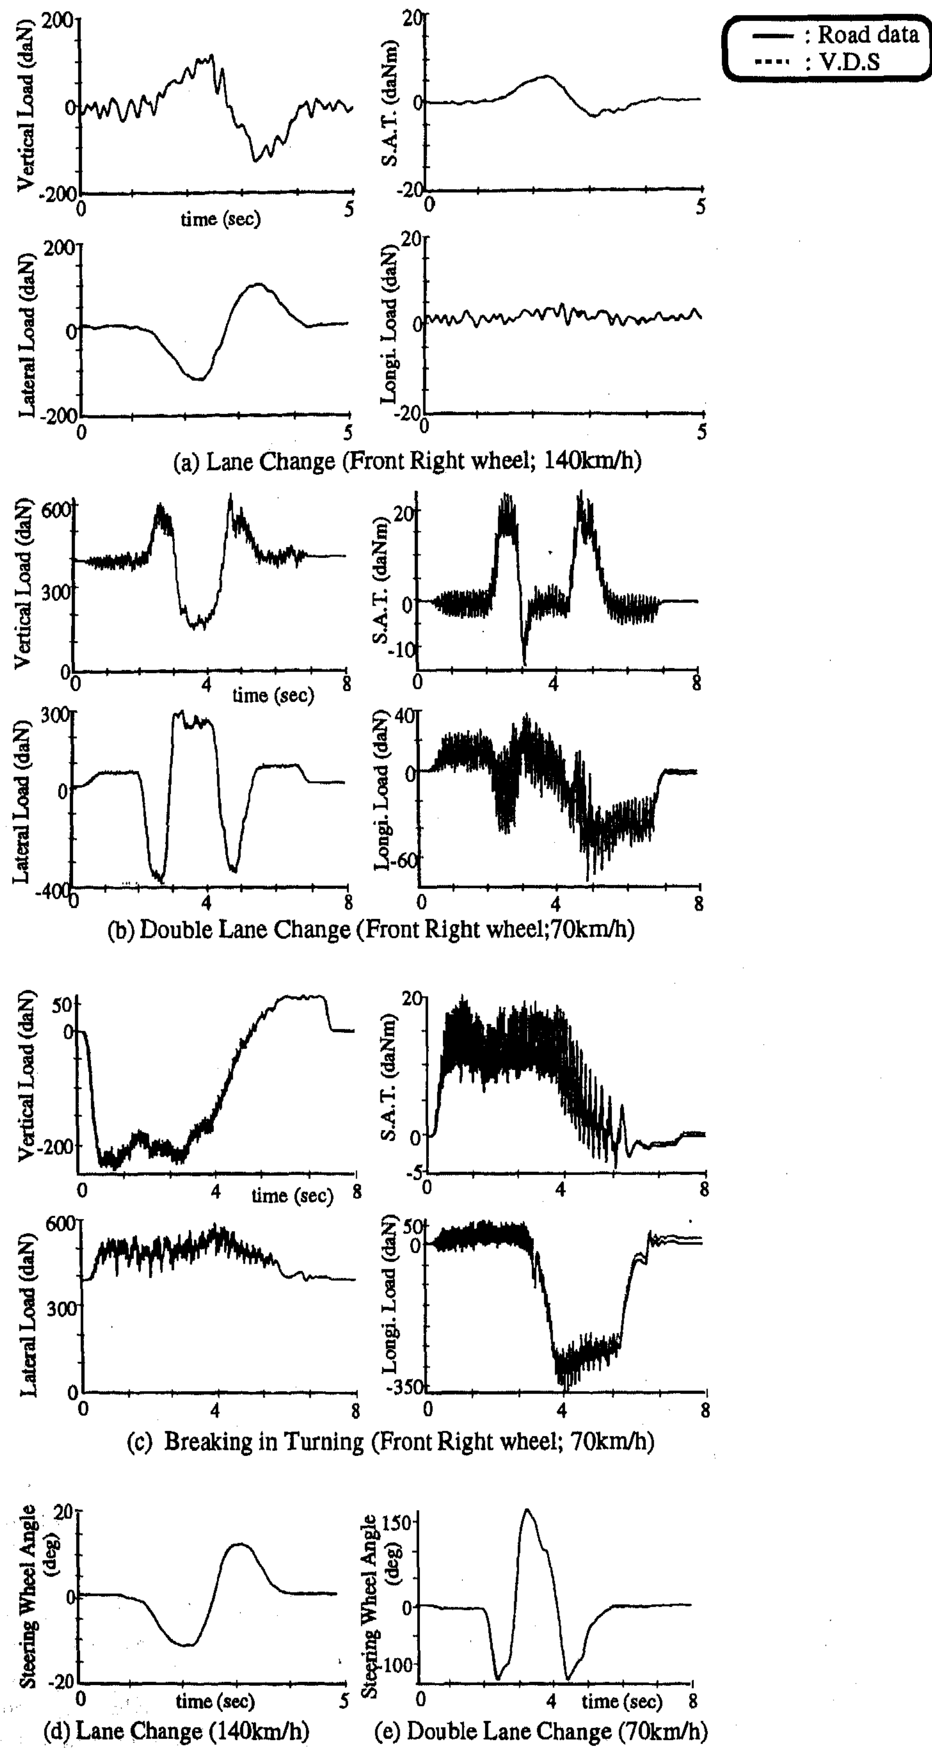

Figure 4: Spindle forces and steering angle repeatability

Table 2: RMS error on each channel

(Double Lane Change)

Channel			Ful scale ／10V	RMS error (%) [≦2%]
Front	left	vertical	2000daN	0.08%
		lateral	2000daN	0.12%
		longi.	2000daN	0.11%
		steer	100daNm	0.52%
	right	vertical	2000daN	0.13%
		lateral	2000daN	0.10%
		longi.	2000daN	0.10%
		steer	100daNm	0.67%
Rear	left	vertical	2000daN	0.05%
		lateral	2000daN	0.04%
		longi.	2000daN	0.03%
		steer	100daNm	0.17%
	right	vertical	2000daN	0.08%
		lateral	2000daN	0.06%
		longi.	2000daN	0.06%
		steer	100daNm	0.69%
Steeringwheel angle			540deg	0.19%

(DC~25Hz)

Table 2 shows the error in terms of RMS value which is the general indicator of the simulation performance of RPC. The fact that the error in the RMS value is less than 1% for every directional component during the double lane change shows that the simulation performance of the system is considered satisfactory. Similar results are obtained in other cases.

Thus, we have secured the simulation of the handling performance from the low turning G area to high turning G area and from the low steering rate area to the high steering rate area with the system, and are thus able to perform the analysis.

EXAMPLE OF APPLICATION

VALIDITY OF ON-ROAD TEST SIMULATION - It is extremely difficult to measure the behavior of the suspension and the force applied to the suspension for four wheels at the same time during the on-road test. A lab tester is required to have excellent simulation performance and repeatability. In our testing system, once we make the simulated excitation waveform, we can simulate the same behavior again and again with this waveform. We can simultaneously obtain a wide variety of data under a single driving condition by setting additional detection devices.

Since our testing system is equipped with the six-component meter on the tire-contacting surface (wheel-pan), the system is capable not only of measuring the displacement (four-wheel stroke, the displacement of the contact point, etc.), but also measuring the exchange of force on the contacting surface at the same time. Moreover, the system is capable of analyzing the pitch, roll, jounce and jack up during the on-road simulation with the body completely fixed by converting the vertical stroke of each wheel. The system also constantly measures the steer angle, the camber angle, and the steering wheel angle relative to the body, and also can easily measure the displacement of the suspension point and the localized body displacement whenever necessary. Figure 5 shows an example of measured behavior.

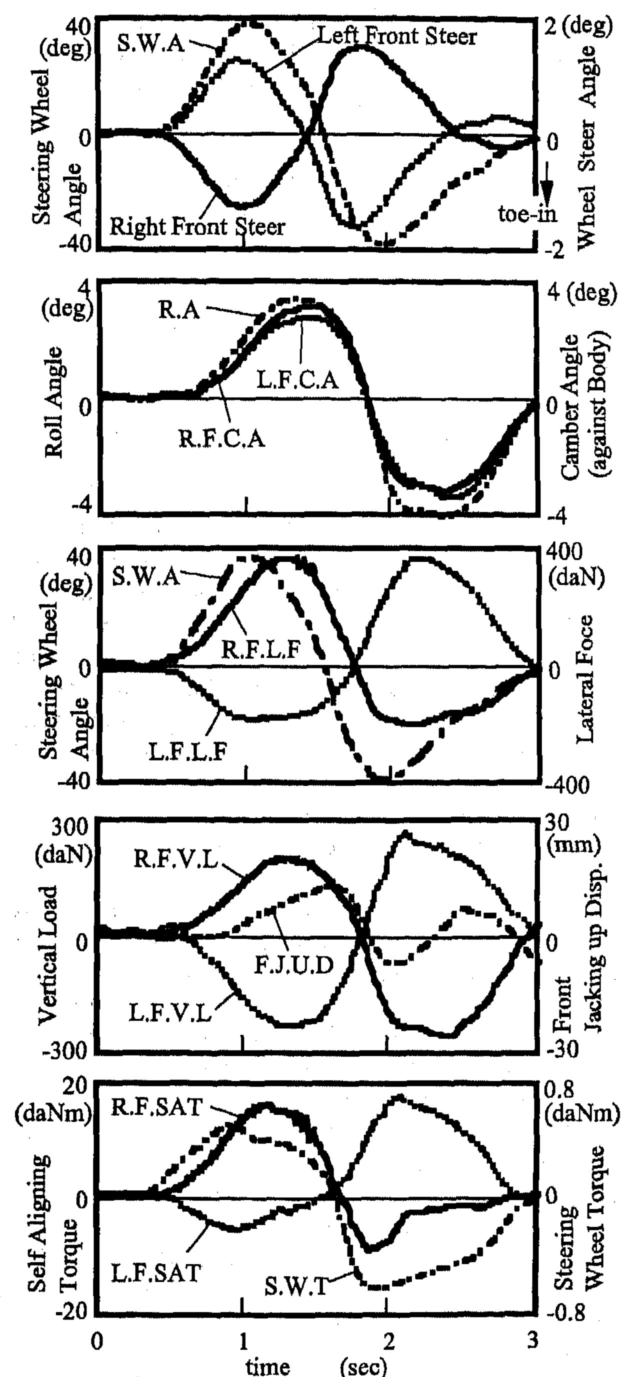

Figure 5: Example of measured results at lane change

Furthermore, the system is capable of synchronized processing of the above data and those data measured during the road test including the body slip angle and the yaw rate in order to determine the tire slip angle of each wheel.

IMPORTANCE OF ANALYSIS OF DYNAMIC COMPLIANCE COMPONENT - When designing a suspension, it is important to determine the geometry (roll steer, roll camber, roll center, etc.) and various compliance characteristics (lateral force steer, lateral force camber, etc.). However, there has been only a few published reports describing how these specifications actually exert an influence on the suspension and at what contribution rate and whether or not these specifications have an actual effect as designed at a specific moment of on-road test under a combination of circumstances (such as application of lateral or longitudinal force while rolling).

For analytical clarification of such contribution rate, we need not only measure the change in the steer angle, but also the motion of each suspension arm and bushing, vertical stroke and the input conditions in a synchronized manner. However, it is extremely difficult to break down the measured data on-road test into various compliance components.

With the ease of reverse input control provided by our testing system, we have developed a technique to clarify the contribution of a specific compliance component at a transient state on an actual vehicle.

DESCRIPTION OF ANALYSIS PROCEDURE - The body is totally fixed, and the on-road test simulation is conducted by inputting the actual running data and through RPC control. With this step, the force applied from the testing system to the contact surface of each tire is determined. On the basis of the waveform to be inputted to the contact surface, RPC control is carried out for example by preparing the simulated desire waveform at the Self Aligning Torque (SAT) of almost zero. Then, the same control is carried out by setting only the lateral force at zero. After conducting a series of simulation to break down the force applied to the contact surface, the control in which only the steering system is moved with the vertical stroke at zero is conducted. It should be noted that the vertical stroke is kept constant during the breakdown of surface force. Then, the data after each control is compared with the data obtained from the waveform simulating the original to check the ratio of each component. Figure 6 is the flow chart of the break down method.

Figure 7 is an example shown in terms of a change in the steer angle, and Figure 8 depicts the change in a schematic form. This diagram shows the results of a rather strong lane change (at 140km/h) of a vehicle with relatively good handling performance, indicating the steering angle, the change in the steer angle of the outer front wheel during the initial steering, and the change in the steer angle of the outer rear wheel.

Figure 7 (a) shows an example of breaking down the change in the steer angle of the outer front wheel in the

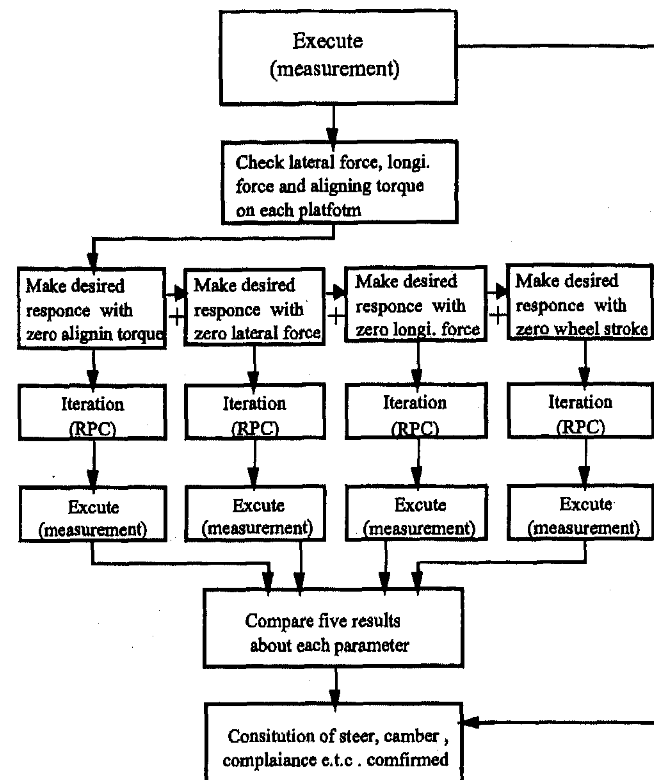

Figure 6: Flowchart of steer constitution analysis method

initial stage of turning into the roll steer component, the lateral force steer component and the SAT steer component. The α curve indicates the change in the steer during the on-road simulation based on the simulation of the original without inputting the torque in the SAT direction, and the increase in the steer angle (oversteer direction) is expressed as the SAT steer component. Likewise, the condition in which the lateral force is canceled is expressed as the lateral force steer component, and the change in the condition where the wheel stroke is canceled as the roll steer component. It goes without saying that the steering wheel angle is so controlled that the same input is made at a transient state in all cases.

Figure 7 (b) shows the case of the rear wheel turning. The same type of on-road simulation can achieve the breakdown analysis for the rear wheel. Such breakdown analysis of compliance components will help us understand the actual contribution of a specific feature of the suspension in a moving vehicle at a transient state, and examine the functioning of the feature in relation to the design target, and design the most suitable chassis system by understanding the characteristics of a vehicle with excellent performance.

EXAMPLE OF ANALYSIS RESULTS AND DISCUSSION - Figure 9 shows the breakdown data obtained during the same lane change for Vehicle B which uses a different type of suspension for both front and rear

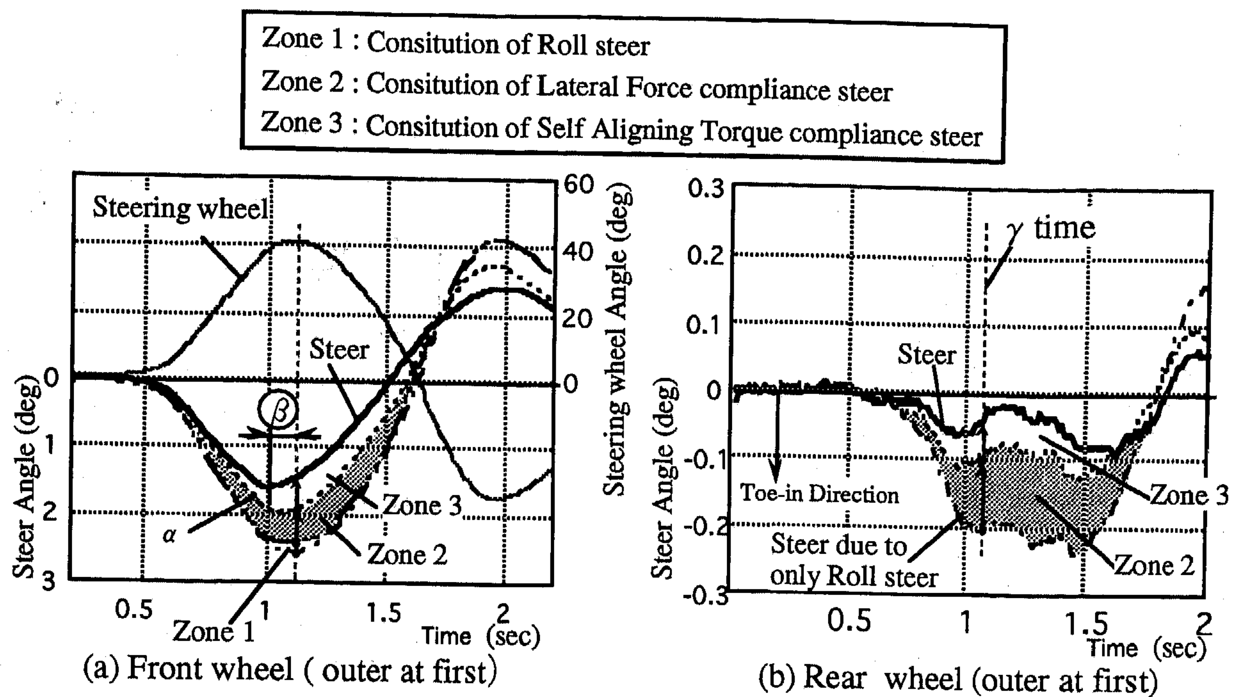

Figure 7: Analysis of steer angle constitution (vehicle A)

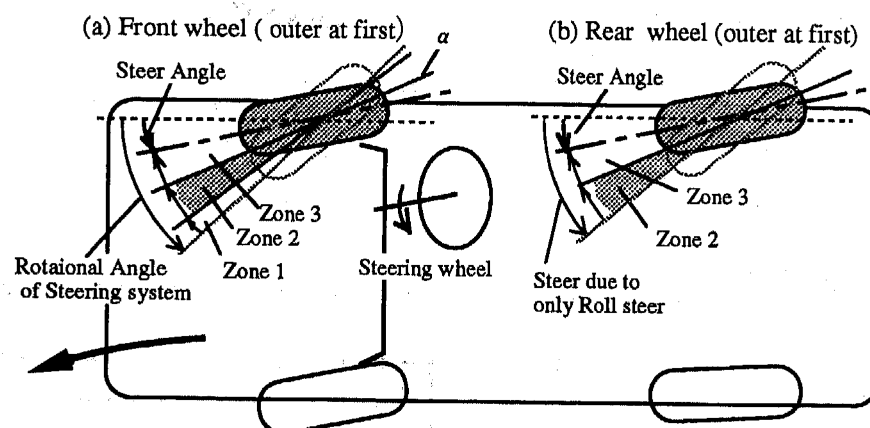

Figure 8: Steer angle constitution model

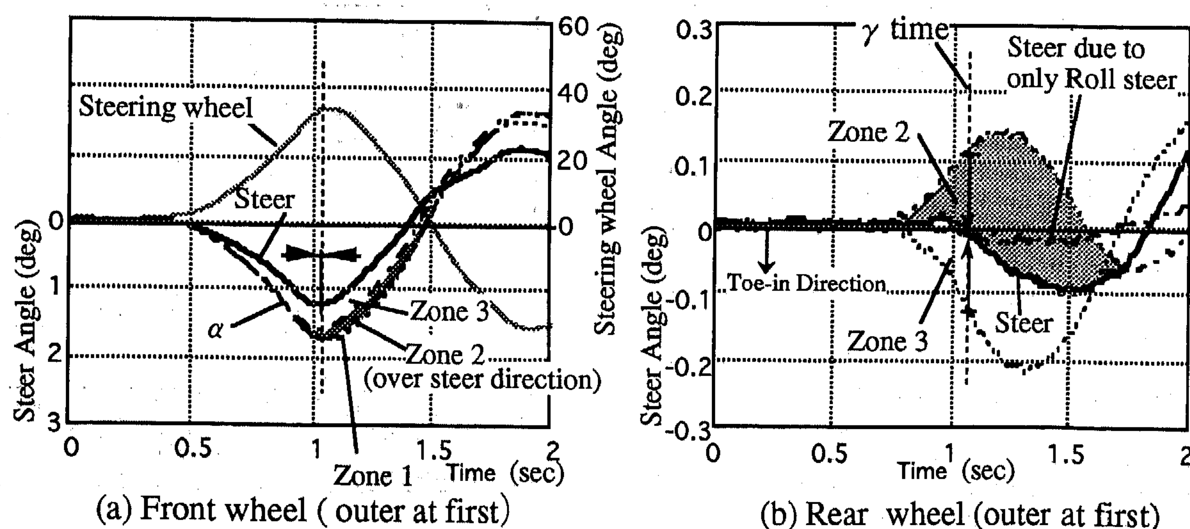

Figure 9: Analysis of steer angle constitution (vehicle B)

wheels. In front wheel, Vehicle B does not display the phase advance in the steer angle against the steering for Vehicle A shown in the section β in figure 7, indicating that the actual steer has lagged in appearance. Figure 10 shows the front wheel slip angle (as calculated from the body slip angle and the front wheel steer angle) of Vehicle A. A considerable lag in the body slip angle indicates that the front wheel slip angle has lagged behind the steering and that the phase advance in the steer angle is still insufficient. A greater lag is predicted for Vehicle B, showing its inferior controllability of the vehicle motion.

The phase lag is caused by the fact that Vehicle B has the SAT steer component as the main component while Vehicle A has the lateral force steer as the main component. Figure 11 shows generation of lateral force and SAT on the front wheel. Since SAT decreases when the tire slip angle is around 3 degrees, the peak of the SAT steer component appears to be advanced relative to the lateral force. Therefore, wherever the SAT steer component is the main component, the steer angle appears to increase (and the steering wheel return component decreases) when the SAT decreases, and the resultant steer angle appears to have less phase advance relative to steering.

Figures 7 and 9(b) show the results of breakdown for the rear suspension. To make the matter simpler, figure 12 shows the steer component at a given moment γ (equivalent to the turning lateral acceleration = 4 m/s²) in a bar chart. In Vehicle A, the roll steer component is significantly large, indicating lateral force oversteer, but the torsional rigidity of SAT direction is relatively high and the SAT steer component is relatively small. In total, the characteristics in the understeer direction have been secured. In Vehicle B, the roll steer is almost neutral, but the lateral force causes understeer. Since the torsional rigidity is low, the SAT steer is significantly changing to the oversteer side. Overall, Vehicle B has secured near-neutral steer.

The results show that in order to improve the steer characteristics of Vehicle B, the lateral force understeer component needs to be increased for the front wheel, and the SAT oversteer caused by an increase in the torsional rigidity needs to be solved for the rear wheel.

ANALYSIS OF OTHER SUSPENSION SPECIFICATION - In addition to breakdown of steer angle components shown above, the testing system is capable of component breakdown for the change in the camber angle, and the contact point displacement (displacement of the vertical load center during a given time period) by making use of the characteristics of the contact surface control. Moreover, this system can perform various analyses other than the suspension characteristics analysis at a transient state. In order to verify the breakdown characteristics of each component shown above, our testing system makes use of the merit of reverse input control to make in-depth measurement of normal suspension characteristics (roll steer, lateral force steer, SAT directional rigidity, lateral force camber, longitudinal force steer, etc.) under a

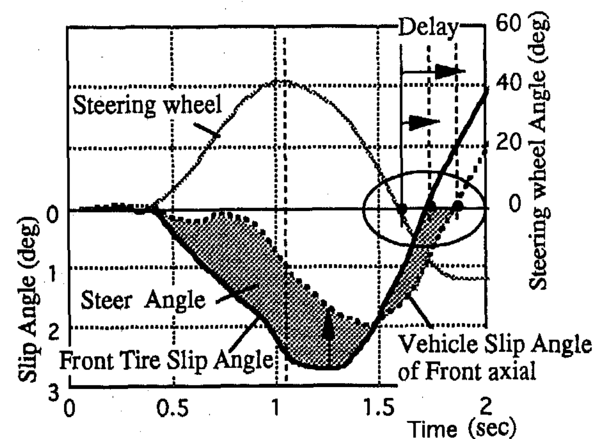

Figure 10: Front wheel slip angle

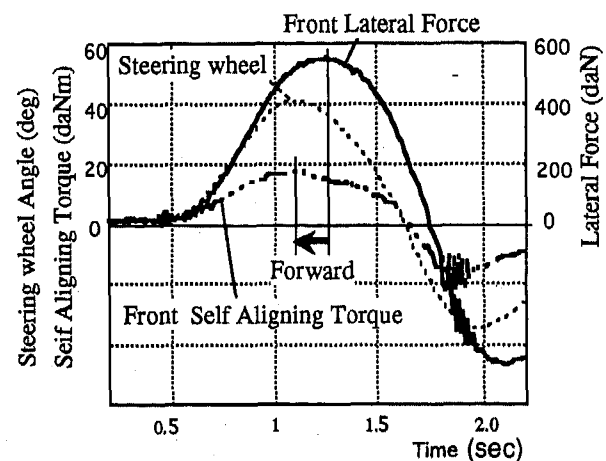

Figure 11: Front wheel lateral force and SAT

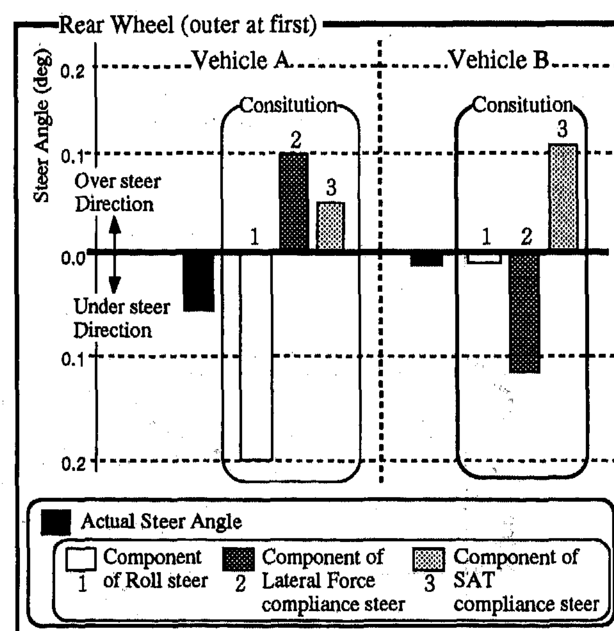

Figure 12: Component of rear wheel steer angle (γ time)

combination of inputs, and also measure above characteristics by making a dynamic input whenever necessary. Furthermore, the system dynamically determines the wheel rate to easily predict the damping force characteristics under the suspension assembly condition by the calculation from the wheel stroke rate, the vertical load and the wheel rate.

As described above, our testing system has made possible in-depth verification and feedback of the data on an actual vehicle at a transient state. By doing so, the system will contribute to improvement of the precision in the prediction of moment-by-moment performance during the design stage, and will help develop a new chassis with superior performance.

DEVELOPMENT OF THE REAL-TIME SIMULATION SYSTEM (RTSS)

We have developed the Real-Time Simulation System (RTSS) which evaluates and analyzes the motion of a vehicle within the framework of a laboratory. As described in the above paragraph of Road Simulation Method, both the on-road test and the lab testing are required in the on-road simulation using the VDS. This testing method achieves an extremely high level of precision in simulating the on-road conditions. Moreover, the system can easily measure the motion of each chassis component relative to the body, and analyze the relationship between the motion of the component and the handling performance in greater detail because the body is completely fixed.

On the other hand, the RTSS is intended for testing in the laboratory alone as in the case of an ordinary bench test, and thus it is capable of evaluation and analysis without on-road testing. This system also has the merit of accurately measuring the exchange of force on the tire-contacting surface because the body is fixed at the virtual gravitational point.

Real-time simulation [7][8] using the actual vehicle has been in use mostly for establishment of ABS and other control systems. We have applied the RTSS to the suspension (and part of the body motion) of an actual vehicle. In our opinion, the system is an effective tool for dynamic behavioral analysis of the chassis (component) motion.

SYSTEM CONFIGURATION - This system is consisted of two major components: one is the VDS and the other is the Real-Time Simulator (RTS). The RTS is a computer application designed to calculate the motion of a vehicle on the two-dimensional surface. Figure 13 shows the overall configuration.

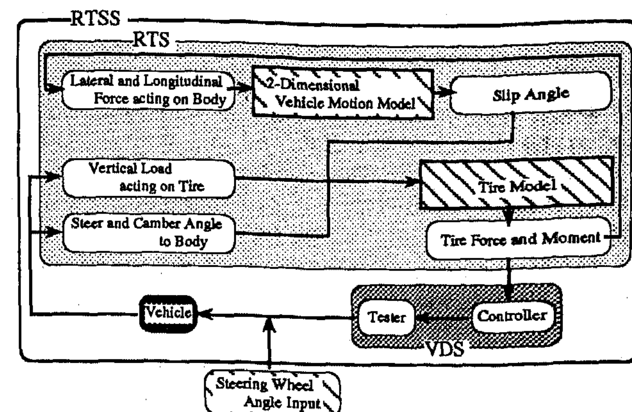

Figure 13: Structure of RTSS

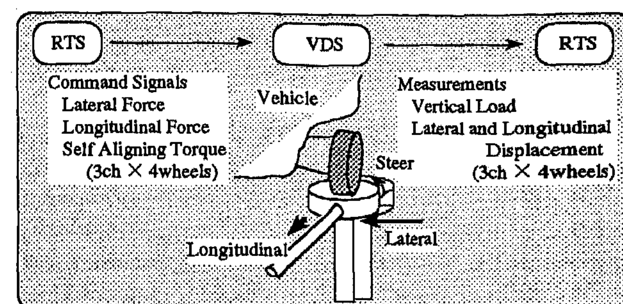

Figure 14: Function of VDS

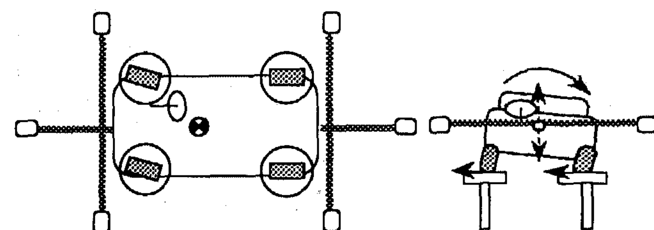

Figure 15: Method of body clamp

This system uses 13 out of 19 degrees of freedom (lateral, longitudinal and steer direction times four wheels plus steering angle) of VDS. The excitation machine is controlled by load control (and torque control). In other words, the excitation machine is so controlled that the load is applied to the vehicle as instructed by the RTS. (The excitation machine is controlled by detecting three components (lateral force, longitudinal force, steer directional torque) with the six-component meter built in each wheel-pan.) (figure 14) The body is fixed by fixing the virtual gravitational point of the vehicle with cables. In fixing the body, a longitudinal axis running through the gravitational point of the vehicle is postulated, and three pieces of cable are used respectively to fix the intersections of this axis and the front end of the body and the rear end of the body. In this method, the body is fixed in longitudinal, lateral and yaw directions, and is left movable in jounce, pitch and roll directions (figure 15). In other words, this system does not simulate the vehicle motion in the horizontal surface direction, but simulates other motions including vertical motion on the bench.

Three laser displacement gages are used for each wheel to measure the steer angle and the camber angle relative to the body. The data are sent to the RTS on a real-time basis, and used for calculation of tire force. A free gyroscope is used to measure the pitch angle and roll angle of the body relative to the ground. The data are sent to the RTS on a real-time basis and used for calculation of the camber angle relative to the ground.

The six-component meter built in the wheel-pan of each wheel is used to measure the vertical load. The measured data are sent to the RTS on a real-time basis, and used for calculation of the tire force (figures 14 and 15).

The stroke of the excitation machine outputted on the testing system side is inputted. The data are sent to the RTS on a real-time basis in terms of the tire-contacting point displacement (lateral and longitudinal) relative to the body (figures 14 and 15). With the testing system, the steering wheel can be turned according to the waveform (e.g. sine wave) intended by the operator. In our verification test, we have simulated the driver's steering waveform during the on-road test in the lab.

ALGORITHM AND MODEL - The RTS is a computer application designed for calculation of the motion of a vehicle on the horizontal surface from the motion of the suspension and the body on the testing system. The RTS has two main parts: one is the tire model and the other is the two-dimensional vehicle motion model. Figure 16 shows the functions of the RTS.

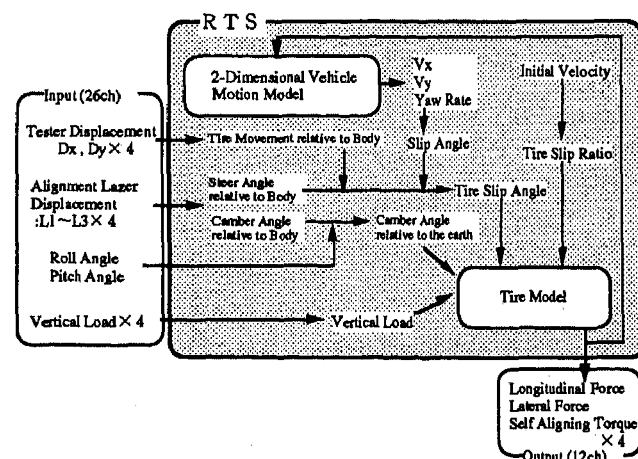

Figure 16: Function of RTS

The tire model used in the RTSS is based on the experimental data already obtained on the flat belt tire tester. The tire model is expressed in mapping of experimental data, and the gap between available data is interpolated. Figures 17 and 18 show the outline of the tire model. The motion of a vehicle on the horizontal surface is calculated from the longitudinal and lateral force generated by the tire. For this model, a number of basic vehicle specifications (empty vehicle weight, yaw moment of inertia, wheel base, etc.) need to be pre-measured. This model is outlined in figure 19.

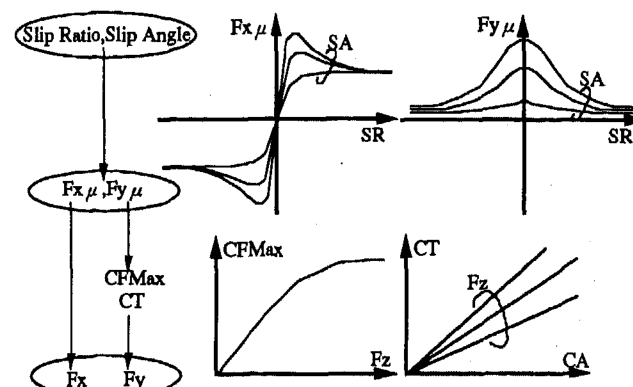

Figure 17: Tire model (lateral and longitudinal force)

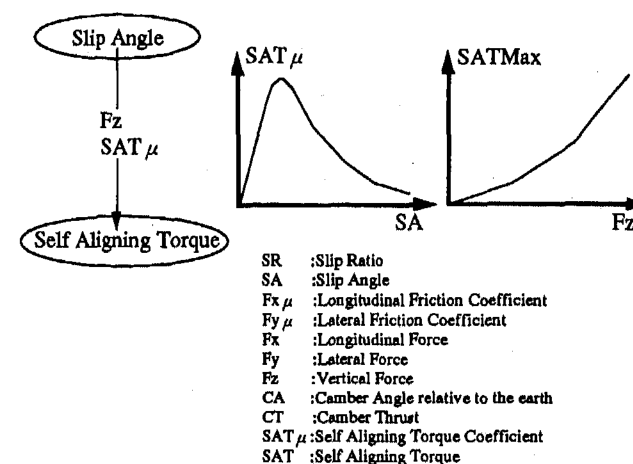

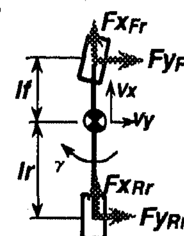

Figure 18: Tire model (SAT)

$$M\left(\frac{dVx}{dt} - Vy*\gamma\right) = Fx_{Fr} + Fx_{Rr} - Cd*Vx^2$$

$$M\left(\frac{dVy}{dt} + Vx*\gamma\right) = Fy_{Fr} + Fy_{Rr}$$

$$I\frac{d\gamma}{dt} = Fy_{Fr}*lf - Fy_{Rr}*lr$$

M :Weight
I :Yaw Inertia
lf / lr :Distance between C.G. and front/rear axle
Vx/Vy :Longitudinal/Lateral Velocity
γ :Yaw Rate
Fx / Fy :Longitudinal/Lateral Force

Figure 19: 2-Dimensional vehicle motion model

VERIFICATION TEST AND RESULTS - We have conducted a test to verify the on-road simulation performance of the RTSS. The running condition is the lane change at 140km/h. We have conducted the on-road test, and then the test using the RTSS in the lab under the same vehicle condition and the same steering input. During the on-road test, we have recorded the measurement at a proving ground. In the RTSS test, the calculated value from

the RTS is used for the motion on the horizontal surface, and all other items including vertical motion are measured in the lab. A picture of the RTSS testing a vehicle is shown in figure 20.

Figures 21 and 22 show a comparison of two-dimensional flat surface motion (Results of on-road test vs. Results of RTSS test calculation). In terms of flat-surface motion (yaw rate and lateral acceleration), the RTSS has simulated the on-road condition almost perfectly. However, the RTSS has not simulated the minor details since disturbance from the ground and any other matters is not taken into consideration in this test. The RTSS has perfectly simulated the steering angle during the on-road test since the steering wheel actuator has been set to simulate the steering during the on-road test.

The RTSS has closely simulated the on-road condition in terms of the motion of the vehicle in the lab (tire force in figure 23, roll angle in figure 24). However, a certain phase delay is found especially in the roll angle, which is caused by the delay in the load control system of the hydraulic excitation machine and the method of fixing the vehicle. Probably because of these factors, the actual vehicle part in the lab has shown the tendency to lag in its motion when we have attempted to simulate a quicker behavior.

However, such tendency can be sufficiently minimized by changing the setting of the load control gain of the excitation machine. There will not be a problem in evaluation and analysis which are the purposes of this system (although the system will have limited range of application).

CONCLUSION

(1) In order to analyze the handling performance of an automobile, we have developed the VDS which analyzes the characteristics of a suspension in a transient state in the lab. We have verified that this testing system is capable of simulating the behavior in the range from low turning G to critical turning G and the range from slow steering to rapid steering in the emergency accident avoidance.
(2) We have established a technique that makes possible breakdown of factors of suspension characteristics of an actual vehicle in a transient state which has been considered difficult. For example, we have shown that the system is capable of clearly indicating the contribution of various steer angle components in a transient state.
(3) Since above steer components (lateral force steer component, SAT steer component,e.t.c.) have different phases in a transient state, we have made use of the difference in characteristics and verified that we can use the system to achieve optimum design of a suspension with excellent stability and controllability.
(4) We have shown that this system is a general-purpose system capable of measuring both static and dynamic specifications at once.
(5) We have developed the RTSS which uses the actual suspension and body of a vehicle and verified that RTSS is capable of simulating the dynamic vehicle motion by the lab test alone. The test with RTSS has the following merits:

- Ease of dynamic measurement of behavior and input load of each chassis component
- The tire model may be modified so that the system can be used for simulation of behavior under various tire and road conditions.

Finally, we would like to thank the people of MTS Systems Corp., MTS Japan Ltd., Toyota Macs Corp., Toyooki Kogyo Co., Ltd., Yokogawa System Engineering Corp., and Fujitsu Ltd. for their generous cooperation in our efforts to introduce this new testing system.

ITT Automotive Europe GmbH

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper describes the contribution of simulation to the development of the new Automotive Stability Management System (ASMS) of ITT. The benefits and limitations of simulation especially with respect to experimental testing with prototype vehicles are discussed. The paper will outline how cost and time to market have been reduced by Off-Line Simulation (OLS) and Real-Time Simulation (RTS). During the development of ASMS, new control algorithms were designed and first validated in the laboratory. Simulation has offered an insight into the vehicle dynamics that is difficult to obtain with prototype vehicles. It has been possible to study the interactions of the vehicle control system and vehicle dynamics under all circumstances. Some simulation examples of typical maneuvers are discussed.

INTRODUCTION

At the end of 1997 the new Automotive Stability Management System of ITT will be available on the market. ASMS combines the well known Anti-Lock Brake System (ABS) and Traction Control System (TCS) with a new Active Yaw Control (AYC) to a comprehensive vehicle safety system. ASMS assists the driver and enhances the vehicle stability under all kinds of driving conditions. In addition to conventional ABS/TCS, the steering wheel angle, yaw rate, lateral acceleration, and master cylinder pressure of the vehicle are measured. AYC monitors the yaw and side slip reaction of the vehicle to driver steering inputs. If the vehicle tends to instability, AYC automatically initiates wheel individual brake intervention. Thus, the driver is able to handle the vehicle safely if the vehicle approaches the limits of lateral stability. The principle effect of ASMS is shown in figure 1. In case of undesired oversteering or understeering, the AYC module of ASMS calculates a compensating yaw torque. ASMS generates this yaw torque by applying brake forces (F_B in figure 1) at the appropriate wheels.

The development of the new vehicle control systems ASMS demands detailed information about vehicle dynamics. This information can be obtained either from testing with a prototype vehicle or from theoretical calculations based on computer simulations. Both methods have particular advantages and disadvantages.

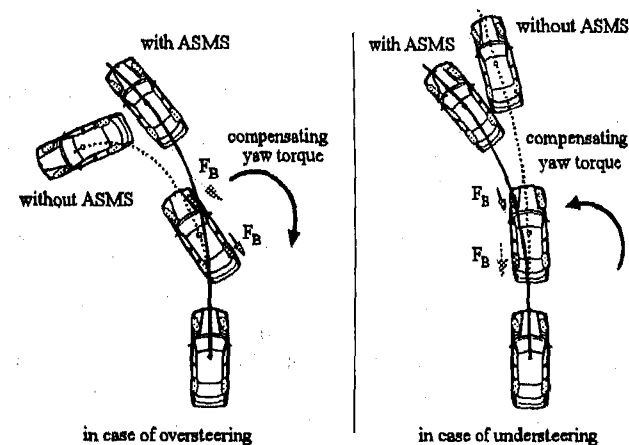

Figure 1: ASMS in case of oversteering and understeering

Testing is time consuming and requires high technical expenditure of vehicles, measurement equipment, testing areas and staff for support and maintenance. Extreme or hazardous maneuvers are difficult to realize and experimental results are not exactly reproducible. However, only experimenting can give final evidence of the functionality of a vehicle control system.

Simulation, on the other hand, can relieve vehicle prototype testing from time consuming work. It enables continuous development in the laboratory and shortens the development process of a new vehicle control system. During the design of algorithms, non-effective strategies are eliminated at an early stage. Basic test procedures are executed automatically. Maneuvers, external influences and failures can be reproduced exactly to compare and evaluate algorithms. The development of the series code can be supported by Real-Time Simulators [1], which combine the controller hardware and software with simulation models of the vehicle and its components.

However, simulation always needs a close relation to vehicle prototype testing. To achieve reliable simulation results, the models have to be verified based on measured data from vehicle testing. The more sophisticated the modeling, the more

parameters have to be provided and adapted to different vehicles. Some parameters can be directly measured at the prototype vehicle or identified from experimental data, for the others construction data from the automobile manufacturers is necessary. This requires close cooperation with customers.

The paper shows how simulation techniques have been used to reduce development time and costs of ASMS. In the following chapter an overview of the simulation tools is given and the modeling techniques for the different components of the control loop are briefly discussed. Afterwards a variety of simulation examples will be presented in detail to demonstrate the functionality of ASMS and to show the contribution of simulation in the development process. Special attention will be paid to maneuvers and external influences on the vehicle dynamics, which are difficult to generate in vehicle tests. Finally, an outlook on future use of simulation techniques in the development of vehicle control systems at ITT will be given.

SIMULATION TOOLS

According to the aim of a simulation study the complexity of modeling and an appropriate simulation tool have to be chosen. Principally, Off-Line Simulation (OLS) and Real-Time Simulation (RTS) are distinguished.

OFF-LINE SIMULATION - In OLS all components are modeled mathematically and represented as software modules. The simulations are run on workstations. The complexity of the models is not limited by real time constraints. With the help of Mechanical-System-Simulation (MSS) tools like ADAMS* the 3D-multi-body-dynamics of a vehicle are represented in detail with a high number of degrees of freedom. The interactions of the vehicle control system and the vehicle dynamics in extreme situations are evaluated. Thus, OLS offers the possibility to analyze 3D-maneuvers which are difficult to realize and reproduce in experiments. Furthermore, internal values are available in OLS, which can not be measured in experiments. In addition to MSS other tools like e.g. Xmath/SystemBuild** are used which support controller design and offer mathematical methods for system analysis and graphical modeling techniques. The postprocessing of simulation results is partially automated. After modifications in the controller software a variety of standard maneuvers are automatically simulated and evaluated to verify basic functionalities of the code.

REAL-TIME SIMULATION - In RTS the ABS, ABS/TCS or ASMS controller is integrated as hardware-in-the-loop. The code runs on the series controller and interacts with the Real-Time Simulator. The hardware of the RTS is a compact and portable device based on a 19" rack, which only needs a standard PC for downloading of the simulation models and parameters as well as for user interactions and disk control. With about $25.000 it is less cost-intensive than workstations running a real-time-OS (e.g. VxWorks). Until today 40 RTS-systems were built up. So, almost each software development engineer has access to such a system and can simulate maneuvers. This ensures short development time and relieves the test department.

MODEL DESIGN - The decisive task of each simulation model is an accurate representation of system dynamics. Furthermore high flexibility and low maintenance costs are advantages of efficient simulation tools. Therefore OLS and RTS environment are structured into the following basic modules:

- vehicle dynamics,
- powertrain,
- tire / road,
- track,
- driver,
- hydraulic unit
- and electronic controller.

Each of the simulation modules have a well defined interface and can be adapted to the specific demands of different examination goals. The combination of these basic modules to an overall simulation environment is shown in figure 2.

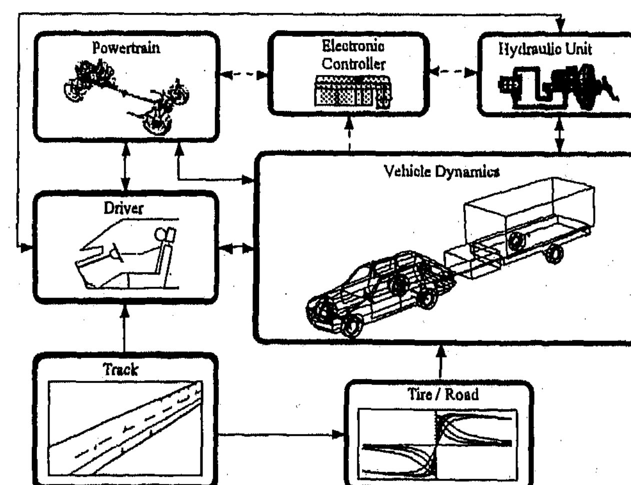

Figure 2: Structure of the simulation environment

The functionality of the modules is briefly described below.

Vehicle Dynamics - Depending on the basic effects which have to be regarded by means of simulation, an appropriate set of differential equations has to be chosen to describe the vehicle dynamics. This equation set determines the number of degrees of freedom of the vehicle model and the complexity of motion representation.

* ADAMS is a trademark of Mechanical Dynamics Inc.

** Xmath and SystemBuild are trademarks of Integrated System Inc.

Simple driving maneuvers on a plane road require at least two translational degrees of freedom in x and y direction and three rotary degrees of freedom in *yaw*, *pitch* and *roll* direction for the vehicle, while the movement in z-direction can be neglected. At the moment, RTS calculates e.g. movements in z-direction only for the sprung rigid car body, and not for the unsprung wheels. This model simplification is necessary due to the limited calculation performance of the processing unit (six T805 transputers) and with respect to real-time constrains.

More complex driving maneuvers which explain the dynamic behavior of a vehicle with respect to downward and sideward inclinations of a road require a full 3D-vehicle model with six degrees of freedom for the vehicle body and additional degrees of freedom for the dynamics of the suspension. ADAMS vehicle models e.g. passenger cars, off-road vehicles or light trucks include among 60 to 70 degrees of freedom.

Furthermore the examination of particular influences like coupling between a vehicle and a trailer demands more sophisticated sets of differential equations. Car / trailer combinations with one or two trailer axles and an overrunning brake contain 40 to 50 parts and have approximately 80 degrees of freedom.

The use of C-coded vehicle dynamics modules or ADAMS descriptions depend on scope of examination.

Powertrain - Especially for examinations in the context of traction control the description of the powertrain becomes an important part of the simulation environment. This module takes into account interdependencies between engine torque, rotational speed, throttle flap angle and interventions of the engine management like fuel cut off or spark retard as well as stiffness and damping of cardan and joint shafts.

Furthermore different drive concepts like front, rear and four wheel drive can be selected. All drive concepts allow an adequate consideration of differential gear locking torques.

Depending on the examination target the dynamic behavior of the powertrain is described with the help of C-coded modules or by means of ADAMS.

Tire / Road - The tire/road module describes the forces and torques which are generated by the interaction between road surface and tire. For simulation of ABS, TCS and ASMS maneuvers

- a modification of the HSRI-tire model which was developed by Dugoff, Fancher and Segel [2] and
- the MAGIC-FORMULA-tire model which was developed by Pacejka [3]

is used. Both tire/road models are described in C-coded modules.

Track - One of the essential advantages of simulation is the simple and repeatable definition of sophisticated environmental constrains. Therefore not only straight line and steady state cornering are offered but also any combination of bit by bit defined straight line parts and bends [4]. Furthermore special maneuvers (e.g. SAE lane change) can be chosen. The up-/downward inclination as well as the sideward inclination of a road can be defined freely. Examples for the possibilities of track definition are illustrated in figure 3 and 4.

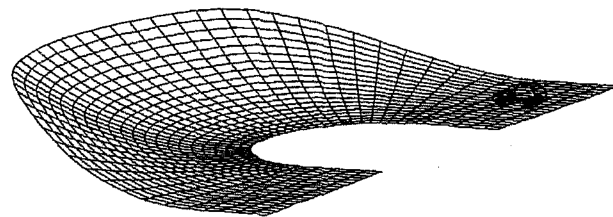

Figure 3: Definition of a banked curve

Figure 3 shows the graphical description of a banked curve which represents a combination of two straight line parts and a semicircle. The sideward inclination of the bank curve can be varied in the open interval $]-\pi/2, \pi/2[$.

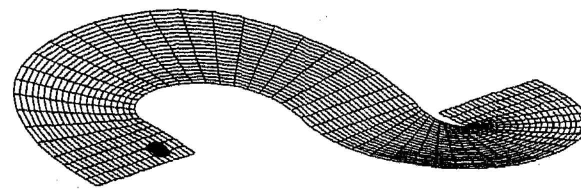

Figure 4: Definition of a serpentine

To simulate the influences of up-/downhill driving, straight lines and bends can be joined together as in figure 4. Here three straight line parts and two semicircles are combined with a downhill inclination. Furthermore a small sideward inclination in both bends is defined.

For the examination of effects of unevenness on the road different kinds of periodic waviness functions can be superimposed to the basic geometry of the road. An example of a sine function with a positive amplitude on the right half of the lane and a negative amplitude on the rest of the road is shown in figure 5.

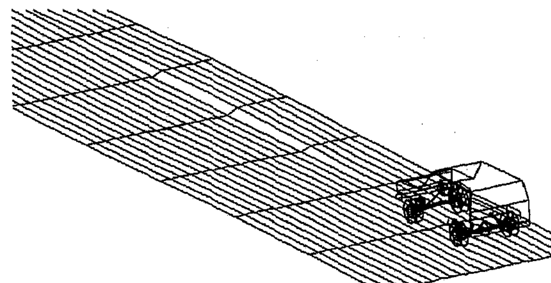

Figure 5: Definition of unevenness on the road

In addition to the geometrical description of the road in 3D, friction coefficients can be assigned to the road surface or parts of it. Therefore the road surface can be split into different parts while each part represents a special tire/road combination. The μ-split hill road in figure 6 is defined with the help of two parts, one part for the low-μ side and one part for the high-μ side.

All track models are described in C-coded modules.

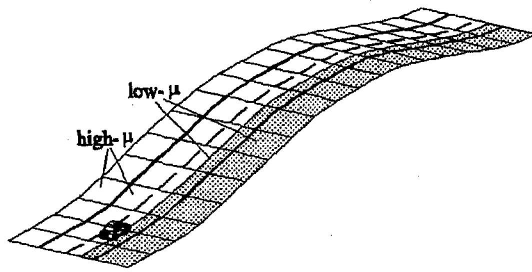

Figure 6: Definitions of road properties

Driver - In the driver module all inputs for vehicle handling are generated. The driver module is able to carry out

- open loop maneuvers and
- closed loop maneuvers.

In case of open loop maneuvers a sequence of time or distance depending actions are predefined and passed to the vehicle actuators. The throttle flap, the clutch, the gear box and the brakes are operated in a repeatable way.

On the other hand closed loop maneuvers like track following, driving with constant velocity or acceleration can be obtained by means of C-coded driver modules.

Hydraulic Unit - In the development of ABS, ABS/TCS and ASMS controllers the hydraulic unit takes an important part. Therefore the differential equations for representing brake fluid behavior are described.

Different configurations like e.g. front/rear or diagonal split hydraulic units with special kinds of pumps and valve arrangements are provided.

The hydraulic unit is normally described by means of C-coded modules but in the case of RTS applications a hydraulic hardware can also be used.

Electronic Controller - All kinds of ABS, ABS/TCS and ASMS controllers can be integrated in the simulation environment. RTS includes hardware controllers while OLS uses the software codes of the control algorithms.

ASMS-SIMULATION

The simulation tools described above have been used to support the development of ASMS. To achieve reliable results the simulation models were verified based on vehicle test data.

VERIFICATION - Measured input signals of test maneuvers can be used as input signals for the simulation. Thus, a direct verification of the models by comparison of simulation and test results is possible. Since ASMS especially affects the yaw response of the vehicle to steering inputs, special attention has to be paid to the reliability of the model of the lateral vehicle dynamics. In figure 7 the measured yaw rate and the lateral acceleration of a testing maneuver and a simulation are compared to verify the vehicle model. During the maneuver the velocity was kept constant. The maneuver was carried out without ASMS.

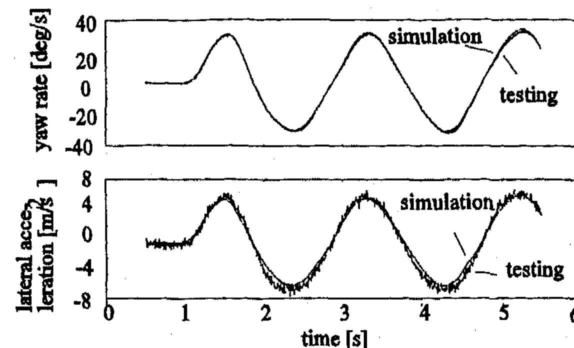

Figure 7: Comparison of testing and simulation

DESIGN OF THE AYC ALGORITHM - The initial idea of an active yaw control was first validated by various Off-Line Simulations. After finding a promising algorithm it was implemented on a prototype controller in a test vehicle which was equipped with the required sensors and an experimental hydraulics system. The development of the AYC algorithm has then been carried out in a parallel procedure both in simulation and vehicle testing. Figure 8 shows the principle structure of the AYC algorithm. AYC includes an internal reference model, that permanently calculates the desired stable reaction of the vehicle to the steering input of the driver. If the deviation between the stable behavior of the reference model and the measured reaction of the vehicle exceeds certain thresholds, a tendency to instability is assumed and AYC stabilizes the lateral dynamics by wheel individual brake intervention which is superimposed to driver braking. The AYC intervention is coordinated with the ABS/TCS functionality.

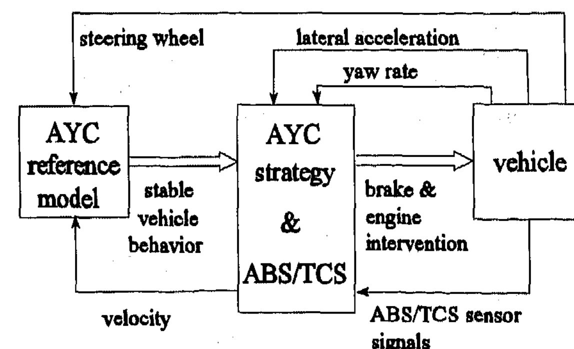

Figure 8: AYC algorithm

Parametrization of the AYC reference model - The parameters of the reference model have to be adapted to the particular type of vehicle to achieve optimal functionality and performance. The design of the reference model is a compromise between two objectives. On the one hand, an accurate representation of the vehicle is required to obtain smooth brake intervention and to prevent undesired reactions. On the other hand, the complexity of the model is limited by the real time constraints of the series micro controller. Some parameters as e.g. the mass of the vehicle can directly be measured. Others are determined in a partially automated procedure in OLS with the optimization function of Xmath as illustrated in figure 9.

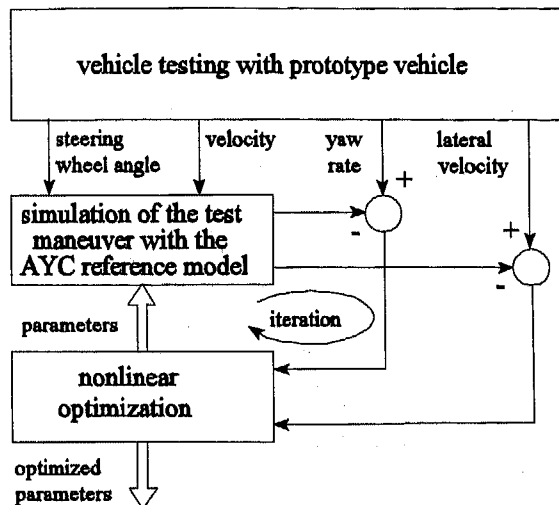

Figure 9: Parameter identification of AYC reference model

The procedure is based on data, that has to be gained from testing with prototype vehicles. A special set of maneuvers is carried out with the prototype vehicle. The maneuvers represent the desired stable behavior of the vehicle over the relevant range of velocity. During each maneuver, the steering wheel input and the velocity as well as the resulting yaw rate and lateral velocity are recorded. In the OLS the steering wheel angle and the velocity are then used to simulate the test maneuver with the AYC reference model and an initial set of parameters. The yaw rate, side slip angle, and lateral velocity are compared with the measured data from vehicle prototype. The result is combined to a quality value that shows how good the reference model fits the real maneuver with the given set of parameters. The nonlinear optimization function modifies the model parameters until an optimal fit is found.

Functionality of the AYC algorithm - The original ASMS control algorithm, as it runs on the series micro controller, was transferred to the workstation on which the OLS is carried out. The functionality of the AYC component of ASMS shall be demonstrated now with a SAE lane change on a snow surface that was executeded out in OLS. Figure 10 illustrates the course of the vehicle with and without ASMS.

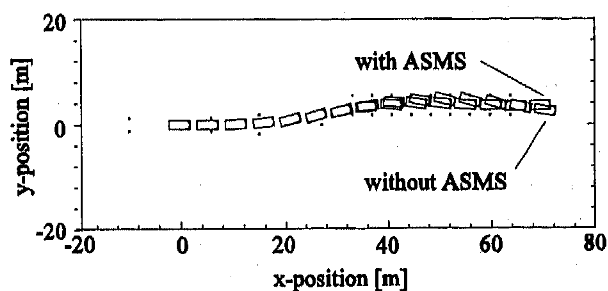

Figure 10: Vehicle course

The vehicle contour is marked in time steps of 0.333 s. The vehicle has an initial velocity of 16 m/s. The driver model of the OLS just tries to follow the course without braking the vehicle. The clutch is open. The brake pressures are plotted in figure 11. After about 1 s, AYC brakes the right front wheel. After about 2.3 s time when the vehicle has reached the left lane, there is a brake intervention at the left front wheel. There are also brake interventions at the rear axle but the level is much lower. With AYC the vehicle can execute the lane change without problems. Without AYC the driver model is not able to stabilize the vehicle in the left lane. The vehicle hits the pylons.

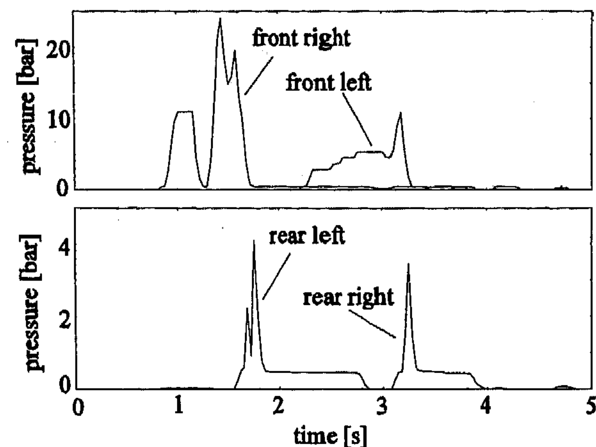

Figure 11: Wheel brake pressures

Figure 12 compares the steering wheel angle, velocity, yaw rate, side slip angle and lateral acceleration with and without ASMS. AYC reduces the steering work that is necessary for the lane change. When the vehicle with ASMS has reached the left lane, the yaw motion and the lateral acceleration are balanced much earlier. The side slip angle is significantly reduced.

Apart from the plots presented here, OLS provides all relevant internal signals of ASMS for an analysis of the functionality of ASMS. Furthermore all states of the vehicle dynamics are available and can be interpreted. To enable an efficient evaluation of the huge amount of data the post processing is automated up to a certain degree. 3D-animations of the maneuver and a standard set of plots can be generated. Different maneuvers can directly be compared with each other or with measurements from vehicle prototype testing. The data is stored in a format that allows an easy exchange between the simulation tools. Thus, a more sophisticated evaluation of results e.g. with numerical methods as they are offered by tools like Xmath is possible. For parameter studies maneuvers can be executed automatically in a loop in batch mode. Characterizing values can be extracted and displayed automatically to show the impact of parameter modifications on the functionality of ASMS.

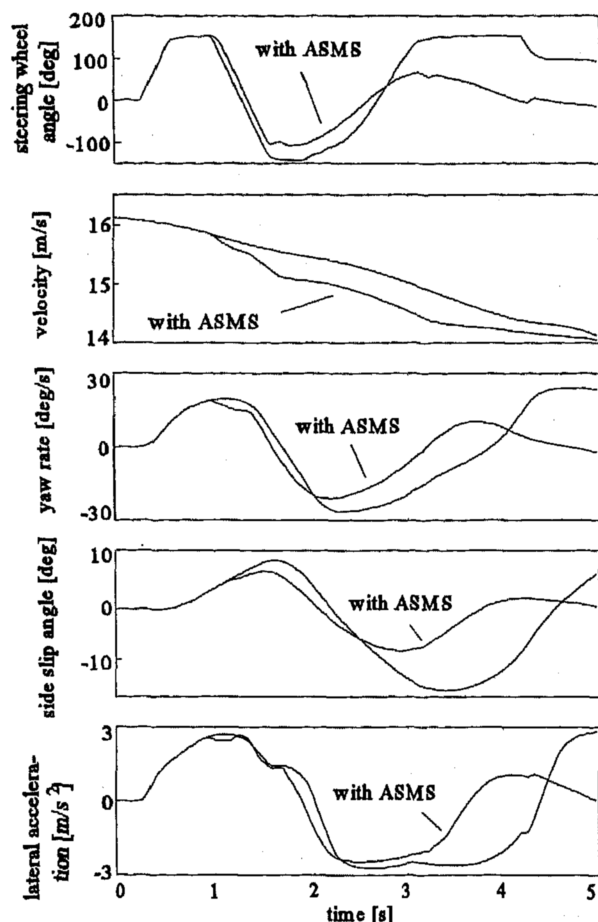

Figure 12: Vehicle states

DEVELOPMENT OF SERIES CODE - After the design of AYC and the decision for a definite algorithm it was necessary to code and integrate the algorithm in a prototype hardware environment. From this point the Real-Time Simulation has taken up an important part at code development because real hardware components (e.g. valve-, pump- and on/off-booster-dummies) are needed. Therefore the I/O-system of the RTS has to be flexible enough to grow with new hardware requirements of the ASMS controller from prototype up to series, that means an extension of the system and a configuration by software has to be possible. Figure 14 shows the basic structure of the RTS environment. We use a 16 bit SMP-bus (from Siemens) controlled by a T805-transputer as master and piggy-back-modules placed on a motherboard, which is equipped with a T225. This transputer works as Communication Interpreter for either a CAN- (Controller Area Network) or SCP- (Standard Corporate Protocol) Communication Controller and controls the transmission and the receipt of messages via the serial communication line. A typical application of field buses in simulation is the transmission of data for engine management and sensor signals e.g. the steering wheel angle. In the RTS different automotive manufacturer-specific communication protocols are implemented and can be selected by the user.

Via the protocol interface, which is a simple unidirectional parallel connection, internal values of the controller are read by the RTS. These data are displayed synchronously to the simulation data. So, incoming and prepared sensor signals or internal values of the controller like the estimated pressure in the wheel brakes can be compared with the corresponding simulation data. Another way to acquire data from both - Real-Time Simulation and internal controller values - is to use the ITT Data Acquisition System (DAS).

By means of a measuring system (DAS-Box) the simulation and controller data are collected with a predefined period of time and sent to a PC if requested. The transmission of simulation values from the RTS to the DAS follows via a serial communication line. Since the test department records the driving maneuvers with the same acquisition system, results of simulated and real maneuvers can be directly compared and verified. The integration of the DAS in the RTS is shown in figure 13.

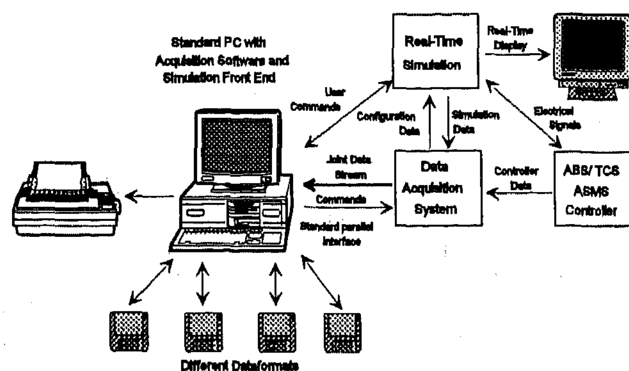

Figure 13: RTS with the ITT Data Acquisition System

Especially at the transition from prototype controller (floating point arithmetic) to series controller (integer arithmetic) and the integration in the existing ABS/TCS code, Real-Time Simulation was a very helpful tool to verify the fail-safe concept, that means electrical and physical range checking of sensor inputs, actuator outputs and the field bus communication. Before testing in the car the software engineers have the opportunity to check, if the modifications are correct and do not unintentionally influence other features of the software.

To ensure a simple use of the RTS, all parameters of the models and the hardware configuration settings for each controller are combined in projects. Furthermore, the simulation provides an appropriate set of standard maneuvers for such a project. With these maneuvers it is very easy to show whether the desired functionality and performance of the ABS, TCS or AYC is reached or not.

3D-COURSES - After describing the design of the AYC algorithm and the development of the series code with the help of RTS, the robustness of the resulting ASMS code under different external disturbances on the vehicle dynamics shall be discussed now. Such influences can e.g. be caused by non-plane driving courses like banked curves and serpentines. OLS offers the vehicle models and the 3D-courses to examine these effects. Due to real-time constraints, such simulations can not yet be carried out in RTS. In relation to experimental tests, OLS has the advantage that a large variety of banked

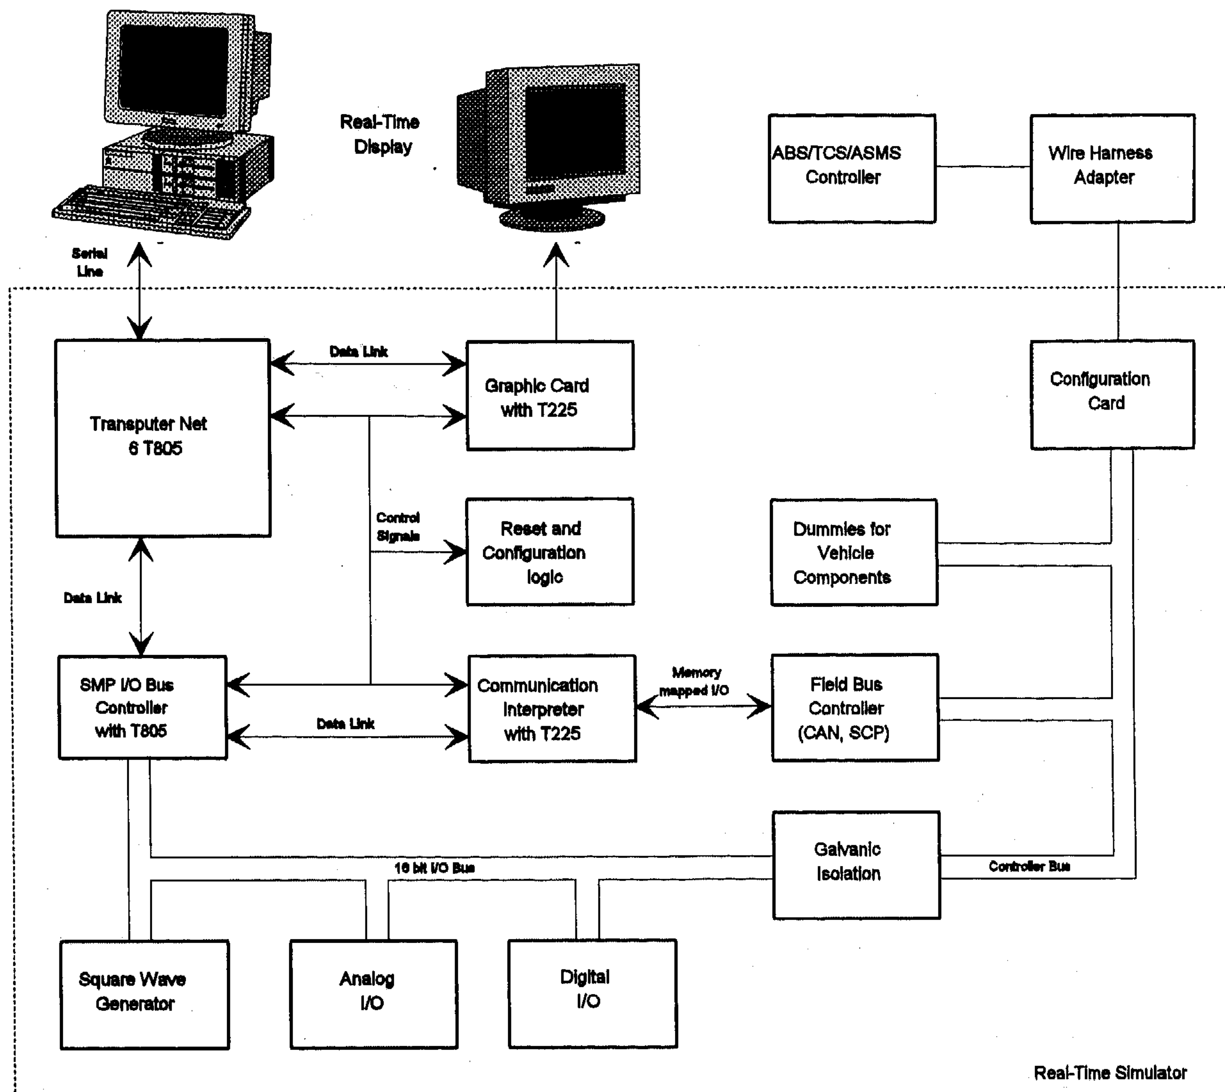

Figure 14: Block diagram of the Real-Time Simulation environment

curves or serpentine characteristics can be examined by simple parameter studies.

As a first example, some simulations shall be discussed that were carried out to study the impact of banked curves on the yaw behavior of a vehicle. Therefore a complex 3D-vehicle model described with the help of ADAMS is used to take 3D-motion effects into consideration.

Figure 15 illustrates the maneuvers. While the vehicle is driving in circle in a banked curve of constant inclination angle it is slowly accelerating to increase the yaw rate. The acceleration is low so that transient effects can be neglected. The driver module keeps the vehicle on a constant radius.

The ratio of the resulting yaw rate to the steering wheel angle as a function of the vehicle velocity is described at the top and the resulting vehicle acceleration at the bottom of figure 16. For a better comprehension of the maneuver dynamics the nominal ratio of yaw rate to the steering wheel angle of an appropriate parameterized linear one-track model is also plotted in the upper diagram.

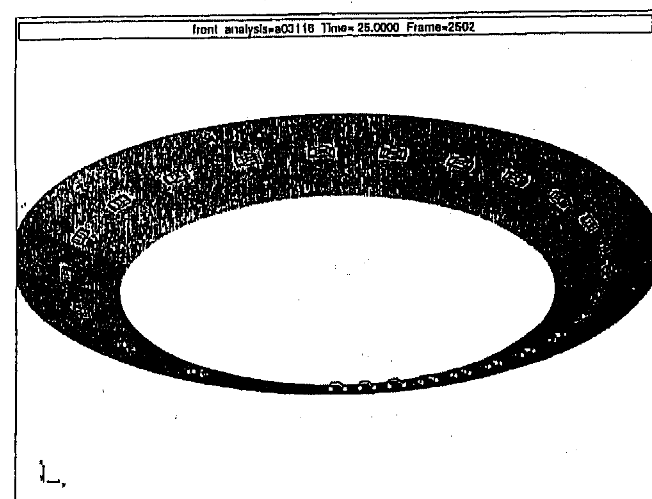

Figure 15: Closed loop driving maneuver in a banked curve

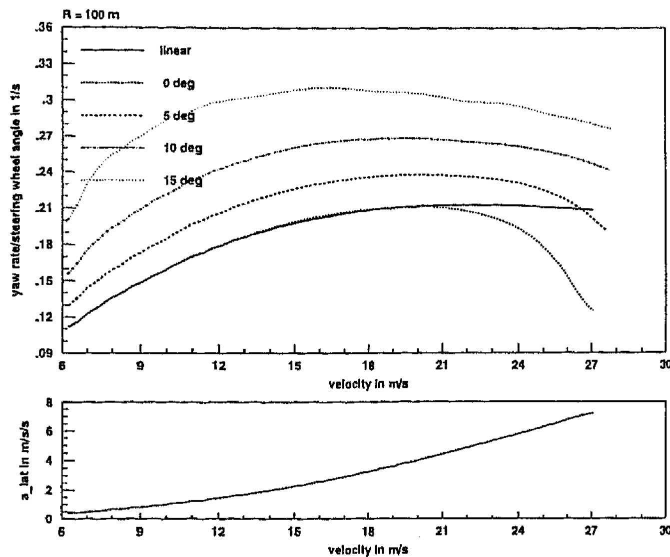

Figure 16: Oversteer/understeer behavior of a vehicle in a banked curve

Like it is expected, the yaw rate to steering wheel angle ratio of the linear one-track model and the simulated vehicle behavior on a banked curve with a 0 degree inclination are almost identical up to a lateral acceleration of 4 m/s². When lateral acceleration increases, a clear difference between the simulated vehicle dynamics and the linear single track model occurs which is caused by nonlinear behavior of the simulation model.

If there is a positive inclination of the road, the ratio of the resulting yaw rate to the steering wheel angle increases. That means that the same steady state yaw rate can be driven with less steering wheel angle. But on the other hand, this advantage of road inclination changes the dynamic behavior of a vehicle and may possibly cause undesired interventions of ASMS controllers if no adequate countermeasures would be integrated into the control algorithms. This is a typical example where OLS provides a deeper evaluation of control algorithms than driving tests can.

Another example to illustrate 3D-effects in the development of control algorithms is downhill driving on serpentines. Figure 17 shows a simple track-following maneuver on a snow-covered road with a rear driven vehicle. During this maneuver the driver runs into trouble caused by the drag torque of the engine. Here, the rear wheels increase their slip and the vehicle looses its stability. Normally an ordinary driver is not able to stabilize the vehicle by counter-steering.

The same maneuver with a rear driven vehicle which is equipped with ASMS is described in figure 18. In this case ASMS recognizes the tendency of instability and supports the driver with adequate countermeasures. This gives an ordinary driver the ability to follow the track easily.

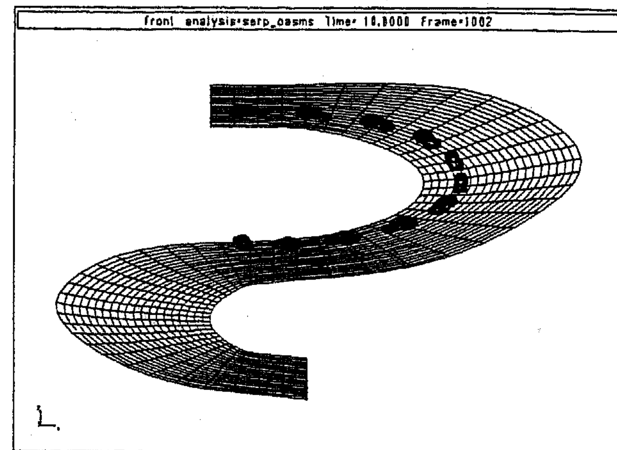

Figure 17: Closed loop driving maneuver on a serpentine without ASMS

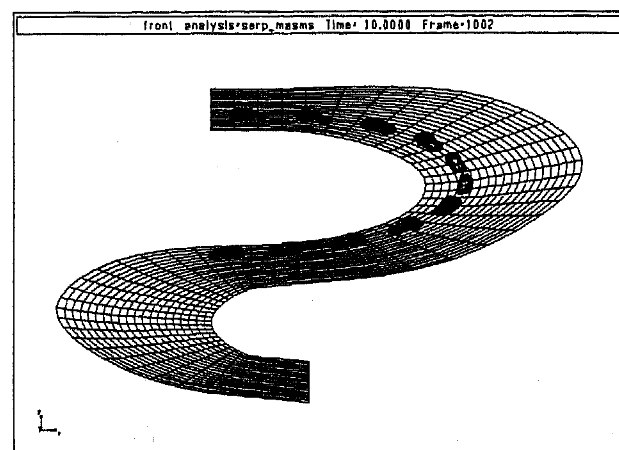

Figure 18: Closed loop driving maneuver on a serpentine with ASMS

CAR/TRAILER COMBINATION - In a similar way as it was described for 3D-courses, OLS offers the possibility to evaluate the robustness of ASMS for car/trailer combinations. Trailers cause additional forces on the vehicles so that the yaw torque around the vertical axis leads to undesired understeer/oversteer behavior. Tests with car/trailer combinations are hazardous for vehicle testing when driving with velocities that are on the limit of stability.

Influence of trailers on the lateral vehicle dynamics - In a first step some standard simulations without ASMS interaction were carried out to show the influence of trailers on the lateral vehicle dynamics. A passenger car/caravan combination and a passenger car/truck trailer combination were created in ADAMS, representing a heavy and light class of trailers. The models were evaluated in comparison to measurement data from literature.

The following example deals with the steady state behavior of the vehicle The velocity is kept constant. As steering wheel input, a ramp over the interesting range of steering wheel angles is given. The gradient of the ramp is small so that transient effects can be neglected.

Figure 19 illustrates the required steering wheel angles to achieve a certain lateral acceleration. Obviously the heavy caravan as the trailer causes the largest deviations to the normal steady state behavior of the vehicle. Consequently the following investigations will focus on the car/caravan combination.

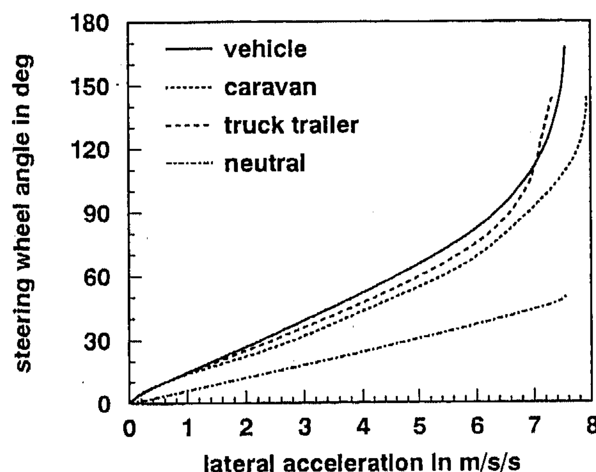

Figure 19: Steady state understeer/oversteer behavior of a passenger car with trailers: lateral acceleration

Lateral stability test - For the modelled passenger car/caravan combination without ASMS a lateral stability test was carried out according to the ISO 9815 standardized criteria. The damping characteristics of the car/trailer combination as the result of the lateral stability test is shown in figure 20. It is characterized by the reference speed damping of 0.1 at 80 km/h, the reference damping speed of 88 km/h (the damping equals 0.05) and the zero damping speed of approximately 93 km/h which means that velocities higher than 93 km/h can lead to trailer oscillations with growing amplitudes of the articulation angle between the towing car and the trailer.

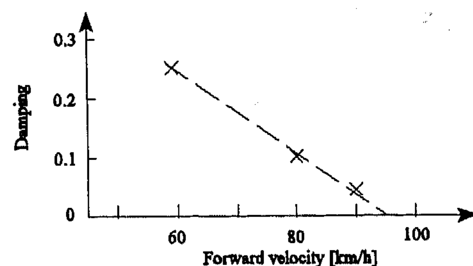

Figure 20: Damping characteristics of the articulation angle of the passenger car/caravan combination

Two selected maneuvers are presented below to demonstrate the effect of ASMS to the passenger car/trailer combination.

Impulse response with ASMS - As a first maneuver the impulse response according to ISO 9815 was simulated on a dry pavement. Figure 21a shows the steering wheel input. The other charts of figure 21 compare the maneuver with and without ASMS. Figure 21b shows the forward velocity. It is chosen as the zero damping speed at the limit of stable trailer behavior.

Figures 21c-e compare the articulation angle between the towing passenger car and the trailer and the yaw rates of car and trailer. The oscillation of the signals decreases with ASMS. Without ASMS the maneuver is instable.

Figure 21f shows the wheel individual brake pressures that are generated by ASMS to reduce the undesired effects of the trailer. Up to a certain degree the ASMS pressure modulation compensates the additional yaw torque around the vertical axis of the car which is caused by external forces of the trailer. Moreover, ASMS has a positive influence on the oscillation of the whole passenger car/trailer combination. The superimposed animation of the maneuver is shown in figure 21g.

Double step response with ASMS - The second maneuver is again carried out on dry pavement. The trailer oscillation is caused by steering to the left, and after a short period of time, by counter steering to the right. The driver input and the velocity are plotted in figures 22a and 22b. The superimposed animation of the passenger car/trailer behavior is illustrated in figure 22g. It shows that the maneuver with ASMS is stable whereas without ASMS the whole combination spins around and slides. The trailer imposes additional forces on the towing passenger car that cannot be compensated without ASMS. The individual wheel pressure modulation of ASMS as it is shown in figure 22f reduces the undesired effects so that the stability is improved. These effects are also illustrated in figure 22c-e. The articulation angle and the yaw rates both of the car and the caravan are much smoother with ASMS.

SENSORS - The simulations above have mainly focused on the robustness of ASMS. However, simulation was also contributed to hardware specifications. The influence of the sensor dynamics, filtering, A/D-conversion and sensor failures on the performance of ASMS can easily be studied in OLS. The following example demonstrates, how the tolerable misalignment of the yaw rate sensor can be specified based on a parameter study in OLS.

Apart from a small sensitivity error the main effect of misalignment is that portions of the pitch and roll motion of the body are superimposed to the yaw rate signal. To study these effects an extreme maneuver at a velocity of 70 km/h was chosen, that is considered to be the worst case. A sine signal of 1.5 Hz with an amplitude of 180° as steer input causes a strong roll motion of the vehicle body. Furthermore a driver brake intervention of 140 bar between 1.0 and 2.0 s of simulation time is simulated to stimulate a pitch motion.

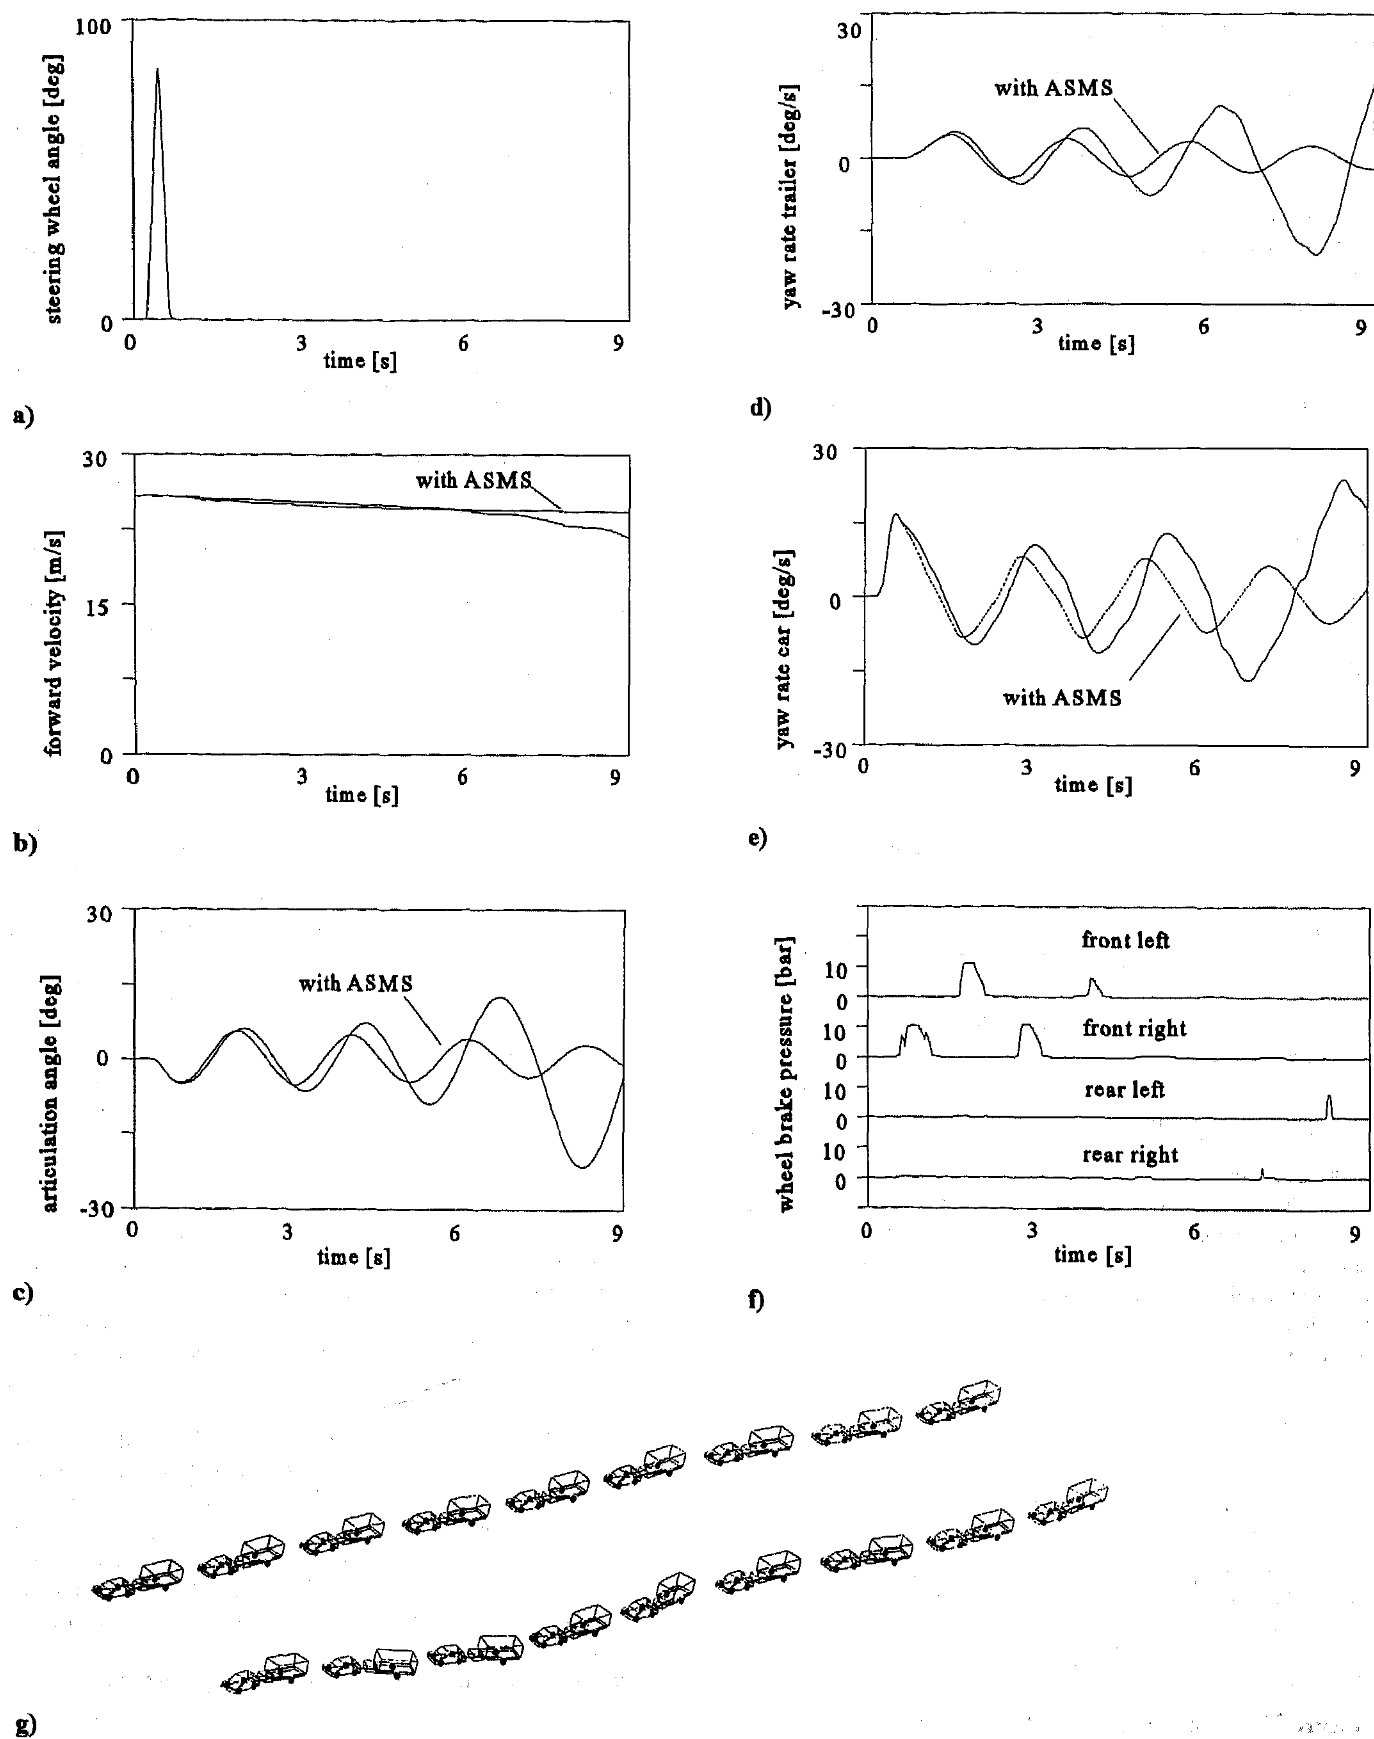

Figure 21: Impulse response

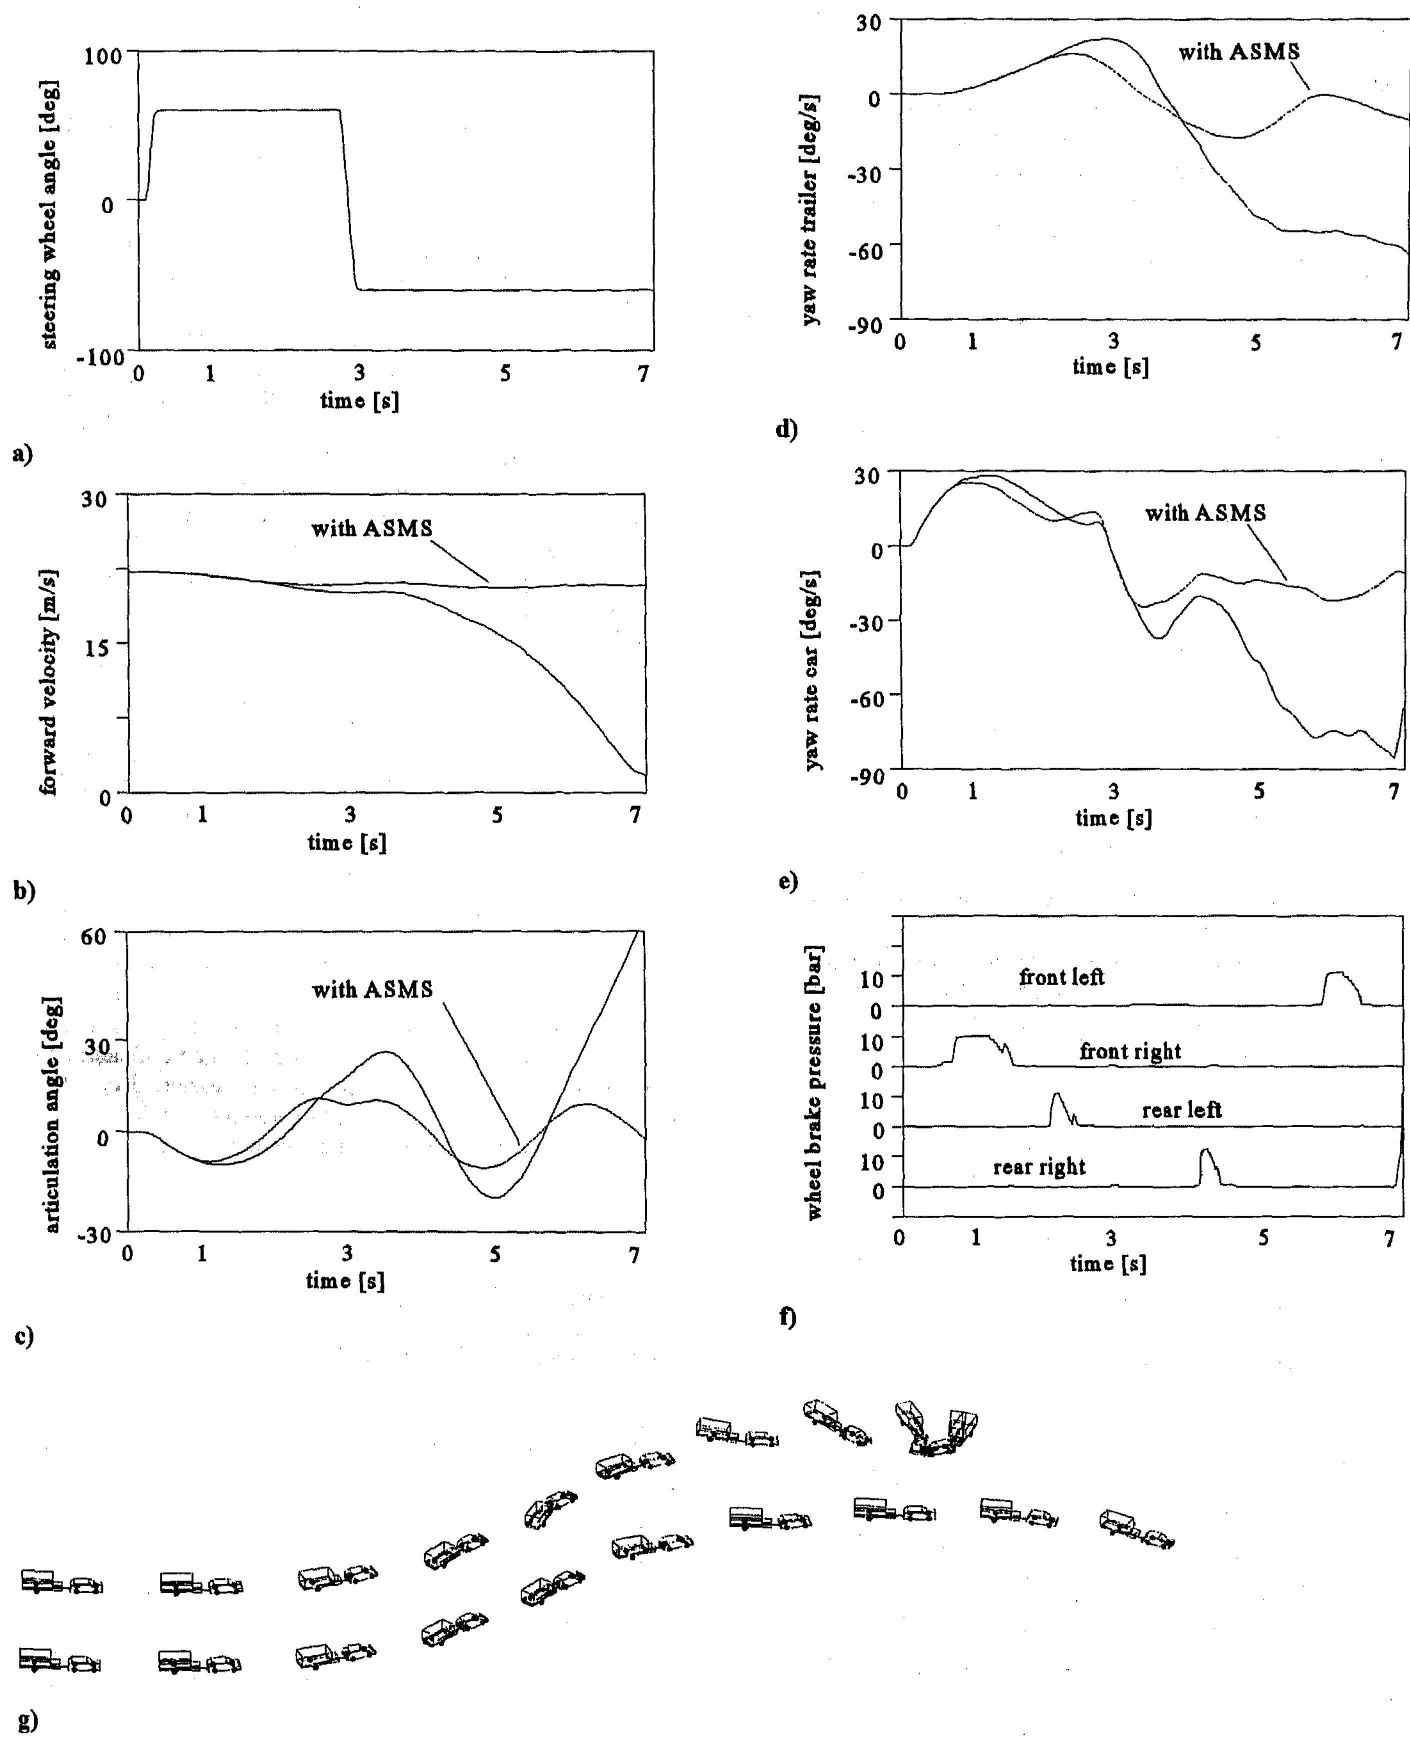

Figure 22: Double step response

Figure 23 shows the yaw, pitch and roll rate of the body calculated in the body frame. In an automated loop the yaw rate signals of the maneuver with all combinations of misalignments around the longitudinal and lateral axis of the body in steps of 1.0 between -10 and +10 have been calculated. The maximum of the absolute error with respect to the real yaw rate for each simulation was evaluated. Finally, the error was plotted as a function of the misalignment along the longitudinal and lateral axis.

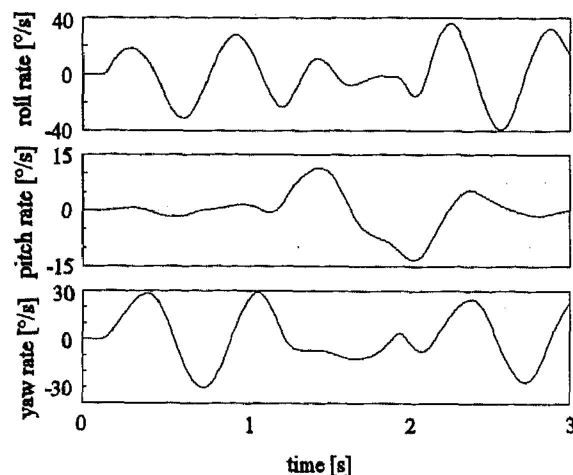

Figure 23: Angular velocities of the body

Figure 24 shows lines of constant error that have been interpolated from the simulation results. The dashed circle shows that with a tolerance of 5 misalignment a yaw rate error of 3.5 /s in the worst case has to be accounted for in the AYC-control algorithm. Furthermore, the parameter study shows, that the sensitivity against misalignment around the lateral axis is higher than around the longitudinal axis.

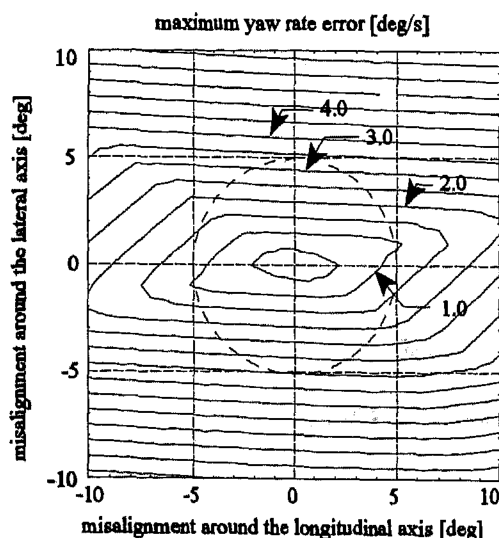

Figure 24: Maximum yaw rate error by misalignment

SUMMARY AND CONCLUSIONS

Simulation has rendered an important contribution to the development of the new Automotive Stability Management System (ASMS) from ITT. In addition to the ABS and TCS function, ASMS includes an Active Yaw Control (AYC) that assists the driver when the vehicle tends to instability. Simulation has offered the possibility of continuous development in the laboratory. Up to a certain level the design of basic control strategies has been carried out in simulation. Simulation has relieved vehicle prototype testing from time consuming work. The development of the code for the series micro controller in integer arithmetics is supported by Real-Time Simulators which combine the series controller hardware with simulation models of the vehicle dynamics and all other components of the control loop. Modifications in the code could be verified by simulating standard maneuvers before testing in the vehicle. In Off-Line Simulation special attention has been paid to those issues which are difficult to study in testing. As it has been pointed out in the examples of the paper, external influences on the vehicle dynamics due to disturbances e.g. by trailers or 3D-courses can be examined in simulation. Simulation offers an insight to dynamic effects that can hardly be obtained in testing. It is possible to configure maneuvers and disturbances arbitrarily. The results are reproducible. Parameter studies with a huge number of simulations can be executed and evaluated automatically. Nevertheless, the functionality and performance of the code always have to be proven by vehicle prototype testing.

The growing functionality and complexity of the vehicle control systems demand more and more testing and simulation efforts for the design and verification of algorithms. The progress in simulation software tools, computer performance and modeling of the vehicle dynamics will offer new possibilities to simulation. The step from the initial idea of an algorithm that is developed in simulation to the verification by vehicle prototype testing will become easier. Regarding shorter product life cycles "Rapid Prototyping" will become a key issue in the development of new vehicle control systems.

The Effects on Motorcycle Behavior of the Moment of Inertia of the Crankshaft

Takeshi Kimishima, Toyokazu Nakamura, and Takahisa Suzuki
Honda R&D Co., Ltd.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The moment of inertia of the crankshaft cannot be ignored when analyzing the dynamics of a motorcycle. In this research, the tire friction force (calculated by drag and tire side force) was used as an index of the drive performance. The ratio of roll rate and steering torque (here after referred to as a roll rate gain) was used as an index of the cornering performance, and it was analyzed as the influence of the moment of inertia of a crankshaft on the drive performance as well as cornering performance.

As a result, the influence on drive performance and cornering performance by the moment of inertia has been found.

INTRODUCTION

An example of the theoretical research of the relationship to the motion of motorcycles and the gyroscopic effects is as follows:(1). When comparing motorcycles with automobiles, the contribution rate to the motion of motorcycle by the rider's body position is much greater. Moreover, in turning while banking, the analysis of motorcycle motion is difficult.

In recent years, however, technological advances have allowed higher engine speed, larger engine displacement, and a lighter engine. The effect of the moment of inertia of the crankshaft on a motorcycle has become an important resarch subject.

In this research, the changing moment of inertia of the crankshaft, and the analysis of the drive performance and cornering performance of a motorcycle was carried out from the viewpoint of engine gyroscopic and flywheel effect.

THEORETICAL ENGINE GYROSCOPIC EFFECT

GYROSCOPIC MOMENTS

Straight Running - The inertial effects by which a rotating object tries to maintain the same direction of the rotation axis and the precession which generates the gyroscopic moments in the rotation axis of that object, when the object rotates on an orthogonal axis are characteristics of that object at high speed. A simple model is shown in Fig.1.

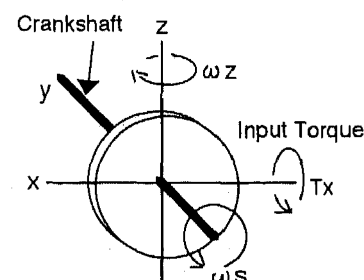

Fig.1 Direction of Generated Gyroscopic Moments

$Ic \times \omega s \times \omega z = Tx$ ----- (1)

Tx : Input Torque on Roll axis
Ic: Moment of inertia of crankshaft (kgm/s^2)
ωs: Engine speed (rad/sec)
ωz: Yaw rate (rad/sec)

In the case of a motorcycle that is running straight as the small moment Tx is input around the roll axis, a gyroscopic moment occurs around the Z axis as shown in formula (1). If Tx is assumed to be a disturbance, the angular moment of the crankshaft $Ic \times \omega s$ represents the stability against the disturbance.

Initiate Action - When attempting to lean the motorcycle, the moment that is input around the roll axis is given as a function of steering torque (Ts) and the moment due to the movement of the rider (Tr).

$$Tx = f1(Ts)+f2(Tr) \text{ ----- } (2)$$

f1(Ts):Moment generated by steering torque
f2(Tr):Moment generated by movement of the rider

It is assumed in the test mode of this study that the moment due to the movement of the rider does not vary depending on the moment of inertia of the crankshaft. This is becauseit is difficult to measure the moment due to the movement of the rider. Attention was paid to the steering torque.

When initiating action to turn from straight running, the moment that is input around the roll axis can be expressed by formula(2)

$$Ix \times \frac{d\omega x}{dt} + Ic \times \omega s \times \omega z = Tx \text{ ----- } (3)$$

Ix: Moment of inertia of Roll axis (kgm/s^2)
ωx: Roll rate (rad/sec)

This shows that (Tx) is divided into the gyroscopic moment around the Z axis, and that the moment lets the body turn in the rolling direction. The complete model is shown in Fig.2

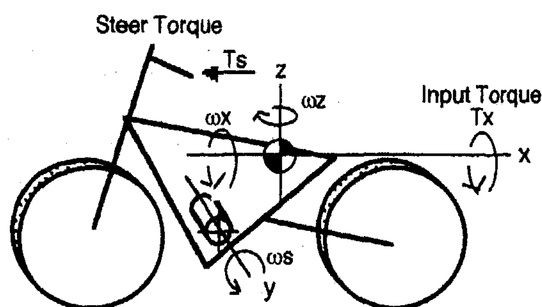

Fig.2 Complete Model

If a motorcycle is consided in a simplistic manner, it can be defined as a two axis free gyro that is supported by contact points of the front and rear tires and is free to yaw and roll.

Wheel and Engine Gyroscopic Moment - Fig.3 shows the engine/transmission system of a typical motorcycle. The gyroscopic moment on motorcycle of 750cc class by which the engine speed of 6000 rpm and the roll rate of 30deg/sec are shown in Fig. 4. The gyroscopic effect of the wheels are larger than the gyroscopic effect of the engine. However, about 9% of all gyroscopic moments that are generated take place within the crankshaft of the motorcycle. The mainshaft has the opposite gyroscopic effect, while the influence on cornering performance cannot be ignored.

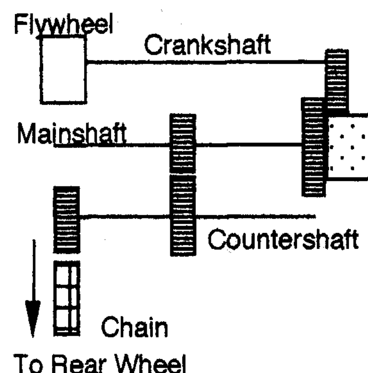

Fig.3 Engine Transmission System of a Typical Motorcycle

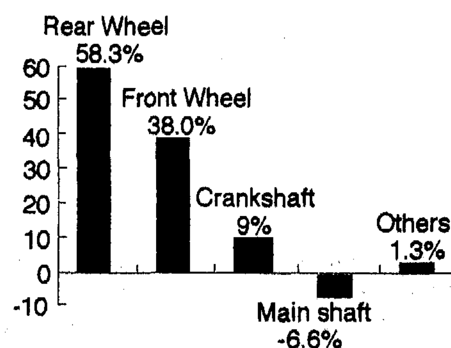

Fig.4 The Gyroscopic Moment Ratios in a Motorcycle with the Transmission System in Fig.3

THEORETICAL FLYWHEEL EFFECT

REAR TIRE FRICTION CIRCLE- The ability to controll engine speed due to throttle operation is enhanced by the adequate moment of inertia of the crankshaft. When this is achieved, the throttle can be operated with ease and the rider of the motorcyclle will be able to control it without exceeding the tire friction circle, as well as balancing drag and side force.

In the research, attention to drag and side force during actual riding and flywheel effect regarding drive performance while turning, were also analyzed.

Fig.5 shows the calculation model. During acceleration a moment is created when the front of the motorcycle is raised. Therefore, changes of axle load (Wb) and rear axle load (Wr') are expressed in formula (4) and (5).

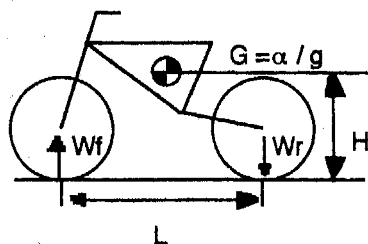

Fig.5 Calculation Model for Change of Axel Load

$$W = (\alpha / g) \times H / L \times W \quad \text{----- (4)}$$

$$Wr' = Wr + Wb \quad \text{-----------------(5)}$$

W: Curb weight
Wr: Rear axle load
Wf: Front axle load
Wb: Change of axle load distribution
a : Acceleration
H: Center of gravity height
L : Wheel base
G : Acceleration G

The side force of the front and rear tires act as the force that balances the centrifugal force on the center of gravity of the motorcycle while it is turning. The tires then generate a force proportional to the contact load. The side force of the front and rear tire can be calculated by simply considering the amount of change in the axle load of the front and rear wheel during turning acceleration and deceleration.

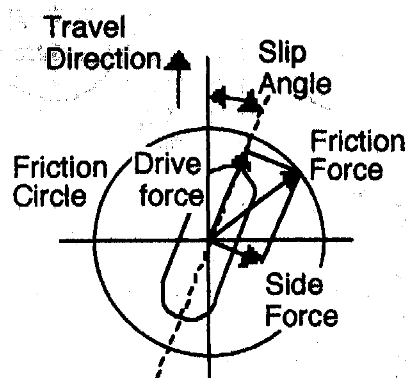

Fig.6 Concept of Friction Circle

$$\mu W \geq F = \sqrt{S^2 + T^2} \quad \text{----------- (6)}$$

F: Composite Force
S: Side force on tire
T: Drag
W: Contact load on tire
μ: Road surface friction coefficient

Fig.6 shows the concept of a friction circle. Formula (6) pertains to the action of drive force while turning. Formula (6) shows that the tire friction force cannot exceed the tire friction circle radius (limit value). The tire friction circle radius is the force resulting from drive force and side force calculated by the contact load and the friction coefficient of road surface.

NUMERICAL SIMULATION

In order to examine the influence of the gyroscopic effect of the crankshaft from a theoretical point of view before the actual running test has been performed, the simulation of a simplified model and motorcycle model using mechanism analysis language was administered through the gyroscopic effects of the engine (2).

SIMULATION OF ROLLING MOTION THROUGH A SIMPLISTIC MODEL - Fig. 7 shows a simplified model. The masses that are assumed as A, B, C, D are shown in Table 1. They are arranged on a rectangular frame which is representative of the body of a motorcycle. The rolling behavior was generated by roll torque being input at the center of gravity of this model, which is assumed to be floating weightless in space. The simulation was executed by four specifications shown in Table 2.

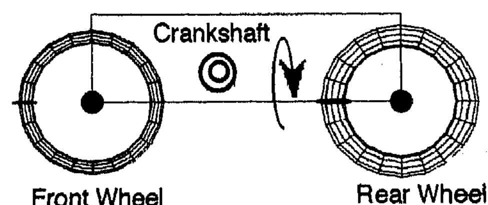

Fig.7 Simplified Model

Table 1 Moments of Inertia
$Kg \cdot m \cdot s^2 \cdot 10^{-4}$

Front Wheel	446.0
Rear Wheel	701.0
Crankshaft	7.7

Table 2 Calculation Specifications

	Front Wheel	Rear Wheel	CrankShaft
A	Not Rotated	Not Rotated	Not Rotated
B	Rotated	Not Rotated	Not Rotated
C	Rotated	Rotated	Not Rotated
D	Rotated	Rotated	Rotated

(The rotation speed of each part corresponds to motorcycle velocity 60km/h.)

Fig. 8 shows the result of the simulation. The roll rate is increased by the input torque and eventually reaches a constant value if the gyroscopic effect is not useful, as in case A Table 2. A yaw rate was not generated.

When the gyroscopic effect is sufficient, as in case B, C, and D in Table 2, the gyroscopic moment is generated by the roll rate. The body of the model is rotated to turn with the yaw axis and the roll rate has been decreased. As the gyroscopic effect increases, the roll rate continues to decrease and the maximum value of the roll rate becomes smaller.

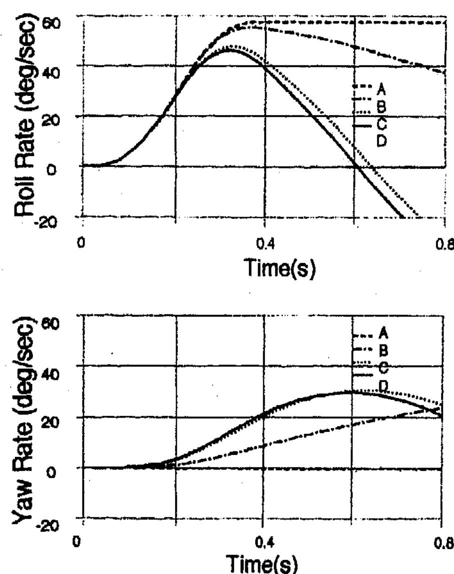

Fig.8 Result of Simplified Model Simulation

SIMULATION FOR INITIATING A TURN BY MOTORCYCLE MODEL - Fig. 9 shows the motorcycle model, and the front and rear suspension and the degree of freedom for the rotation of steering system are given.

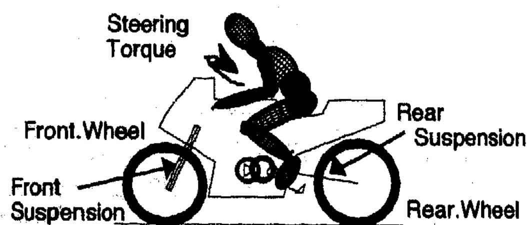

Fig.9 Motorcycle and Rider Model

The simulations of transient characteristic for initiating a turn by the input steering torque shown in Fig. 10 at 60 km/h were compared with the moment of inertia of the crankshaft shown in Table 3. (There was no input by the body movement of rider. The rider model was fixed on the motorcycle model.)

Table 3 Moment of Inertia of Crankshaft

$Kg \cdot m \cdot s^2 \times 10^{-4}$

Case.1 (Small Mass)	7.7
Case.2 (Large Mass)	17.7

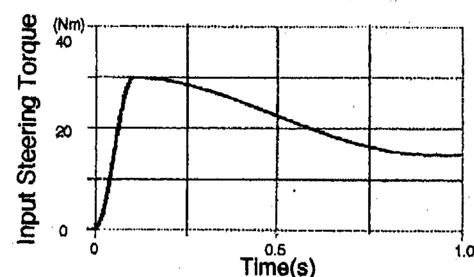

Fig.10 Input Steering Torque

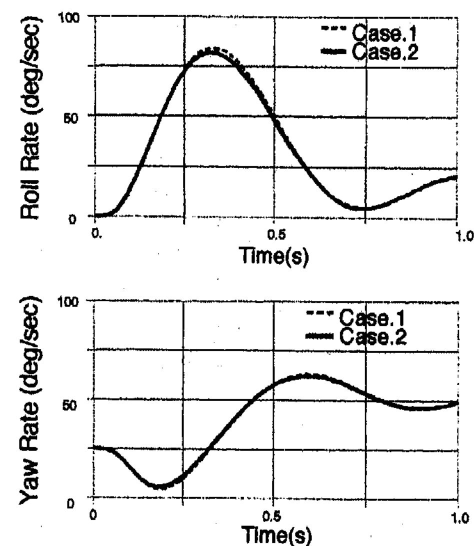

Fig.11 Result of Motorcycle Model Simulation

The maximum value of roll rate was found to be smaller with a larger moment of inertia of the crankshaft, as shown in Fig. 11. From simulation results mentioned above, there is an influence on the rolling motion during the initiation of a turn when the moment of inertia of the crankshaft increases, while the roll gain decreases.

OUTLINE OF TEST

TEST MOTORCYCLE AND TEST RIDER - The motorcycle used in this test is a sports type. The engine displacement of 750cc shown in (Fig.12), as well as the parameters are shown in Table 4. The test rider was a skilled rider who had an understanding of motorcycle dynamics.

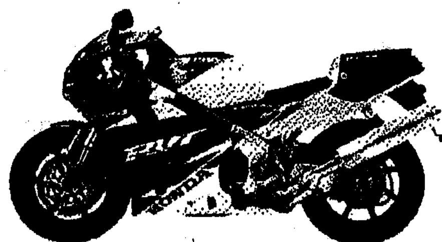

Fig.12 Test Motorcycle

Table 4 Specifications of Test Motorcycle

Curb Mass (kg)	211
Wheel Base (mm)	1410
Caster Angle (deg)	24.5
Trail (mm)	92
Front Tire Size	130/70ZR16
Rear Tire Size	190/50ZR17
Displacement (cm^3)	749

SPECIFICATIONS OF MOMENT OF INERTIA - The specification of the moment of inertia were changed by replacing a flywheel mass on the left end of the crankshaft (shown in Fig. 13). Specifications that concern the moment of inertia are shown in Table 5. The testing of cornering performance was executed by using specifications 1, 2, 3, and 4. Specifications 1, 2, and 3 were also used in order to test drive performance.

TEST RESULTS

CORNERING PERFORMANCE - Fig.14 illustrates an example of the measurement data used in the analysis of cornering performance based upon the results of the simulation. The results of the subjective evaluation test on cornering performance and steer effort based on a 5-point scale are shown in Fig.15. Attention was given to cornering ability (ease in cornering).

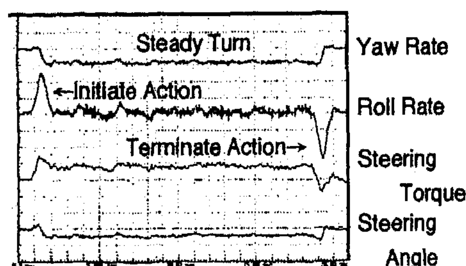

Fig.14 Example Data of Loop Turn

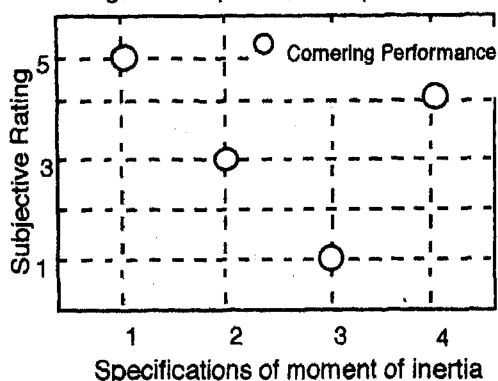

Fig.15 Subjective Rating of Cornerint Performance

As a constant to represent the cornering performance, the yaw rate convergence time as shown in Fig.16 was defined and its values in different specifications of the crankshaft were compared.

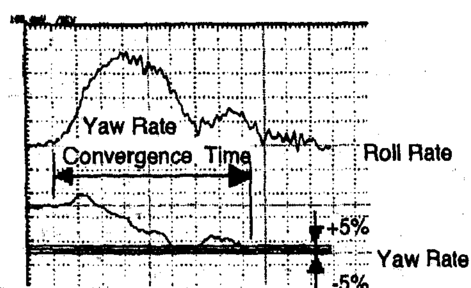

Fig.16 Yaw Rate Convergence Time

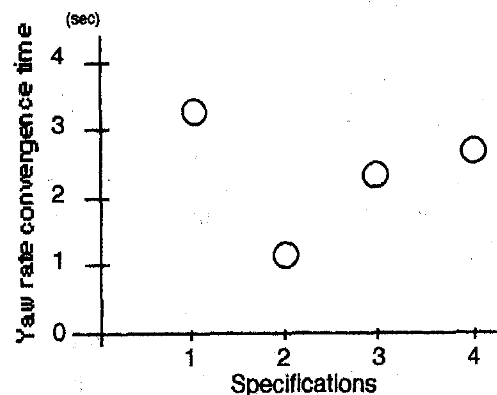

Fig.17 Comparison of Yaw Rate convergence Time

Fig.17 shows a comparison of yaw rate convergence time. Specification 2 has a short yaw rate convergence time and can obtain cornering stablity quickly. Specification 1 has a long yaw rate convergence time and while turning, is increased in time to obtain cornering stability. From this result, one can say that a motorcycle which has an adequate moment of inertia of the crankshaft can quickly obtain cornering stablity.

We considered the difference betweeen yaw rate convergence time by the ratio of the roll rate and steering torque. Comparisons of roll gains using specifications 1, 2, 3, and 4 are demonstrated in Fig. 18.

As for specification 1, the roll rate to the steering torque oscillates and the maximum value of the roll rate is smaller than other specifications. Apparently, the the rider is unable to steer well because of the sensitivity of cornering performance.

The steering torque and roll rate of specification 2 are larger than that of specification 1 and 3. It is possible that the rider can actively steer the motorcycle due to the fact that the cornering performance is only moderately sensitive.

The roll rate gain of specification 3 is smaller than 2 because the cornering performance of 3 is less sensitive than specification 2. Furthermore, in a steady turn the steering torque becomes agitated and unstable.

In specification 4 both the steering torque and roll rate were increased by an enlargement of the moment of inertia in the main shaft. This enlargement in the mainshaft incrased more than specification 2. However, the steering torque during a steady turn remained unstable.

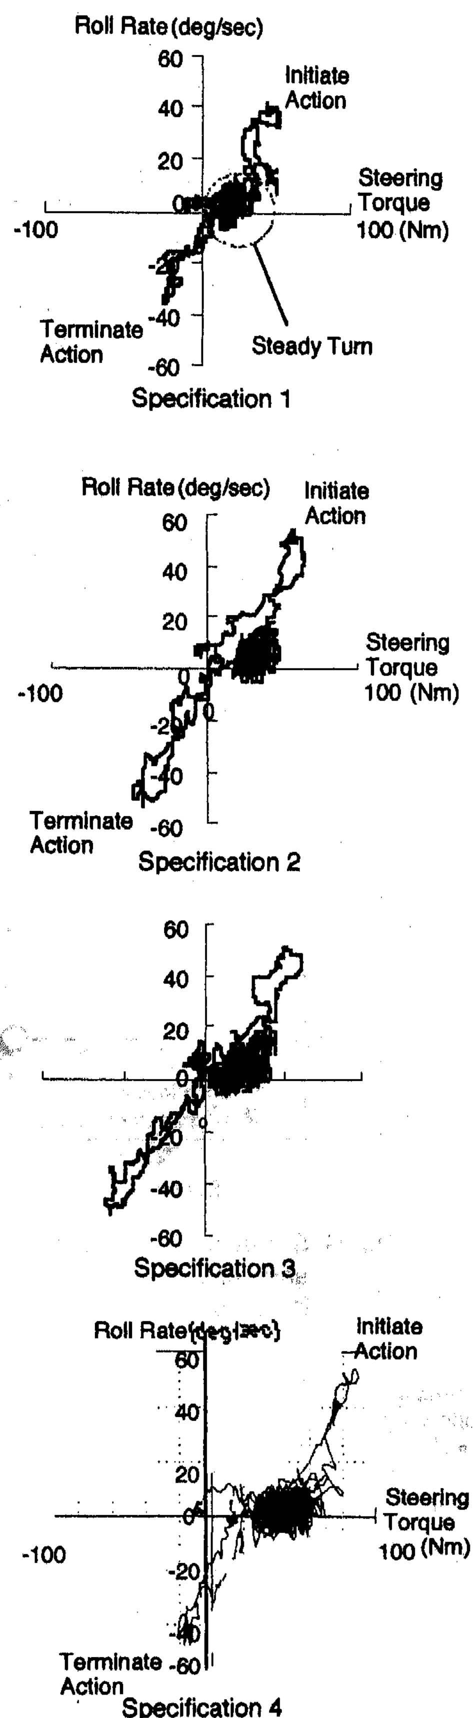

Fig.18 Comparison of Roll Gain

In Fig.19, the linear regression calculation excludes the steady turn portion of the roll rate gain data. The linear regression coefficient is defined as the roll gain coefficient. The results are demonstrated in Fig. 20. Without specification 1, the roll gain coefficient coincides with the inclination to subjective evaluation in cornering performance. The sensitivity and insensitivity of cornering performance will be expressed by the roll rate gain coefficient.

Fig.20 illustrates that the roll rate gain coefficient of specification 3 was smaller than specification 2, and the specification 3 exhibited insensitive cornering performance in the subjective evaluation. Therefore, the cornering performance will be insensitive due to the increase in the moment of inertia of the crankshaft.

Moreover, becauseof the fact that specification 4 is seen as having a more sensitive cornering performance than specification 2, one can say that an increase in cornering performance sensitivity correlates with an inclease in the moment of inertia of the main shaft. This is because the gyroscopic effect of the main shaft acts contrary to the crankshaft.

As mentioned above, the influence of the moment of inertia of the crankshaft on cornering performance is assesed by the roll rate gain.

Fig. 21 shows the comparison of the gyroscopic moment of the crankshaft and main shaft for each test specification. The gyroscopic moment of the crankshaft and mainshaft are almost the same as specification 2. Specification 2 receives a suitable subjective evaluation result in cornering performance. Thus, it balabces both gyroscopic moments and results in good cornering performance.

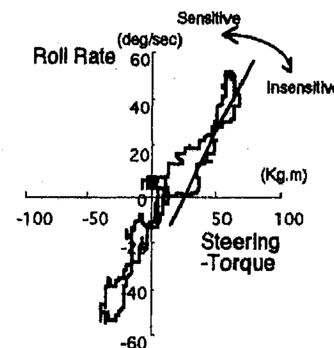

Fig.19 Example for Linear Regression

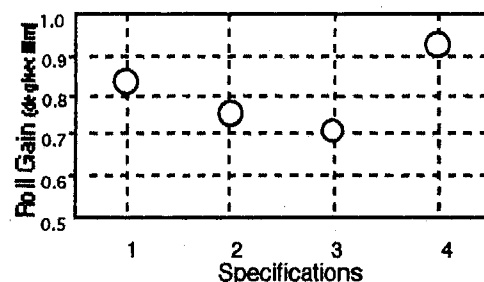

Fig.20 Comparison of Roll Gain

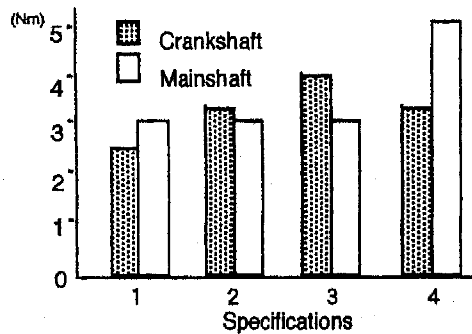

Fig.21 Comparison of Gyro Moment of Crankshaft and Mainshaft

Due to the gyroscopic effect, the moment of inertia of the crankshaft becomes larger, and the stability increases. This is demonstrated in the theoretical formula. Therefore, roll rate generated by the steering torque becomes smaller, and the roll rate gain decreases. From the results illustrated above, one can say that an optimum moment of inertia of the crankshaft provides good cornering performance.

DRIVE PERFORMANCE - Although it is known that reduced moment of inertia of the crankshaft enhance responses from the engine and provide greater linear accelerating performance, the response becomes too sensitive during cornering acceleration, which causes driving to be difficult. In this paper, the flywheel effect and the acceleration characteristics of cornering were studied in order to determine an adequate moment of inertia of the crankshaft.

Chassis Dynamometers Measurement - Fig.22 shows the waveforms of torque on the crankshaft and the countershaft of the transmission as measured using a chassis dynamo. Each torque fluctuation of specification 1 is larger than in specificatio 2. This is considered to be the cause of difficulty in throttle controlability.

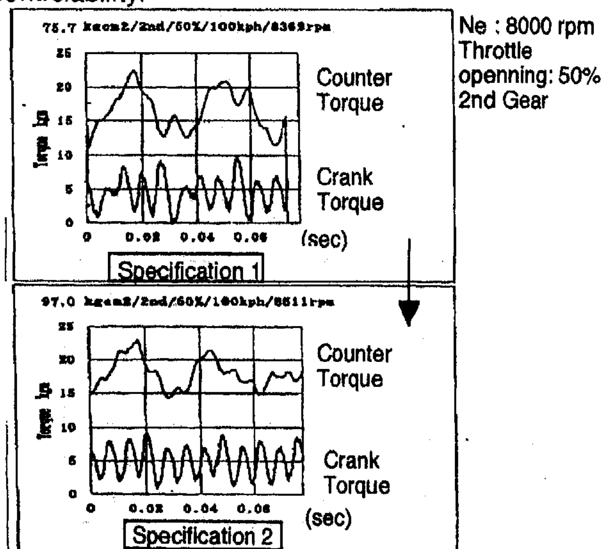

Fig.22 Crankshaft and Countershaft Torque Waveform

Acceleration mode in turn - Fig.23 displays an example of measurement data. The results of the evaluation of acceleration, throttle control, and drive feelilng in a turn utilizing a 5-point scale can be seen in Fig.24.

Specification 2 obtained a favorable subjective evaluation result in cornering performance, and overall test results that were quite good.

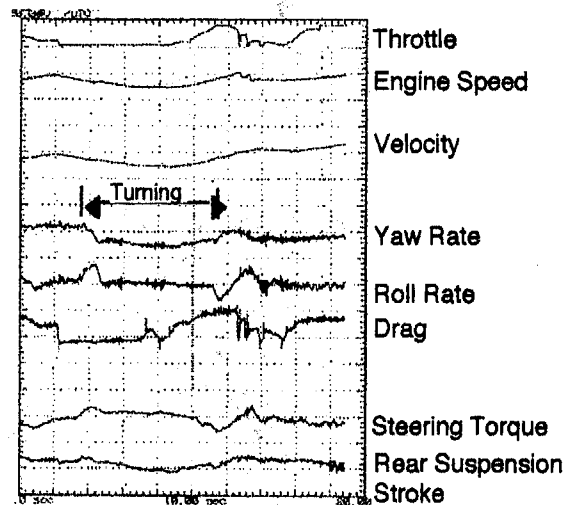

Fig.23 Exsample Data Acceleration in Turns

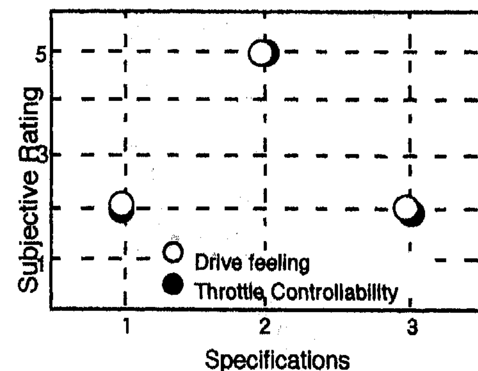

Fig.24 Subjective Evaluation of Acceleration and Throttle Control and Traction in Turns

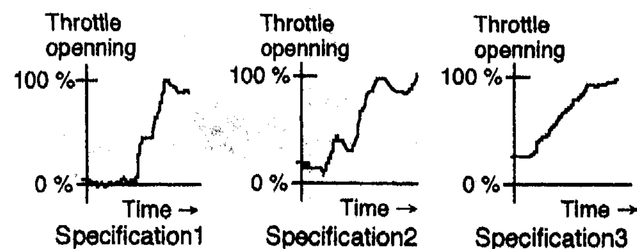

Fig.25 Comparison of Throttle Time Wave form

Changes in throttle operation over time are shown in Fig.25. It demonstrates that the rider cannot open the throttle due to an overly sensitive response in specification 1. The throttle of the motorcycle in specification 3 can open earlier, however, the engine response is insensitive and the motorcycle is unable to run at a highspeed.

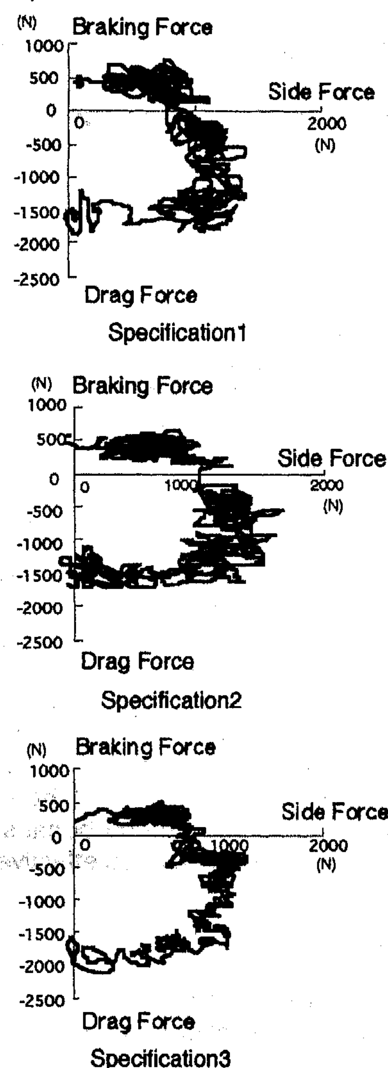

Fig.26 Comparison of Side Force and Drag in ActualRunning

The diagram for driving force and side force of the rear tire is demonstrated in Fig. 26. Side force increases rapidly because the moment of inertia of the crankshaft in specification 1 is small. In specification 2, the driving force and side force are balanced and a large tire friction circle is obtained. The tire friction circle of specification 3 was smaller than specification 2.

Fig. 27 shows an average value of the tire friction force calculated by formura (6),(7) from the initiation to the termination of the turn in each specification.

$$\bar{F} = \frac{\sum \sqrt{S^2+T^2}}{N} \quad \text{------------ (7)}$$

$\bar{F}$: Average Composite Force

S: Side force on tire

T: Drag

N : Number of Datas

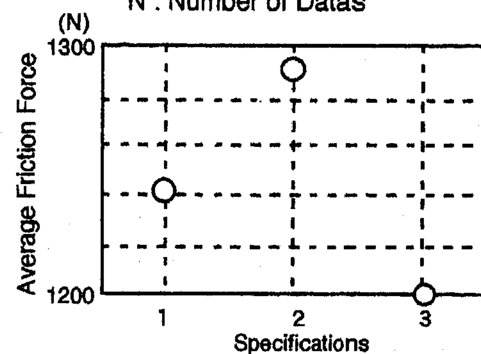

Fig.27 Comparison of Average Friction Force

The driving force and side force are effectively used in specification 2. Therefore, it can be said that the tire friction force will influence the traction.

Investigation of Tire Friction Circle Limit - If the moment of inertia of the crankshaft is reduced, the engine response becomes sensitive. This results in driving difficulty, so sliping will occur easily. Therefore, we studied the threshold for slippage from the test results on a tire (3).

Fig.28 is an illustratin of the tire friction circle. The relation to the tire friction circle limit was investigated by using the tire friction force during actual running and the tire characteristic data used in this research. The camber angle was fixed at 20 degrees, and the measurement of the tire characteristic was executed.

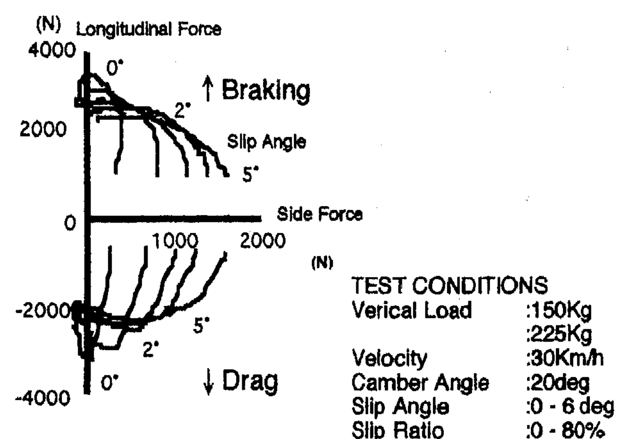

Fig.28 Measured Tire Friction Circle

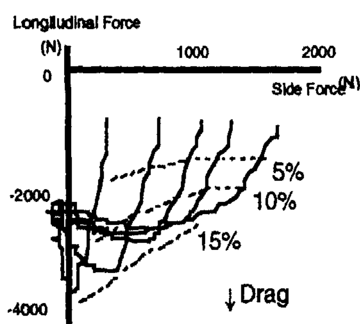

Fig.29 friction circles for each slip ratio

Fig.29 shows the tire friction circle for each slip ratio. The actual running data of specification 1 has been combined with the data of tire characteristics and is displayed in Fig.30. The rear axle load is ridden by the motorcyclist in a static (150kg) and has a maximum value wile turning (225kg). The data of tire characteristics in each rear axle load was used.

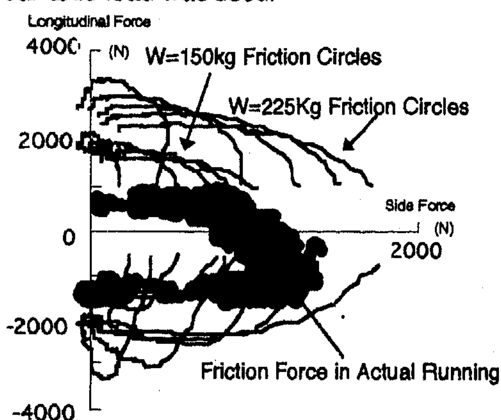

Fig.30 Friction Circle and Drag and Side Force of Specification 1

Slip ratio waveform is demonstrated in Fig.31. A worn tire was used in order to test cornering acceleration mode. The test indicated that the slip ratio was about 20%.

From Fig.29,30 and 31, one can conclude that the maximum slip ratio expected in specification1 is about 10%. The effect of slip angle at 10% slip ratio on the longitudinal friction coefficient shown in Fig.32 is small but it can be seen that the lateral friction coefficient largely varies due to the slip ratio shown in Fig.33.

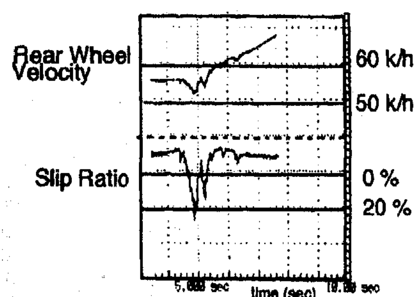

Fig.31 Slip Ratio Waveform

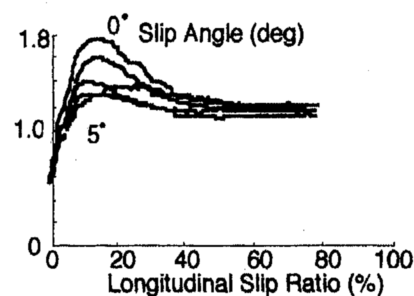

Fig.32Coeffecient of Longitudinal Friction

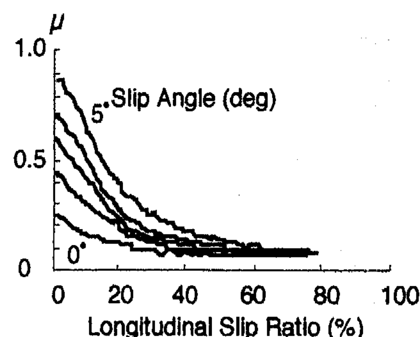

Fig.33 Coeffecient of Lateral Friction

The torque fluctuation of the crankshaft and countershaft of the transmission in specification 1 is fairly large. The motorcycle in specification 1 may be prone to slipping due to the maximum side force generated near the limit of the friction circle.

In the results mentioned above concerning the flywheel effect, the change of the moment of inertia of the crankshaft increases the ability to control the engine speed with the throttle. This verified the fact that the feeling of traction was enhanced because the rider utilized driving force and side force effectively.

CONCLUSION

The effects of the moment of inertia of the crankshaft in a motorcycle can be concluded as follows:

1. Both the gyroscopic effect of moment of inertia of the crankshaft and the main shaft influences the cornering performance of motorcycles.
2. In acceleration during a turn, a small moment of inertia of the crankshaft enhances the acceleration performance, but the engine speed control by throttle operations becomes sensitive. Riders can effectively use driving force and side force when the moment of inertia of the crankshaft is at the optimum value and the traction feeling is enhanced.
3. Good cornering performance and good driving performance (traction feeling) are produced by the optimum moment of inertia of the crankshaft on the motorcycle.

This research is a part of fundamental investigation of the gyroscopic effects on motorcycle handring dynamics. The necessity of further analysis on cornering and traction performance, as well as the need for additional research concerning the dynamics of motorcycles are expected in the future.

Comparison of Ideal Vehicle Lane-Change Trajectories

Nathaniel H. Sledge, Jr. and Kurt M. Marshek
University of Texas

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

This paper seeks to compare various models of desired, or *ideal*, vehicle lane-change trajectories or paths and to determine which is best based on selected criteria. Background information is presented covering the utility of lane-change maneuvers, lane-change terminology, and known desired open-loop trajectories. The performance of a vehicle may be assessed by measuring its deviation from an ideal path during simulated or actual limit lane-change maneuvers. Therefore, several techniques for assessing vehicle performance against an ideal trajectory are demonstrated. Similarly, in the present effort, performance indices such as integral penalty (cost) functions are used for assessing candidate lane-change trajectories. Therefore, ideal trajectory comparison is essentially treated as an optimization problem with prescribed continuity and boundary conditions, where a path's length, curvature, and rate of change of curvature are taken as its costs. The maximum constant velocity or *critical speed* is employed as an additional discriminator between the candidate paths. The results of side-by-side comparison of candidate ideal trajectories are presented and discussed.

1. INTRODUCTION

Several decades ago, straight-line running ability was considered the most important vehicle handling characteristic. Today, the lane-change maneuver has become a common method of measuring vehicle performance [1]. Many automotive researchers have used lane-change maneuvers for vehicle dynamic studies. The literature indicates overwhelmingly that lane-change tests are useful for evaluating vehicle directional control and handling performance, especially during limit maneuvers – that is, maneuvers that involve high-g lateral motion. There are several applications under this heading for lane-change analysis such as: transient response [2], open-loop performance [3][4], closed-loop performance [5][6][7], vehicle control engineering [8][9][10], intelligent vehicle studies [11][12], driver assessment and subjective evaluations [1][7][13], accident reconstruction [14][15], semi-trailer truck handling [17], motorcycle handling [18], and modeling and simulation studies [8][9][10][13][19]. Additionally, Fancher et al. [19] presented a comprehensive review of attempts to standardize lane-change handling performance test procedures.

The foregoing notwithstanding, a comparison of various ideal trajectories of the lane-change maneuver apparently has not been attempted, and therefore, this paper, presents a comparison of *ideal* vehicle trajectories for high-speed lane-change maneuvers. Trajectory functions are presented in closed form when possible under the assumption of constant velocity and in terms of path attributes: (1) curvature, (2) lateral displacement, and (3) longitudinal displacement. The primary means of comparison of desired vehicle trajectories in lane-changes are (1) length, (2) curvature, (3) the derivative of curvature, and (4) critical speed.

This paper is organized as follows. Section 1 presents an introduction to the subject of lane-change maneuvers. Section 2, Background, clarifies basic lane-change terminology, lists methods for assessing vehicle performance using ideal trajectories, and describes known desired lane-change trajectories. The problem statement is given in Section 3. In Section 4, Analysis, the comparison approach is explained, which includes criteria, assumptions, and the path measures of performance used to discriminate between the candidate paths. Results and discussion of results are presented in Section 5. Section 6 presents conclusions. Appendix A summarizes the concept of critical speed and explains its relation to lane-change kinematics.

2. BACKGROUND

2.1 TERMINOLOGY – Various vehicle maneuvers may be classified as lane-change maneuvers. Fricke [15] called one-half of a lane-change maneuver (at obstacle clearance) a *critical turn-away* maneuver. Figure 2.1 illustrates what Fancher et al. [19] defined as a *single lane-change* maneuver, which is the action of applying steering in one direction to displace a vehicle laterally followed by counter steering to recover the original direction of travel, while maintaining directional control and minimizing displacement to approximately one lane width. The *double lane-change* maneuver is similar, but

includes additional steering input to recover the original direction of travel in the original lane of travel. The double lane-change maneuver is sometimes referred to as a *sinusoidal steer* maneuver. The foregoing maneuvers may be termed collectively as lane-change maneuvers. However, this paper is concerned primarily with the features of the ideal single lane-change trajectory.

A single lane-change trajectory describes the motion of a vehicle (center of gravity) along a path from one lane to another as shown in Figure 2.2 In this paper the terms curve, path, pathline, and trajectory are used interchangeably to describe vehicle position throughout a lane-change maneuver.

In Figure 2.2, $f(x)$ is a single-valued function describing the trajectory (path) of the vehicle center of gravity, x is the longitudinal distance, y is the lateral displacement, x_e is the total longitudinal distance, y_e is the total lateral displacement, and $\theta(x)$ is the tangent direction angle.

2.2 EVALUATING VEHICLE PERFORMANCE USING IDEAL TRAJECTORIES – According to Fancher et al. [19], the three basic reasons for conducting lane-change maneuver tests are: (1) the maneuver's geometry emphasizes important facets of vehicle control or performance--vehicle yaw and sideslip response and vehicle ability to "recover tight directional control", (2) the lane-change maneuver is representative of maneuvers performed frequently on highways--obstacle avoidance and high-speed passing maneuvers, and (3) it can be used to discriminate between vehicles--luxury passenger cars vs. performance and "sports" cars--because vehicle performance during lane-changes varies significantly across the spectrum of vehicle types and models.

Many authors [3][2][10][20][21] have used lane-change maneuvers to assess vehicle lateral response, mostly for vehicle design purposes. Common performance measures, gathered from various sources, for both open- and closed-loop studies are listed in Table 2.1. The comparison approach of this paper is best related to the pathline deviation and curvature performance measures–Nos. 11 and 14 of Table 2.1.

Pathline deviation may be measured by various error performance indexes that have been proposed in the literature. The integrals of EQ (2.1) give examples of generic penalty or cost functions [22], which have their origin in the *calculus of variations*.

$$J=\int_o^T e^2\,dt \qquad J=\int_o^T te^2\,dt$$
$$J=\int_o^T |e|\,dt \qquad J=\int_o^T t|e|\,dt$$
$$J=\int_o^T\left(e^2+\dot{e}^2\right)dt \qquad J=\int_o^T t\left(\left|e^2\right|+\left|\dot{e}^2\right|\right)dt \qquad (2.1)$$

where $e = e(t)$ is error or deviation as a function of time, t, with $e(t) = y_c(t) - y(t)$, $\dot{e}$ is the rate of change of the error with respect to time, $y_c(t)$ is the objective or desired path, $y(t)$is the actual or simulated path, and the upper time limit, T, is chosen sufficiently longer than the maneuver period.

Similar performance measures have also been used specifically for lane-change studies. Fancher et al. [19] report use of the following measure of performance termed *lane-change deviation*:

$$\delta=\frac{1}{3.4}\int_o^{3.4}\left|y_e-y\right|dt \qquad (2.2)$$

where the chosen period 3.4 seconds is chosen based on experimental results. Similarly, Zellner et al. [18] proposed a variation on the *integral- square-error criterion*, $\overline{y^2}$ – see EQ (2.3) – to determine the experimental "departure of a [actual] response from the desired or optimum response." To measure the time required to complete a lane-change maneuver, Zellner et al. used the *integral-time absolute-error criterion*, $\tilde{y}$ – see EQ (2.4). This criterion "weights the path error multiplicatively," such that "errors occurring late in the transient response are penalized heavily" [22].

$$\overline{y^2}=\frac{1}{T}\int_o^T\left(y_e-y\right)^2dt \qquad (2.3)$$

where $T = x_e/V_0$ and

$$\tilde{y}=\frac{1}{T}\int_o^T t\left|y_e-y\right|dt \qquad (2.4)$$

2.3 KNOWN DESIRED LANE-CHANGE TRAJECTORIES – Various functions have been used to describe ideal lane-change paths. Some notable trajectory description schemes are listed in Table 2.2.

Circular Arcs Fett [23], Fricke [15], and Daily [14] provide derivations and geometry for the circular arc representation of an ideal lane-change path. Figure 2.3 depicts the critical turn-away distance for obstacle avoidance.

Fricke [15] presents a formula for one-half of the single lane-change maneuver for the purpose of determining the critical turn-away distance, d_x. He does so using the geometry of Figure 2.4, from which EQs (2.4) and (2.5) are derived for the purpose of determining the center of gravity path radius of curvature, ρ [24].

$$\rho=\frac{\left(2d_x\right)^2}{8d_y}+\frac{d_y}{2} \qquad (2.5)$$

$$d_x=\sqrt{2d_y\rho-d_y^2} \qquad (2.6)$$

The radius can also be described as shown in EQ (2.7), in terms of the critical speed formula – EQ (A.2).

$$\rho=\frac{V^2}{\mu_m g} \qquad (2.7)$$

and the equation

$$d_x = \rho \sin\varphi \qquad (2.8)$$

where

$$\sin\varphi = \sqrt{1-\cos^2\varphi} = \sqrt{1-\left(1-\frac{d_y}{\rho}\right)^2} \qquad (2.9)$$

and φ is the angle swept by the critical turn-away circular arc. After substitutions are made, EQ (2.10) provides an estimate of the required critical turn-away distance. EQ (2.10) can be recognized as Fricke's evasive maneuver distance formula [15]. EQ (2.11) echoes Limpert's [16] expression for lane-change distance under limit conditions because it is a critical turn-away equation where only 67 percent of the maximum lateral acceleration is used.

$$d_x = V\sqrt{\frac{2d_y}{\mu_m g}} \qquad (2.10)$$

$$d_x = V\sqrt{\frac{2d_y}{0.67\mu_m g}} \qquad (2.11)$$

where μ_m is the maximum value for the tire-road coefficient of friction.

Daily [14] takes this approach one step further by connecting the critical turn-away path segment to its mirror image, doubling the distance, d_x, to $x_e = 2d_x$, thereby completing the geometry of a single lane-change maneuver as shown in Figure 2.5. In contrast to Fricke's definition of d_y as the lateral displacement to avoid an obstacle, Daily considers the lateral distance, $y_e = 2d_y$, as the total lateral distance for completion of a single lane-change. A modification of EQ (2.10) to account for the total lateral displacement yields EQ (2.12). EQ (2.12) is a common form of the total lane-change distance equation.

$$x_e = 2.82V\sqrt{\frac{y_e}{\mu_m g}} \qquad (2.12)$$

where $x_e \equiv$ the total longitudinal distance
$y_e \equiv$ the total lateral displacement

Fett [23] described the geometry for the circular arc path of a single lane-change maneuver. He noted that the radius of curvature is a function of speed and friction, but he also contended that it is a function of the prescribed lateral displacement and the lane-change duration, t_e. Assuming constant velocity, the longitudinal position at time t is $x=V_0 t$ and the lateral position is given by

$$y(x) = \rho - \sqrt{\rho^2 - x^2} \quad 0 \le x < \frac{x_e}{2} \qquad (2.13)$$

$$y(x) = y_e - \rho + \sqrt{\rho^2 - x^2 + 2xx_e - x_e^2} \quad \frac{x_e}{2} \le x \le x_e \qquad (2.14)$$

where, in accordance with the geometry of Figure 2.4, the constant radius of curvature is described by

$$\rho = \frac{x_e^2 + y_e^2}{4y_e} \qquad (2.15)$$

For the circular path, Fett relied on experimental data and assumes the duration of a "forced" lane-change to be about 3.0 seconds. A forced lane-change is effectively one in which an oncoming obstacle approaches rapidly or where headway decreases quickly. Therefore, at constant velocity, he considers the total longitudinal distance for the lane-change maneuver to be $x_e = V_0 t_e$.

There are two other ways to set up the circular trajectory. *First*, the start and end points can be prescribed, then based on the curve geometry, the maximum velocities and lateral acceleration can be determined for stable traversal of the given path. *Second*, the maximum lateral acceleration, velocity, and lateral displacement can be prescribed, leading to the estimate of the total longitudinal lane-change distance, x_e.

Fett [23] noted the following disadvantages and shortcomings for simulating lane-changes using connected circular arc paths: *First*, special measures must be undertaken to determine which circle the vehicle is on. This problem is presented by the discontinuity at the inflection point between the two circular arcs. *Second*, neither circular arcs nor circular arc tangents will accommodate changing velocity (i.e., The path will over- or under-shoot the desired lateral position). And *third*, changing velocity produces a non-smooth curve and requires a more complex vehicle and/or trajectory model.

Polynomial – Eshelman and Desai [17] and Nelson [25] both explored the use of a single Cartesian polynomial (SCP) to describe an ideal lane-change maneuver path. The polynomial can be of any power, but high order polynomials increase complexity and computation time. EQ (2.16) is the general form of a polynomial of degree-n.

$$y(x) = a_0 + a_1 x + a_2 x^2 + \ldots + a_n x^n \qquad (2.16)$$

Eshelman and Desai [17] determined an ideal lane-change path for semi-trailer trucks using a seven-degree polynomial and the following conditions: $y(0) = y'(0) = y''(0) = y'''(0) = 0$, $y(x_e) = y_e$, and $y'(x_e) = y''(x_e) = y'''(x_e) = 0$. Solving for the constant coefficients, they arrived at the following degree-7 polynomial:

$$y(x) = \frac{y_e}{x_e^7}\left[35x_e^3x^4 - 84x_e^2x^5 + 70x_ex^6 - 20x^7\right] \quad (2.17)$$

Another single Cartesian polynomial for lane-changes that satisfies the constraints given in Table 2.3 is provided by Nelson [25]:

$$y(x) = y_e\left[10\left(\frac{x}{x_e}\right)^3 - 15\left(\frac{x}{x_e}\right)^4 + 6\left(\frac{x}{x_e}\right)^5\right] \quad (2.18)$$

A comparison of curvatures and trajectories for both the 5th and 7th degree SCPs is shown in Figures 2.6 and 2.7.

Ramp Sinusoid – Several authors [16][18][23] have recommended the use of a ramp sinusoidal function to describe the ideal lane-change path. Fett [23] held that a sinusoidal trajectory was preferable to connected circular arcs because it provides a continuous function of continuous curvature and it accommodates changing velocity. The geometry for ramp sinusoidal analysis is shown in Figure 2.8.

Zellner et al. [18] proposed the following function for a sine-shaped lane-change path.

$$y(t) = \frac{y_e}{x_e}V_0t - \frac{a_yx_e^2}{4\pi^2V_0^2}\sin\left(\frac{2\pi V_0t}{x_e}\right) \quad (2.19)$$

where $x = x(t) = V_0t$ is the linear displacement in the direction of travel, $y(x)$ is the lateral displacement (usually equivalent to the lane width), and lateral acceleration, a_y, takes the form:

$$a_y = \frac{y_e}{x_e^2}2\pi V_0^2 \quad (2.20)$$

Substituting x for V_0t and EQ (2.20) for a_y reduces EQ (2.19) to a more familiar form [16].

$$y(x) = y_e\left[\frac{x}{x_e} - \frac{1}{2\pi}\sin\left(\frac{2\pi x}{x_e}\right)\right] \quad (2.21)$$

For the path function, $y(x)$, the minimum radius is given by:

$$\rho_{min} \cong \frac{x_e^2}{2\pi y_e} \quad (2.22)$$

Limpert identified four levels of lateral acceleration for lane-change distance and time estimation formulas: (1) *normal* describes relatively low lateral acceleration, (2) *severe* describes moderately high lateral acceleration, (3) *limit* indicates high acceleration, and (4) *maximum* is reserved for very high lateral acceleration. Limpert considered the assignment of the maximum lateral acceleration to single direction steering situations only, like critical turn-aways, which can be likened to the first half of a single lane-change maneuver [14][15]. Limpert provided a menu of choices for modification of the lateral acceleration, a_y:

(1a) Normal (single lane-change): $a_y = (0.1 - 0.0013V)g$
(1b) Normal ("feels" safe): $a_y = [0.025V - (V/44)^{1.85}]g$
(2) Severe: $a_y = (0.22 - 0.002V)g$
(3) Limit: $a_y = 0.67a_{y,\max}$
(4) Maximum (critical turn-away): $a_y = 0.85a_{y,\max}$

EQ (2.23) is in the form typically used to represent the total longitudinal distance for a lane-change.

$$x_e = C_xV\sqrt{\frac{y_e}{a_y}} \quad (2.23)$$

In EQ (2.23), the lateral acceleration, a_y, is equivalent to $\mu_m g$, where μ_m is the maximum coefficient of friction between the tire and road. Limpert [16] cites experimental results that yield a distribution of values for the constant coefficient, C_x, with modes at 2.6 and 2.67. Based solely on algebraic manipulation, C_x is approximately equal to 2.51.

Spirals – Kanayama and Miyake [26] proposed a novel lane-change trajectory while researching smooth local path planning for autonomous vehicles. They maintain that Eulerian, or Cornu, spirals are preferable to straight lines and circular arcs because of continuous and smooth paths and curvature. As shown in Figure 2.9, we construct a lane-change path by specifying two *endpostures* where the curvature is null. The endpostures are a combination of position and orientation information; for example: $(p_0, p_e) \rightarrow p_0=(x_0, y_0, \theta_0)$ and $p_e=(x_e, y_e, \theta_e)$, where position coordinates $(x_0, y_0) \neq (x_e, y_e)$ and θ_0 is the tangent direction of the path at each posture point. The piecewise continuous *curvature* for the Cornu spiral path varies linearly. Taking this feature into account, lane-change path curvature has the following piecewise structure:

$$\begin{aligned} \kappa(s) &= c(s,w)\, s + \kappa_0 && 0 \le s < l/4 \\ &= -c(s,w)\, s - 2\,\kappa_1(l/4) + \kappa_0 && l/4 \le s < 3\,l/4 \\ &= c(s,w)\, s - 4\,\kappa_2(3\,l/4) + \kappa_0 && 3\,l/4 \le s \le l \end{aligned} \quad (2.24)$$

Where l is the total *positive length* of the curve, κ_i are curvature constants, and $c(s,w) = 2/w(\beta)^2$ is the *sharpness* of the curve, and $w = w(\beta)$ is the *roundness* factor. β is the orientation angle between the first and final points and is given by

$$\beta = \tan^{-1}\left[\frac{y_e - y_0}{x_e - x_0}\right] \quad (2.25)$$

The key parametric variables describing the lane-change path are defined as follows:

$$\theta(s)=\int_0^s \kappa(\zeta)d\zeta \quad 0\le s\le l \tag{2.26}$$

$$x(s)=\int_0^s \cos\theta(\zeta)d\zeta \quad 0\le s\le l \tag{2.27}$$

$$y(s)=\int_0^s \sin\theta(\zeta)d\zeta \quad 0\le s\le l \tag{2.28}$$

where ζ is a "dummy" integration variable.

The endpostures are said to be symmetric if $\theta_0 - \beta = -(\theta_e - \beta)$; and this is the condition for parallel endpostures such as those for a single lane-change. The size d and deflection α of a symmetric curve (velocity is constant) are defined respectively as follows:

$$d=\sqrt{(x_e-x_0)^2+(y_e-y_0)^2} \tag{2.29}$$

$$\alpha=\theta_0-\theta_e \tag{2.30}$$

where θ is the curve tangent direction angle. For example, the deflection for a left turn is $\alpha = \pi/2$, and the deflection for a lane-change is $\alpha = 0$.

For a description of lane-change paths of constant velocity vehicles, the parallel case ($\theta_0 = \theta_e$, so $\alpha = 0$) of the Cornu spiral is used. The path inflection point is given by the intermediate posture that Kanayama and Hartman [27] refer to as the *least cost split point, q*.

$$q=\left(\frac{x_0+x_e}{2},\frac{y_0+y_e}{2},\beta-(\theta-\beta)\right) \tag{2.31}$$

The split point used in conjunction with each endposture yields two *clothoid* pairs that describe the ideal lane-change path. The minimum radius of curvature occurs at the turning points B and D as depicted in Figure 2.9 and 2.10.

Acceleration Profile – Prescribing a lateral acceleration profile enables analysis of the effect of lateral acceleration on a lane-change trajectory. Figure 2.11 compares three examples of acceleration profiles where $a_{y,\max} = \mu_m g$. The first is *sinusoidal* with a maximum amplitude equal to $a_{y,max}$ [12], the second is *trapezoidal* with maximum amplitude equal to 0.85 $a_{y,\max}$ [11], and the third, the crudest, is represented by a *square wave* with a maximum amplitude of 0.67 $a_{y,\max}$ [16].

Chovan et al. [12] prescribed a sinusoidal lateral acceleration (a_y) profile as a function of time:

$$a_y=a_{y,m}\sin(\omega t)=\left(\frac{2\pi y_e}{t_e^2}\right)\sin\left(\frac{2\pi t}{t_e}\right) \tag{2.32}$$

where $a_{y,m} \equiv$ maximum lateral acceleration = $0.7g$
$\omega \equiv$ lane-change angular frequency = $2\pi/t_e$
$y_e \equiv$ lane-change total lateral displacement
$t \equiv$ elapsed time into the lane-change
$t_e \equiv$ total time to complete the lane-change

The expression for lateral acceleration, a_y, can be integrated to determine lateral velocity and position:

$$V_y=v=\left(\frac{y_e}{t_e}\right)\left[1-\cos\left(\frac{2\pi t}{t_e}\right)\right]+v_0 \tag{2.33}$$

$$y(t)=\left(\frac{y_e t}{t_e}\right)-\left[\frac{y_e}{2\pi}\sin\left(\frac{2\pi t}{t_e}\right)\right]+v_0 t+y_0 \tag{2.34}$$

Chee et al. [11], in their attempt to control vehicle motion in an automated highway system (AHS), introduced the term virtual desired trajectory (VDT) for ideal lane-change curves. They acknowledged the use of lane-change trajectories based on reverse circular arcs and polynomial functions. They also introduced a trapezoidal lateral acceleration profile to prescribe a VDT. Their analysis focused on the maximum lateral acceleration capability of AHS vehicles during lane-change maneuvers.

Taking into account issues and constraints such as passenger comfort and vehicle capabilities, Chee et al. [11] first prescribe a trapezoidal acceleration profile and then observed its effect on the trajectory. EQ (2.35) represents the acceleration profile by a piecewise function of time, where $J_{\max}$ is the maximum jerk and the lateral acceleration is limited to 85 percent of the nominal maximum corresponding to Limpert's *maximum* case. The acceleration profile must be integrated to yield the velocity and position graphs depicted in Figure 2.13.

$$\begin{aligned} a_y &= J_{\max} t && 0 \le t < t_1 \\ a_y &= 0.85\, a_{y,m} && t_1 \le t < t_2 \\ a_y &= -J_{\max} t + 2\,(.85)\, a_{y,m} && t_2 < t \le t_3 \\ a_y &= -0.85\, a_{y,m} && t_3 < t \le t_4 \\ a_y &= J_{\max} t - 4\,(.85)\, a_{y,m} && t_4 < t \le t_e \end{aligned} \tag{2.35}$$

Limpert [16] used a square wave acceleration profile with an amplitude equal to 67 percent of the nominal maximum as an average lateral acceleration. This acceleration profile is represented by one period of a square wave as shown in Figure 2.14.

Bezier-Spline – In the Bezier spline approach, the spline algorithm interpolates only the prescribed endpoints; the other points are used to control the shape of the spline curve [28]. According to Apetaur and Opicka [8], a simple form of the Bezier Spline equation is:

$$B(p)=\sum_{k=0}^{n} p^k(1-p)^{n-k} S_{k+1} \tag{2.36}$$

In Figure 2.15, the spline trajectory is constructed using lane-change dimensions y_e=3.66 m and x_e = 62.14 m. These dimensions are inputs to the following knot algorithm:

$$x = x_e \frac{n}{n-1} \quad (2.37)$$

$$y = 0,\ 0 <= x <= \frac{x_e}{3};\ y = x\left(\frac{3y_e}{x_e}\right) - y_e,$$
$$\frac{x_e}{3} < x < \frac{2x_e}{3};\ y = y_e,\ \frac{2x_e}{3} <= x <= x_e \quad (2.38)$$

where n = 7 is the number of knots (points) and n-1 is number of equal segments along the x-axis. Again, the vehicle speed is assumed to be constant; therefore, the knot locations are symmetrical about the path center ($x_e/2$, $y_e/2$). In Figure 2.15, the Bezier spline curve is displayed along with the *cubic spline* curve using the same knots. For the given number of knots, the Bezier spline path is more desirable.

Other Lane-Change Trajectories – Several other trajectories, not presented in detail here, are discussed in the literature. Nelson [25] proposed replacing the circular arc with polar polynomials with continuous curvature. Guldner et al. [29] used *curvature profiles* to design reference paths for assessing automatic steering controllers. Kanayama and Hartman [27] offered the *cubic spiral* as an improvement over the Cornu spiral. Martinez-Alfaro and Flugrad [30] synthesized *B-Spline* curves to obtain optimal collision-free paths for automated vehicles. Finally, Chan [31] formulated trajectory design as an optimization problem using weighted penalty functions for acceleration and jerk.

Table 2.3 summarizes and provides representative mathematical descriptions of the trajectories presented in this subsection.

3. PROBLEM STATEMENT

The primary objective of this paper is to compare several lane-change trajectory functions and determine which is superior, based on selected criteria and assumptions. The lane-change trajectories to be compared are: (a) reverse circular arcs, (b) 5th degree Cartesian polynomial, (c) 7th degree Cartesian polynomial, (d) ramp sinusoid, (e) Bezier Spline, and (f) Cornu spiral.

3.1 CRITERIA – Table 3.1 is compiled from various sources [8][23][25][27][32] and provides a list of commonly desired criteria for ideal lane-change paths. In general, the criteria prescribe minimal length paths for smooth lane traversal with minimal yaw transients and jerk.

4. ANALYSIS

4.1 COMPARISON APPROACH – There are various ways to establish a common reference for comparing the candidate ideal lane-change trajectories. *First*, the maximum lateral acceleration, velocity and lateral displacement may be prescribed, allowing an estimate of the total longitudinal lane-change distance, x_e, and the path length, l – see Appendix A. *Second*, for geometrical consistency, the overall dimensions (x_e and y_e) may be prescribed, then, based on the resulting path geometry, the maximum velocities and maximum lateral acceleration can be determined for stable traversal of the given path – see Appendix A.* The second method will be used in this paper to compare the candidate paths, where x_e and y_e are prescribed and curvature and critical speed are determined.

Two important features of lane-change trajectory functions are curvature, $\kappa(x)$ and radius of curvature, $\rho(x)$. EQ (4.1) defines curvature in *explicit* form using Cartesian coordinates.

$$\kappa(x) = \frac{y''(x)}{\left[1 + y'(x)^2\right]^{3/2}} \quad (4.1)$$

EQ (4.2) also defines curvature in Cartesian coordinates but in *parametric* form, where $x = x(t)$ and $y = y(t)$ [33].

$$\kappa(t) = \frac{\dot{x}\ddot{y} - \dot{y}\ddot{x}}{\left(\dot{x}^2 + \dot{y}^2\right)^{3/2}} \quad (4.2)$$

EQ (4.3) shows the reciprocal constitutive relationship between curvature and the radius of curvature.

$$\rho(x) = \frac{1}{|\kappa(x)|} \quad (4.3)$$

We seek the path with minimal curvature and relatively large minimum radius to minimize vehicle yaw transients, lateral acceleration, and jerk. Since there is a reciprocal relationship between $\kappa(x)$ and $\rho(x)$, the determination of the curvature function and its maximum value will suffice for finding the path function with minimal curvature and the largest minimum radius. Table 4.1 gives the functions for curvature of the candidate paths and Table 4.2 gives relations for the minimum radius.

4.2 IDEAL TRAJECTORY MEASURES OF PERFORMANCE – Table 4.3 lists the path measures of performance chosen to satisfy the criteria introduced in Section 3.

As a starting point, the path and curvature boundary conditions are to be verified for compliance with those listed in Table 3.1. Next, the continuity and differentiability of each path and its curvature will be checked within the interval [0, x_e] or [0, t_e], as applicable.

Relative minimal length is assessed through three measures of performance. Figure 4.1 illustrates these

* The references to Appendix A emphasize the connection between the maximum lateral acceleration and the critical speed formula.

measures of performance. The *first*, the maximum deviation from a directed straight line, Δ_{max}, is found using

$$\Delta_{max} = \text{Max}[line(x) - y_c(x)] \cos\beta$$

or

$$\Delta_{max} = \text{Max}[line(t) - C(x(t),y(t))] \cos\beta \qquad (4.4)$$

where $line(x) = (y_e / x_e)x$, and $\beta = atan(y_e / x_e)$. The *second* measure of performance is the area, A, between the path and a straight line for one half of a single lane-change maneuver, which is given by

$$A = \int_0^{xe/2} [line(x) - y_c(x)] dx$$

or

$$A = \int_0^{te/2} [line(t) - C(x(t), y(t))] dt \qquad (4.5)$$

where y_c and C are single-valued and parametric path functions, respectively. Finally, the *third* measure of performance is the total path length, l. Where path length is given by

$$l = \int_0^{xe} \sqrt{1 + y'(x)^2}\, dx$$

or

$$l = \int_0^{te} \sqrt{\dot{x}(t)^2 + \dot{y}(t)^2}\, dt \qquad (4.6)$$

A normalized form of this metric is the *length ratio* $= l / x_e$.

While maximum curvature and minimum radius of curvature are computed from the relationships in Tables 4.1 and 4.2, respectively, relative minimal curvature and relative minimal jerk are evaluated by computing the integral of the curvature squared and the derivative of curvature squared, respectively. These cost functions – EQs (4.7) and (4.8) – were employed by Kanayama and Hartman [27] to synthesize smooth paths for autonomous vehicles, but the reasoning behind such usage is supported by the principles of *variational calculus*.

$$Kcost = \int_0^l \kappa(s)^2\, ds$$

or

$$Kcost = \int_0^{xe} \kappa(x)^2 \sqrt{1 + y'(x)^2}\, dx \qquad (4.7)$$

$$Jcost = \int_0^l \dot{\kappa}(s)^2\, ds$$

or

$$Jcost = \int_0^{xe} \kappa'(x)^2 \sqrt{1 + y'(x)^2}\, dx \qquad (4.8)$$

From a dynamical standpoint, "the instantaneous centripetal acceleration of the vehicle is proportional to its curvature." Therefore, *Kcost* takes lateral acceleration as the cost and *Jcost* takes the rate of change of lateral acceleration, or *jerk*, as path cost [27].

4.3 ASSUMPTIONS – The following assumed parameter values apply to the trajectories in this study:

a. Tire-road coefficient of friction, $\mu_m = 0.7$
b. Gravitational acceleration, $g = 9.81$ m/s^2
c. Total lateral displacement, $y_e = 3.66$ m (12 ft)
d. Total longitudinal distance, $x_e = 62.14$ m (204 ft)

Parameters μ_m and y_e are representative of conditions for a highway lane-change. The value for x_e is typical for a lane-change conducted at approximately 26.8 m/s (96.5 km/h or 60 mph) and $a_{y\,max} = 0.47g$ — see [16].

5. RESULTS

5.1 STATEMENT OF RESULTS – Tables 5.1 and 5.2 give the results of application of the measures of performance.

5.2 DISCUSSION OF RESULTS – Based on numerical results alone, the reverse circular arc path appears to be superior; but close examination reveals that it is the least desirable of all the trajectory functions examined. A sudden change from a straight run to a circular path would entail an instantaneous change in the lateral acceleration, from zero to V^2/ρ, with an infinite rate of change – *jerk* = ∞. Moreover, at the inflection point between the two circular arcs, the lateral acceleration abruptly changes polarity. Therefore, circular arcs do not provide a realistic depiction of lane-change motion. From an analytical standpoint, the circular function does not meet the criteria $\kappa(0) = \kappa(x_e) = 0$ and $\kappa'(0) = \kappa'(x_e) = 0$, because the curvature is constant throughout the lane-change. In effect, the curvature is "evenly distributed" over the entire path. This implies that a vehicle traversing the circular arc path experiences constant lateral acceleration – i.e., *jerk = 0*. The abrupt lateral acceleration sign change and the fact that the circular arc function does not meet the initial and final curvature constraints invalidate the favorable numerical results. Therefore, the circular arc function has little utility as an ideal lane-change path.

Results indicate that the 5th-degree polynomial and the Bezier spline paths meet all criteria and are equally superior to the other lane-change path functions. The next two path functions–ramp sinusoid and 7th-degree polynomial–also meet all criteria. The ramp sinusoid performed nearly as well as the 5th-degree polynomial and the Bezier spline. The 7th-degree polynomial is not as suitable because it has high maximum curvature. The Cornu spiral produced the least favorable results.

Overall, the differences between the candidate paths appear to be minor, and each candidate path function provides a

reasonable kinematic description of a lane-change maneuver. However, when an additional metric — implied critical speed, V_{crit} — is applied, a clearer view of the relative "goodness" of the candidate ideal trajectories is achieved. Table 5.2 shows, based on the constant velocity and the minimum radius of curvature, that the critical speed is a clear discriminator for the candidate paths. Put simply, the superior ideal path description allows higher traversal speed for the same geometric boundary conditions and tire-road friction.

On a qualitative basis, the 5th-degree polynomial, the ramp sinusoid, and the 7th-degree polynomial paths are the easiest to implement without automation. Conversely, the Bezier spline and Cornu Spiral are relatively complex functions that require at least a modest level of programming.

Given the numerical and qualitative results, the 5th-degree polynomial is the preferred functional description of an ideal lane-change among the candidates examined. In rank order, and based on both qualitative and numerical results, the other preferred lane-change functions are the ramp sinusoid, Bezier spline, 7th-degree polynomial, and the Cornu spiral.

6. CONCLUSIONS

The primary contribution of this paper has been the comparison and assessment of known lane-change paths. The method of approach employed to compare six candidate ideal trajectories was guided by reasonable criteria and assumptions. The criteria and assumptions are reasonable because they draw on previous lane-change studies and are based on realistic conditions. The choice of fixing y_e, x_e, and μ_m provided a reference point for kinematic and dynamical consistency during comparison of the candidate trajectories. On a kinematic basis, this enabled the determination of performance on the basis of path length and curvature. From a dynamical standpoint, the approach allowed for comparison on the basis of the critical speed, given equivalent geometric boundary conditions. Therefore, this study has contributed to the understanding of the connection between critical speed and lane-change path design – Appendix A – and showed that this understanding is necessary for realistic and credible trajectory analysis.

The trajectories presented here spanned a wide spectrum of complexity, but there was no correlation between complexity and path efficiency. Of the two best ideal lane-change trajectory functions, the 5th-degree polynomial is the simpler. All ideal lane-change trajectories complied with commonly accepted path and curvature criteria except the reverse circular arc function. Among those paths meeting all criteria, there are nonnegligible numerical and qualitative differences – curvature, length, critical speed, continuity, differentiability, and ease of use.

NOMENCLATURE*

A	one-half area between a directed straight-line and an ideal path
a_x	vehicle longitudinal acceleration/deceleration
a_y	vehicle lateral acceleration (V^2/ρ)
$a_{y,\,max}$	vehicle maximum lateral acceleration
c	path sharpness parameter
$C(x,y)$	ideal or desired trajectory function – parametric
d_x	longitudinal distance for critical turn-away
d_y	lateral displacement for critical turn-away
e	superelevation (road surface, axle direction, $tan\theta$)
g	gravitational constant
J	jerk (da_y/dt)
$Jcost$	derivative of curvature squared cost function
k	counter
$Kcost$	curvature squared cost function
l	total path length
m	total vehicle mass
n	number of knots in the Bezier spline
r	vehicle yaw rate
s	path length parameter
t	time
t_e	total time to complete a lane-change
T	lane-change period
V	vehicle forward velocity (tangent to path of curvature)
V_{crit}	critical speed (at the point of incipient side-skid)
w	path roundness parameter
x	longitudinal position (abscissa)
x_e	total longitudinal lane-change distance
y	lateral position (ordinate)
$y_c(x)$	ideal or desired trajectory function – single-valued
y_e	total lateral lane-change displacement
α	endposture-to-endposture deflection angle
β	endposture-to-endposture orientation angle; vehicle side-slip angle
δ, Δ	pathline deviation
Δ_{max}	maximum pathline deviation
κ	path curvature
μ_m	maximum coefficient of friction
ψ	vehicle yaw angle
$\theta(x)$	tangent angle; slope angle
ρ	radius of curvature of center of gravity path
ρ_{min}	minimum radius of curvature
ω	lane-change angular frequency
ζ	dummy integration variable

* All velocities and accelerations are measured relative to the vehicle local coordinate system.

APPENDIX A

LATERAL ADHESION, CRITICAL SPEED, AND LANE-CHANGE MANEUVERS

The study of lane-change trajectories includes a consideration of lateral resistance and its limits. During lane-change maneuvers, lateral resistance is required to counteract the inertial force inherent during vehicle yaw motion. Lateral resistance is provided by tire side friction forces and banking of the roadway. Maximum lateral resistance occurs when a vehicle achieves its *critical speed.* The critical speed is the vehicle speed at which the tires reach the limit of side friction and side-slip begins [34]. In other words, critical speed is reached when the vehicle centrifugal force due to vehicle motion in a circular path equals the opposing centripetal force provided by friction and superelevation at the tire-road interface. The critical speed formulas are used to estimate the vehicle speed at *incipient side-slip*. Incipient side-slip describes small, but non-negligible, side-slip at the tire-road interface. Side-slip occurs when a vehicle exceeds its critical speed and slips laterally for an appreciable distance.

Oversteer vehicle motion beyond the critical speed is characterized initially by side-slip; but motion may become dynamically unstable at higher speeds, ultimately resulting in spinout. The condition of dynamic instability occurs when a vehicle is directionally unstable. For example, a vehicle that has exceeded the critical speed may continue to diverge from its original path, depending on the nature of the vehicle's stability [35].

Yaw motion describes a vehicle's rotation about its vertical axis (*z*-axis) [35]. Yaw motion occurs anytime a vehicle changes its heading in the fixed *x-y* plane, as in a lane-change maneuver. Circular motion is an example of yaw motion. Figure A.1 illustrates the oversteer yaw motion of a vehicle that has exceeded its critical cornering speed.

In order for a vehicle to traverse a curved path, the vehicle must not exceed the maximum lateral acceleration determined by the maximum tire-road adhesion. In the case of limit lane-change maneuvers, vehicle lateral acceleration is a function of tire-road lateral resistance and usually exceeds $0.3g$ [10][32][36][37]. If certain assumptions are made [38], then as shown in EQ (A.1), the maximum lateral acceleration, $a_{y,max}$, is proportional to the forward velocity squared and inversely proportional to the path radius of curvature. The maximum lateral acceleration is also limited by the lateral resistance present at the tire-road interface, represented in EQ (A.1) as the maximum value for the coefficient of friction, μ_m.

$$a_{y,\max} = \mu_m g = \frac{V^2}{\rho} \qquad \text{(A.1)}$$

where $\mu_m \equiv$ maximum coefficient of friction

g ≡ gravitational acceleration
V ≡ vehicle forward velocity
ρ ≡ center of gravity path radius of curvature

EQ (A.2) represents the basic form of the critical speed equation for flat road surfaces [15].

$$V_{crit} = \sqrt{g\rho\mu_m} \qquad \text{(A.2)}$$

where μ_m ≡ maximum coefficient of friction
g ≡ gravitational acceleration
ρ ≡ center of gravity path radius of curvature

Another common form of the basic critical speed formula, which accounts for superelevation between ±10 percent (nearly ±6 degrees), is shown in EQ (A.3) [14][15].

$$V_{crit} = \sqrt{g\rho(\mu_m \pm e)} \qquad \text{(A.3)}$$

where e is the superelevation, θ is the superelevation angle, and $e = tan\theta$.

There are other formulas of varied complexity and accuracy used in the determination of critical speed – see [38]. The critical speed equation used for lane-change trajectory analysis depends on the availability of computer resources, the complexity of the study, and the desired fidelity.

When the limits of vehicle performance are sought during lane-change simulations, the critical speed formula chosen theoretically influences the calculated maximum lateral acceleration and hence, the shape of the trajectory. The critical speed equation(s) can be used for the determination of the ideal lane-change trajectories, particularly in calculating the total longitudinal distance, x_e, required to complete the lane-change maneuver, when the constant velocity, V_0, and coefficient of friction, μ_m, are given.

Either EQ (A.1) or (A.2) can be rearranged to be explicit in minimum radius of curvature as follows:

$$\rho_{min} = \frac{V_0^2}{\mu_m g} \qquad \text{(A.4)}$$

Equating EQ (A.4) with any expression for the minimum radius of curvature listed in Table 4.2 yields an expression for the total longitudinal distance, x_e. If, for example, the ramp sinusoid trajectory is selected, we arrive first at the following equation:

$$\frac{x_e^2}{2\pi y_e} = \frac{V_0^2}{\mu_m g} \qquad \text{(A.5)}$$

Then, by rearrangement, the total longitudinal distance is determined as

$$x_e = \sqrt{2\pi} V_o \sqrt{\frac{y_e}{\mu_m g}} \qquad \text{(A.6)}$$

Using the same procedure, a similar expression for circular arcs is determined as

$$x_e = \sqrt{\frac{4y_e V_0^2}{\mu_m g} - y_e^2} \qquad \text{(A.7)}$$

For the more complicated expressions for minimum radius of curvature, iterative techniques are required to solve for x_e.

Rearranging EQ (A.1), the maximum curvature of a lane-change trajectory is limited by the following:

$$\kappa_{max} = \frac{\mu_m g}{V_0^2} = \frac{1}{\rho_{min}} \qquad \text{(A.8)}$$

Therefore, if x_e is specified along with y_e, and μ_m, V_0 may be determined and vice versa.

APPENDIX B

TABLES

Table 2.1 Common Lane-change Performance Measures
[1][18][19]

No.	Description
1	Duration to achieve lateral displacement
2	Duration for passing course completion
3	Maintenance of directional control
4	Steering effort versus control
5	Course fidelity (lane violations)
6	Symmetry of yaw and side-slip angle responses
7	Fourier spectrum of steering input
8	Maximum normalized steering amplitude
9	Minimum longitudinal distance to achieve specified lateral displacement
10	Velocity versus lane-change distance ratio (V/x_e)
11	Pathline deviation, Δ
12	Maximum side-slip angle, β_m, and rate, $d\beta/dt$
13	Maximum yaw rate, r_m, where $r = d\psi/dt$
14	Maximum path curvature, κ_m
15	Over- and under-correct tendency, $Y_{u/o}$
16	Left-to-right symmetry, $Y_{L/R}$
17	Time and lateral position at start of recovery phase (time lag of vehicle response)
18	Crossover frequency
19	Phase margin
20	Response latency
21	Closed-loop damped natural frequency
22	Vehicle steering gain
23	Yaw time constant, T_r
24	Directional mode frequency
25	Damping ratio
26	Observer subjective ratings
27	Driver subjective ratings

Table 2.2 Trajectory Description Schemes

Name/Description	Author/Reference
Reverse Circular Arcs	Fett [23], Daily [14], Fricke [15]
Single Cartesian Polynomial	Eshelman and Desai [17], Nelson [25]
Polar Polynomial	Nelson [25]
Sinusoidal Ramp	Zellner et al. [18], Limpert [16]
Cornu Spiral	Kanayama and Miyake [26]
Cubic Spiral	Kanayama and Hartman [27]
Acceleration Profile	Guldner et al. [29], Chee et al. [11], Chan [31]
Bezier Spline	Apetaur and Opicka [8], Nelson [25], de Boor [28]
Curvature Profile	Apetaur and Opicka [8], Guldner et al. [29]
B-Spline	Martinez-Alfaro and Flugrad [30]

Table 3.1 Criteria for Ideal Lane-Change Paths

Criteria	Description of Criteria
1	Continuous and smooth curvature
2	Minimal length
3	Minimal curvature
4	Minimal jerk
5	Curvature boundary conditions: $\kappa(0) = \kappa(x_e) = 0$ and $\frac{d\kappa}{dx}(0) = \frac{d\kappa}{dx}(x_e) = 0$
6	Single-valued function boundary conditions: $y(0) = 0,\ y(x_e) = y_e,\ \frac{dy}{dx}(0) = \frac{dy}{dx}(x_e) = 0$, and $\theta(0) = \dot{\theta}(0) = \theta(x_e) = \dot{\theta}(x_e) = 0$
7	Parametric boundary conditions: $x(0) = y(0) = \dot{y}(0) = \dot{y}(t_e) = 0$ $x(t_e) = x_e\ ,\ y(t_e) = y_e$, and $\theta(0) = \dot{\theta}(0) = \theta(t_e) = \dot{\theta}(t_e) = 0$

Table 2.3 Candidate Ideal Trajectory Functions

Trajectory Name	Trajectory Function
Reverse Circular Arcs	$y(x) = \rho - \sqrt{\rho^2 - x^2} \quad 0 \le x < \frac{x_e}{2}$ $y(x) = y_e - \rho + \sqrt{\rho^2 - x^2 + 2xx_e - x_e^2} \quad \frac{x_e}{2} \le x \le x_e$
Step Acc. Profile	Square wave with a maximum amplitude of $0.67\, a_{y,\max}$
Trapezoidal Acceleration Profile	$a_y = J_{\max}\, t,\ 0 \le t < t_1;\quad a_y = c_a\, a_{y,m},\ t_1 \le t < t_2;$ $a_y = -J_{\max}\, t + 2\, c_a\, a_{y,m},\ t_2 < t \le t_3$ $a_y = -c_a\, a_{y,m},\ t_3 < t \le t_4;\quad a_y = J_{\max}\, t - 4\, c_a\, a_{y,m},\ t_4 < t \le t_e$ where c_a is a factor that limits a_y (e.g., $c_a = 0.85$)
Sinusoidal Acceleration Profile	$a_y = a_{y,m} \sin(\omega t) = \left(\frac{2\pi y_e}{t_e^2}\right)\sin\left(\frac{2\pi t}{t_e}\right)$
7th Degree Polynomial	$y(x) = \frac{y_e}{x_e^7}\left[35x_e^3x^4 - 84x_e^2x^5 + 70x_ex^6 - 20x^7\right]$
Sinusoidal Ramp	$y(x) = y_e\left[\frac{x}{x_e} - \frac{1}{2\pi}\sin\left(\frac{2\pi x}{x_e}\right)\right]$
5th Degree Polynomial	$y(x) = y_e\left[10\left(\frac{x}{x_e}\right)^3 - 15\left(\frac{x}{x_e}\right)^4 + 6\left(\frac{x}{x_e}\right)^5\right]$
Bezier Spline	$B(p) = \sum_{k=0}^{n} p^k(1-p)^{n-k} S_{k+1}$
Cornu Spiral	$\theta(s) = \int_0^s \kappa(\zeta)\,d\zeta \quad 0 \le s \le l$; where $\kappa_1(s) = c(s,w)\ s + \kappa_0$ $x(s) = \int_0^s \cos\theta(\zeta)\,d\zeta \qquad y(s) = \int_0^s \sin\theta(\zeta)\,d\zeta;$
Cubic Spiral	Same as Cornu Spiral, but with curvature: $\kappa(s) = c(\frac{l^2}{4} - s^2) + \kappa_0$
Curvature Profile	$\kappa(t) = \frac{a_{y,\max}}{V^2}\sin(\omega t) = \left(\frac{2\pi y_e}{V^2 t_e^2}\right)\sin\left(\frac{2\pi t}{t_e}\right)$
B-Spline	$F(t) = \sum_{k=0}^{n} B_{i,k}(t)P_i$; degree k, order $k+1$, control points P_i, and knot vector $T = \{t_0, \ldots, t_m\}$

Table 4.1 Curvature Functions for Selected Lane-Change Trajectories *

Trajectory	Curvature: $\kappa(x)$ or $\kappa(s)$	
Circular Arcs	$\dfrac{4y_e}{x_e^2+y_e^2}$	
7th Degree Polynomial	$\dfrac{420x^2(x_e-2x)(x_e-x)^2 y_e}{x_e^7\left[1+\dfrac{19600x^6(x_e-x)^6 y_e^2}{x_e^{14}}\right]^{3/2}}$	
Ramp Sinusoid	$\dfrac{2\pi y_e \sin\left(\dfrac{2\pi x}{x_e}\right)}{x_e^2\left[1+\dfrac{4y_e^2}{x_e^2}\sin^4\left(\dfrac{2\pi x}{x_e}\right)\right]^{3/2}}$	
5th Degree Polynomial	$\dfrac{60x(2x^2-3xx_e-x_e^2)y_e}{x_e^5\left[1+\dfrac{900x^4(x_e-x)^4 y_e^2}{x_e^{10}}\right]^{3/2}}$	
Bezier Spline	$\dfrac{9.15\times10^{-4}x-4.42\times10^{-5}x^2}{\left[1+\left(4.57\times10^{-4}x^2-1.47\times10^{-5}x^3\right)^2\right]^{3/2}}$	
Cornu Spiral	$c(s,w)\ s+\kappa_0$	$0\le s< l/4$
	$-\ c(s,w)\ s-2\ \kappa_1(l/4)+\kappa_0$	$l/4\le s<3\ l/4$
	$c(s,w)\ s-4\ \kappa_2(3\ l/4)+\kappa_0$	$3\ l/4\le s\le l$
